Several enzymes in this class have substrates with a built-in α-keto acid functionality and thus do not require 2-oxoglutarate as a co-substrate. These enzymes appear to have different topologies from enzymes utilizing 2-oxoglutarate and include 4-hydroxyphenylpyruvate (HPP) dioxygenase and 4-hydroxymandelate synthase, which utilize the same substrate but catalyze different transformations. Nonfunctional mammalian HPP dioxygenase has been linked to conditions of tyrosinaemia type III and hawksinuria related to the build up of metabolites of tyrosine.[79,98] 4-Hydroxymandelate synthase and HPP dioxygenase exhibit 43% sequence similarity and 34% identity.[99] A third member of this subset is α-ketoisocaproate dioxygenase, which is involved in leucine metabolism.[100]

Figure 10 illustrates the range of the reactions catalyzed by α-keto acid-dependent iron enzymes. In many cases, the substrate is hydroxylated as shown in Figures 10(a) and 10(b), respectively for prolyl hydroxylase where the requisite α-keto acid is 2-OG and HPP dioxygenase where the α-keto acid function is built into the substrate. For these reactions, one atom of dioxygen is incorporated as the hydroxyl oxygen of the product, while the other ends up on the carboxylate derived from the oxidized keto acid, so both these enzymes are technically considered dioxygenases. As shown in the transformations of Figures 10(c) and 10(d), this class of enzymes can also catalyze heterocyclic ring expansion, heterocyclic ring formation, and desaturation. In these cases,

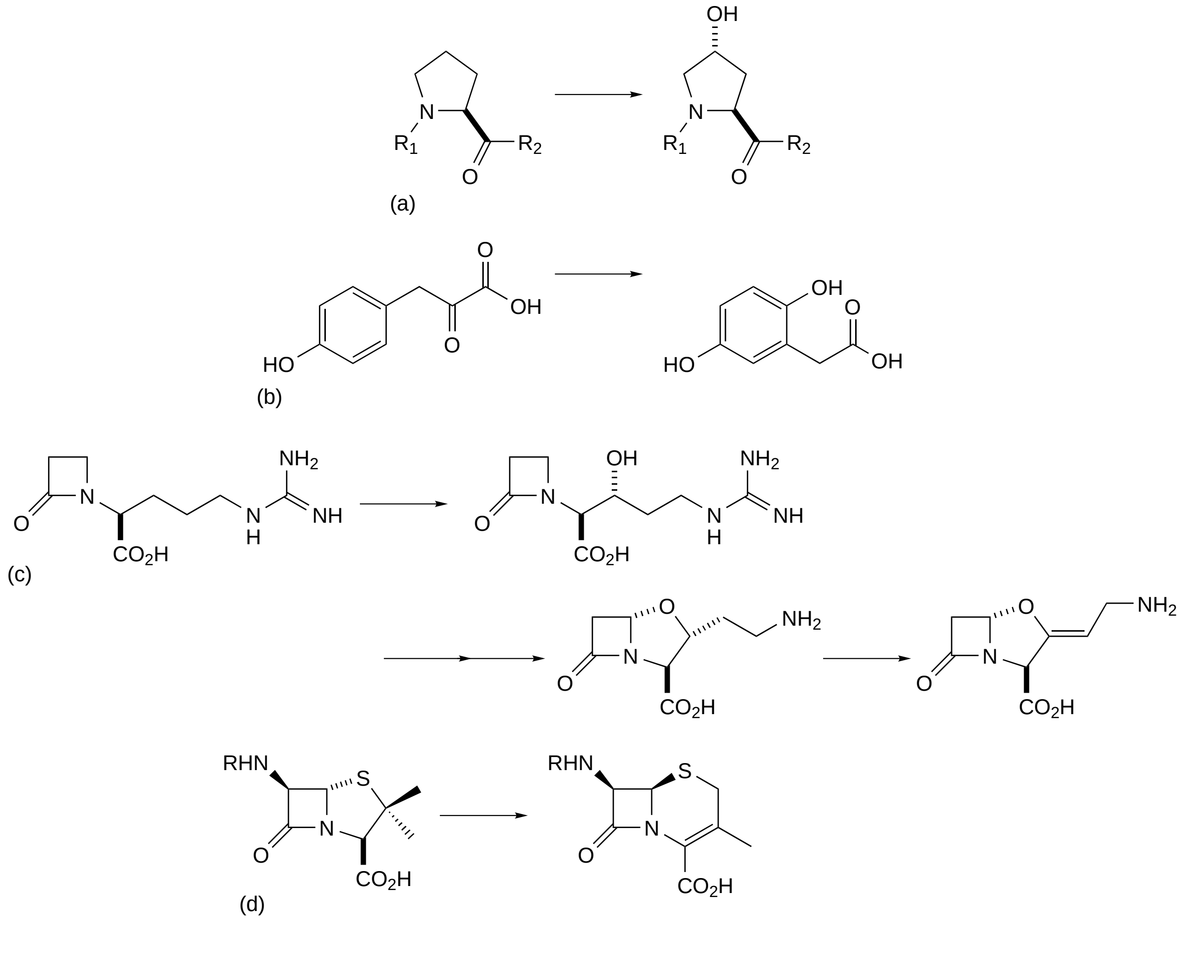

Figure 10 Several reactions catalyzed by α-keto acid-dependent iron enzymes, (a) prolyl 4-hydroxylase, (b) deacetoxycephalosporin C synthase (DAOCS), (c) 4-hydroxyphenylpyruvate (HPP) dioxygenase and (d) clavaminate synthase 2 (CAS)

dioxygen is incorporated only into the succinate byproduct and the other oxygen atom is reduced to water.

Crystal structures for a number of enzymes in this family are now available.[49,78] Despite the fact that many of these enzymes exhibit minimal sequence identity, they have a conserved Hx(D/E)x$_n$H sequence that provides the three endogenous protein ligands of the recurring 2-His-1-carboxylate facial triad motif that binds the high-spin iron(II) center. Three solvent molecules on the opposite face complete the iron coordination sphere.

Steady-state kinetic studies on a number of enzymes support an ordered mechanism in which the α-keto acid binds first.[101–107] This observation suggests the formation of an iron-α-keto acid adduct to initiate the activation of O_2. Consistent with this notion, crystallographic and spectroscopic studies show that the α-keto acid acts as a bidentate ligand displacing two of the solvent water molecules on the six-coordinate iron(II) center (Figure 11a). Upon substrate binding, the third water molecule is displaced to afford a five-coordinate iron(II) center poised to bind O_2 (Figure 11b),[108,109] which is confirmed by the crystal structure of an NO adduct (Figure 11c) with NO serving as an O_2 surrogate.[110]

Figure 12 shows a generally accepted reaction sequence for these enzymes. O_2 can bind trans to any of the facial triad residues forming an adduct that may be described as an iron(III)-superoxide complex as shown in Figure 12d. This superoxide then attacks the electrophilic carbonyl carbon of 2-OG to form iron(IV)-peroxo adduct Figure 12e, which in turn undergoes C–C bond cleavage and subsequent O–O bond

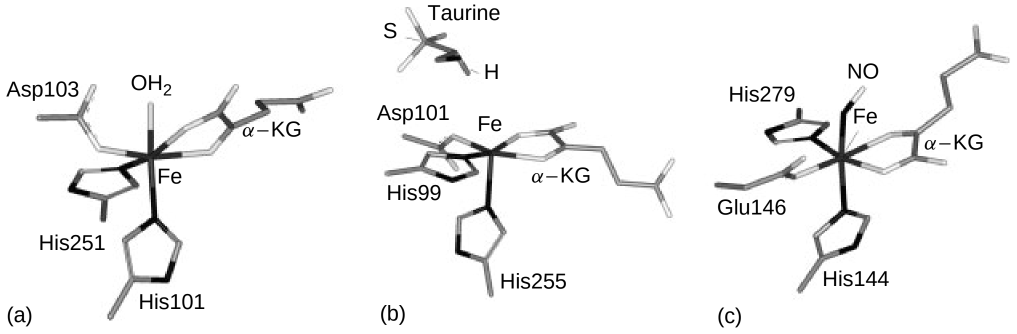

Figure 11 Crystal structures of stages in the catalytic cycle of α-keto acid-dependent enzymes: (a) the binary complex of CarC (1NX4.pdb), (b) the ternary complex of TauD (1GQW.pdb), and (c) the NO adduct of the ternary complex of CAS (1GVG.pdb)

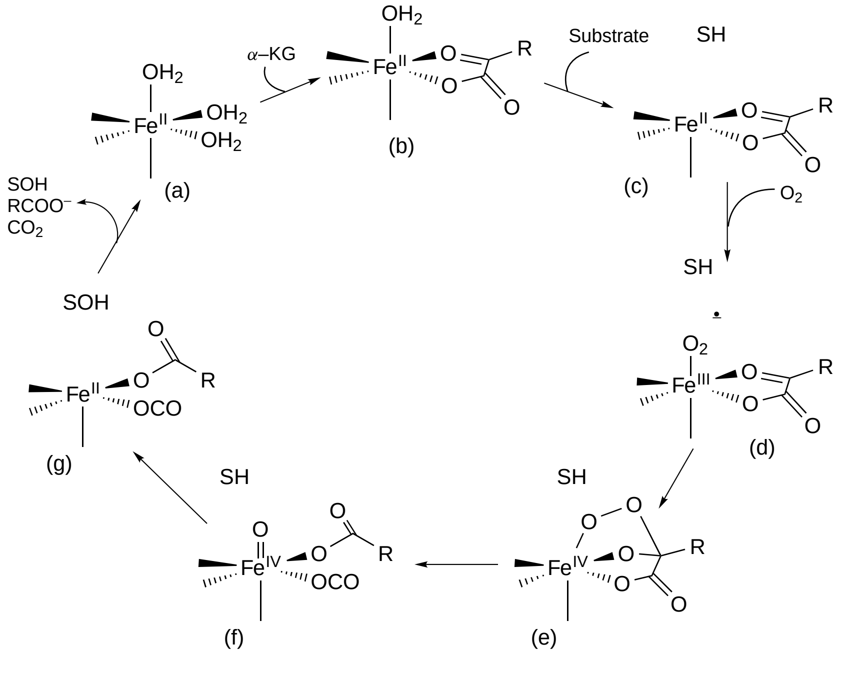

Figure 12 Proposed mechanism for the α-keto acid-dependent iron enzymes, where substrate is indicated as SH

heterolysis to form an iron(IV)-oxo intermediate Figure 12f that is responsible for the oxidation of the substrate. The oxidized product, the carboxylate byproduct, and carbon dioxide (Figure 12g) subsequently leave the active site to prepare for another turnover.

Experimental evidence has thus far been obtained for only one intermediate after O_2 binding. An iron(IV)-oxo moiety of TauD has been observed by stopped flow kinetics and trapped by rapid-freeze-quench experiments.[111] This species has an absorption feature near 320 nm ($\varepsilon_{320} \sim 1500\,M^{-1}\,cm^{-1}$) whose rate of decay is dependent on whether the target C–H bond on taurine is hydrogen or deuterium.[112] (A kinetic isotope effect of about 30 is observed.) Mössbauer spectroscopy of the intermediate reveals an iron center with an isomer shift of $0.31\,mm\,s^{-1}$, whose high field behavior corresponds to that of a high-spin iron(IV) ($S = 2$) center. The presence of an $Fe^{IV}{=}O$ unit is indicated by an oxygen-isotope-sensitive feature at $821\,cm^{-1}$ from flow resonance Raman studies,[113] and a short (1.62 Å) Fe–O distance determined from an EXAFS study.[114] Taken together, these results provide evidence for intermediate shown in Figure 12f.

Synthetic complexes modeling α-keto carboxylate-dependent enzymes have played a key role in furthering our understanding of these enzymes. Several [Fe^{II}(L)(α-keto acid)] complexes have been reported as functional models using tetradentate and tridentate ligands.[49] All of the model complexes that react with O_2 afford quantitative yields of the decarboxylated α-keto acid, but in only two cases was the active oxidant trapped. Intermolecular olefin epoxidation has been observed in the case of [Fe^{II}(Tp^{Me2})(BF)] complex.[115] This complex reacts with O_2 to form a species capable of stereospecific oxidation of *cis*-stilbene to its oxide as the product. However *trans*-stilbene is not epoxidized, suggesting that the active oxidant is capable of steric discrimination.

The other example is an intramolecular hydroxylation of a ligand phenyl ring of [Fe(Tp^{Ph2})(BF)] upon exposure to O_2.[116,117] The hydroxylated product is obtained within an hour in 70% yield. In contrast, the corresponding [Fe(Tp^{Ph2})(benzoate)] complex also reacts with O_2 to give the same product in 55% yield, but this reaction requires 2–3 days, clearly demonstrating the key role the α-keto group plays in activating O_2. The use of $^{18}O_2$ resulted in the incorporation of one labeled oxygen into the benzoate product and the other into the hydroxylated phenyl ring of the Tp ligand. The absence of ^{18}O incorporation when the reaction is carried out in the presence of $H_2{}^{18}O$ suggests that an iron(IV)-oxo species, if involved in the mechanism, has too short a lifetime relative to $H_2{}^{18}O$ exchange in the biomimetic transformation.

A significant recent development has been the generation of high-yield synthetic oxoiron(IV) complexes in a nonheme ligand environment.[118–123] The $Fe^{IV}{=}O$ unit is stabilized by coordination to polydentate nitrogen ligands such as the macrocyclic TMC, the tetradentate tripodal TPA, and the pentadentate N4Py and Bn-TPEN. A crystal structure of [Fe^{IV}(O)TMC]$^{2+}$ has been reported revealing a Fe–O bond distance of 1.646 Å, the first high-resolution determination of this unit. Unlike the TauD intermediate, these complexes are low-spin ($S = 1$) iron(IV) complexes. Nevertheless these first examples of synthetic nonheme oxoiron(IV) complexes serve as excellent starting points to obtain detailed information about the electronic structure and reactivity properties of this intriguing, high-valent oxidant in iron biochemistry.

6 ISOPENICILLIN *N* SYNTHASE

Isopenicillin *N* synthase (IPNS) is a nonheme iron enzyme found in *Cephalosporium*, *Penicillium*, and *Streptomyces* strains. It activates O_2 and catalyzes the formation of isopenicillin *N* from δ-(L-α-aminoadipoyl)-L-cysteinyl-D-valine (ACV) (Figure 13). Interestingly, it has the conserved HX(D/E)X_mHX_nRXS sequence motif, similar to those found in many 2-oxoglutarate-dependent enzymes but does not require 2-oxoglutarate for activity.[78,124]

Crystallographic studies have established IPNS as another member of the superfamily of nonheme iron enzymes with active sites containing a 2-His-1-carboxylate facial triad. The extensive crystallographic information available provides a wealth of mechanistic insight. The Mn(II)-substituted IPNS from *Aspergillus nidulans* has been crystallized in the absence of substrate to reveal a six-coordinate metal center with four endogenous protein ligands (His214, Asp216, His270, and Gln330) and two H_2O molecules occupying the remaining cis ligand sites (Figure 14a).[125] As shown by the crystal structure of the Fe^{II}·IPNS·ACV complex, substrate binding results in the displacement of the Gln ligand by the ACV thiolate sulfur (Figure 14b),[126] confirming earlier EXAFS results that showed a sulfur scatterer at 2.3 Å.[127]

O_2 can interact with the metal center only at this stage. This suggests that the coordination of the ACV thiolate primes the iron(II) center for its reaction with O_2, presumably by shifting the Fe^{III}/Fe^{II} redox potential to a

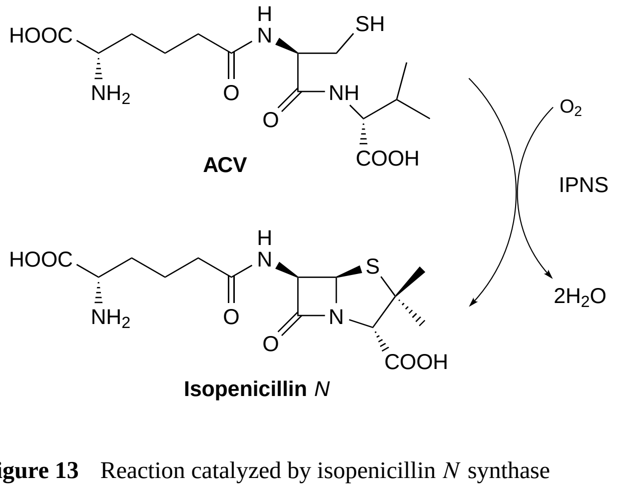

Figure 13 Reaction catalyzed by isopenicillin *N* synthase

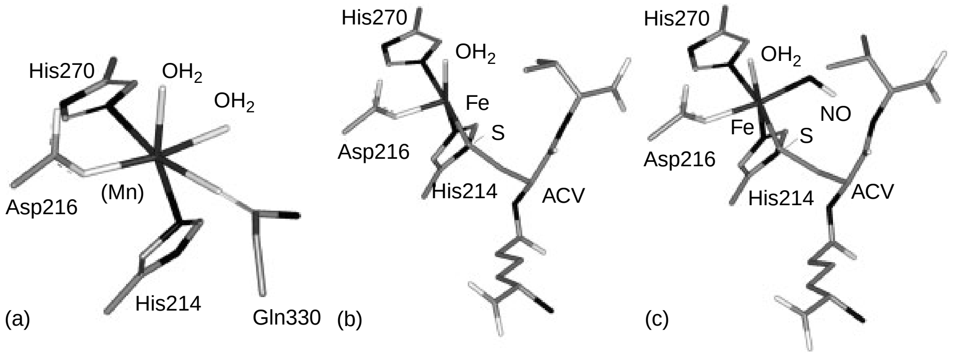

Figure 14 Crystal structures of IPNS complexes (a) Mn·IPNS (1IPS.pdb), (b) Fe·IPNS·ACV (1BKO.pdb), and (c) Fe·IPNS·ACV·NO (1BLZ.pdb)

less positive value, similar to the mechanisms proposed for the extradiol-cleaving dioxygenases and the α-keto acid-dependent enzymes. To date there is no spectroscopic evidence for a Fe^{II}·IPNS·ACV·O_2 adduct, as such an intermediate appears to be too reactive to be trapped. However the corresponding Fe^{III}IPNS·ACV·NO adduct has been studied. Exposure of NO to the substrate-bound iron(II) center engenders an $S = 3/2$ EPR signal characteristic of high-spin iron(II)-nitrosyl adducts[128] and gives rise to a short (1.7 Å) Fe–NO bond observed by EXAFS.[127] The crystal structure of the ternary enzyme·substrate·NO complex (Figure 14c) confirms many aspects of the active site earlier deduced from spectroscopic experiments and shows that NO binds trans to Asp216, with its oxygen atom equidistant from both the valine nitrogen and the cysteinyl β-carbon.[129] Assuming that NO serves as an O_2 surrogate, these are the atoms from which a hydrogen atom must be abstracted to close the β-lactam ring in the first stage of isopenicillin formation.

The elegant and comprehensive work of Baldwin and coworkers[130] using a number of ACV analogues has provided insight into the steps subsequent to O_2 binding and led to the mechanism for IPNS action shown in Figure 15. The reduction of O_2 occurs in two stages with the sequential formation of the β-lactam and the thiazolidine rings corresponding to

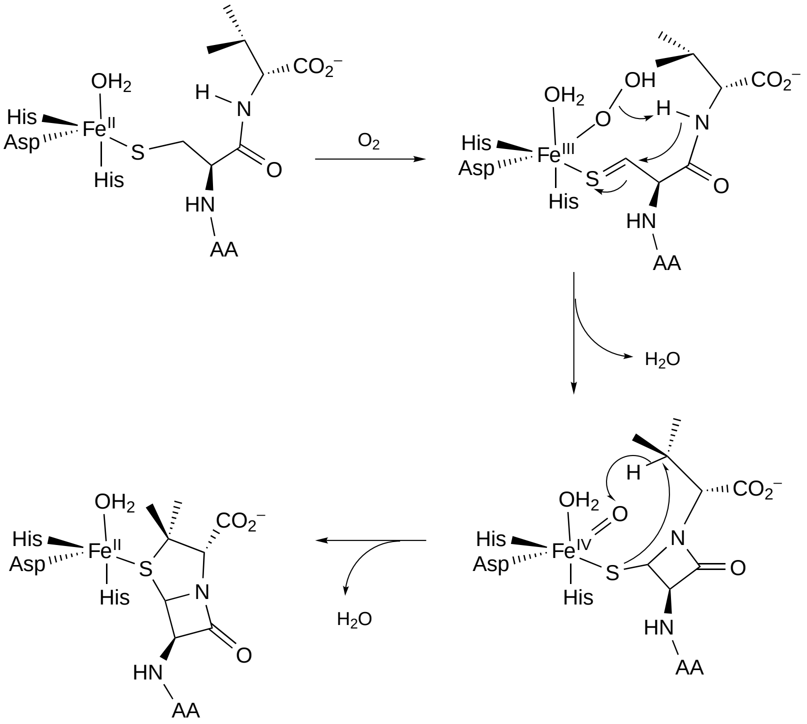

Figure 15 Proposed mechanism for the reaction catalyzed by isopenicillin N synthase

two distinct two-electron reduction steps. In the first stage, O_2 is reduced to the peroxide oxidation level concomitant with the oxidation of the Cys thiolate to a thioaldehyde (or some equivalent moiety). O–O bond heterolysis leads to the abstraction of the proton from the valinyl peptide nitrogen, generating an $Fe^{IV}{=}O$ intermediate and the amidate anion. The latter then nucleophilically attacks the thiocarbonyl carbon to form the β-lactam ring and regenerates the thiolate. The $Fe^{IV}{=}O$ moiety then initiates the second stage of the reaction by abstraction of the valinyl C3-H hydrogen atom, followed by C3-S bond formation to generate the thiazolidine ring. A crystal structure of the Fe^{II}·IPNS·IPN product complex shows the thiazolidine sulfur atom bound to the metal center (Figure 16a).

Much of the recent crystallographic work on IPNS has involved brief exposure of crystalline enzyme-substrate complexes to hyperbaric O_2 followed by cryo-crystallography.[131,132] With AC*O*V, the substrate analogue wherein the valine peptide bond is converted to an ester linkage, β-lactam ring formation is not possible and the thiolate of the ACV substrate is instead oxidized to a thio-carboxylate, with one atom of O_2 incorporated into the thiocarboxylate (Figure 16b). On the other hand, ACmC, the substrate analogue where the valine residue is replaced by S-methylcysteine, affords a product wherein the reaction cycle is interrupted after the formation of the β-lactam ring; the $Fe^{IV}{=}O$ moiety is instead trapped by the S-methylcysteine to form a sulfoxide that is coordinated to the iron center trans to the Asp residue (Figure 16c). This result corroborates the proposal that O_2 binds trans to the Asp residue, as indicated by the NO complex, and is converted to an oxo group in the latter part of the reaction cycle. Besides oxo transfer to sulfide, the $Fe^{IV}{=}O$ moiety can also epoxidize double bonds, as demonstrated by the substrate analogue with the valine replaced by allylglycine,[133] and can carry out hydrogen-atom abstraction, as shown by a ring opening isomerization of the product derived from the cyclopropylalanine analogue.[134] Thus there is strong experimental evidence for the various steps of the proposed IPNS mechanism (Figure 15). This scheme is also strongly supported by DFT calculations.[135]

7 PTERIN-DEPENDENT HYDROXYLASES

The pterin-dependent oxygenases, typified by the aryl amino acid hydroxylases, are a small family of closely related enzymes, which are essential to mammalian physiology.[136,137] This class of metalloenzymes employs tetrahydrobiopterin (BH_4) as a two-electron donating cofactor for the activation of O_2. Members of this class include phenylalanine (PheH), tyrosine (TyrH) and tryptophan (TrpH) hydroxylases, which effect regiospecific aromatic hydroxylations of the namesake amino acids.

Phenylalanine hydroxylase is located primarily in the liver and affords the major pathway for phenylalanine catabolism. In contrast, the other two enzymes function primarily within the central and peripheral nervous system, providing the rate-limiting initial steps in biosynthetic pathways for a range of neurotransmitters including dopamine, norepinephrine, and epinephrine for TyrH and serotonin and melatonin for TrpH. Dysfunctions of these essential enzymatic activities have been implicated in several severe neurological and psychological diseases, and this has stimulated the significant body of biochemical and biomedical research to date.[137]

High-resolution crystal structures have now been solved for PheH, TyrH, and TrpH.[49,138] Most of these structures have been obtained from enzymes with truncated catalytic domains in an inactive, oxidized form with iron(III) and BH_2 bound. Very recently, structures have become available for the active human PheH catalytic domain as the iron(II) complex, the binary BH_4 complex (Figure 17a), and ternary complexes with BH_4 and the substrate analogues *l*-thienylalanine (Figure 17b) or *l*-norleucine.[139–141]

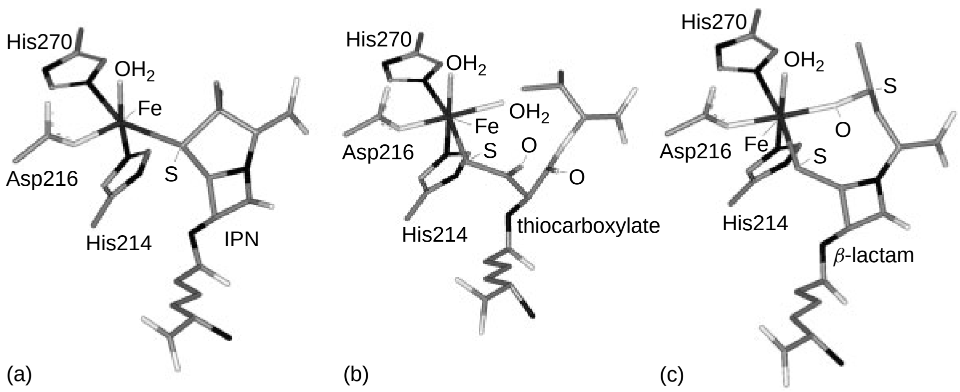

Figure 16 IPNS-product complex crystal structures with varying substrates: (a) IPN (1QJE.pdb), (b) AC*O*V (1HB4.pdb), and (c) ACmC (1QJF.pdb)

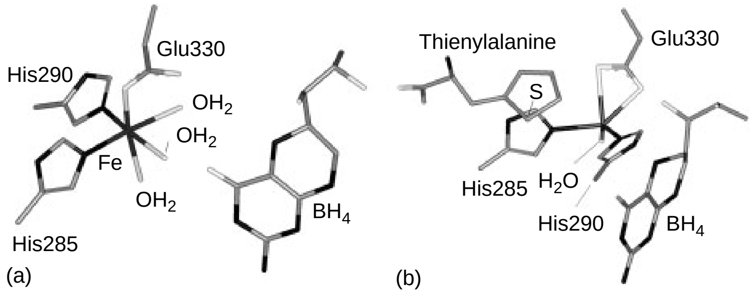

Figure 17 Crystal structures of phenylalanine hydroxylase: (a) the binary enzyme·BH_4 complex (1J8U.pdb) and (b) the ternary complex with *l*-thienylalanine (1KWO.pdb)

The iron active site can be found in a deep central cleft some 10 Å beneath the enzyme surface.[138] The six-coordinate iron center is ligated to a 2-His-1-carboxylate facial triad (consisting of His285, His290, and Glu330 in *H. sapiens* PheH) and three water molecules (Figure 17a). The pterin binds to a site located just beyond the iron center at the very base of the cleft, and is π-stacked against a conserved phenylalanine (Phe254). The pterin also hydrogen bonds to a number of residues, particularly to a conserved glutamate (Glu286) via the hydroxypropyl sidechain. The stereochemistry of the pterin cofactor oxidation product has been determined, and only a single diastereomer corresponding to hydroxylation of the structurally exposed face of the pterin is formed.[142] The distance from the metal to the reactive pterin C4a is on the order of 6 Å in both the iron(II) and iron(III) structures.

Large changes are observed upon binding of substrate to form the ternary enzyme-pterin-substrate complex. As shown by the crystal structure of the ternary PheH·BH_4·*l*-thienylalanine complex, the iron center becomes 5-coordinate and adopts a square pyramidal geometry (Figure 17b).[140] Two water ligands are lost and the monodentate Glu330 becomes bidentate. Moreover, the pterin is significantly displaced towards the iron center, as indicated by a decrease in the distance between Fe and C4a from 5.9 to 4.5 Å. These changes in principle facilitate dioxygen binding at the metal as well as attack of the nearby pterin. However, the single water ligand retained in the ternary complex occupies the apical position of the square pyramid proximal to the BH_4 moiety, so formation of an Fe–O–O–pterin adduct would require the loss or shift of this water ligand. Near IR, MCD, and XAS studies of the PheH·tetrahydrobiopterin·phenylalanine complex in frozen solution are in accord with the crystallographic results, showing that the iron(II) center is 6-coordinate in the resting iron(II) form and the binary complexes with either phenylalanine or a pterin cofactor analogue, but attains a 5-coordinate square pyramidal geometry upon formation of the ternary complex.[143,144]

The structural and spectroscopic studies provide a firm foundation upon which to postulate a catalytic mechanism, but unfortunately give little insight into the activation of dioxygen within the reactive quaternary complex. Two key intermediates are presented in Figure 18. The first is an adduct of the coordinatively unsaturated iron(II) center, O_2 and the nearby C4a of the BH_4 cofactor, which is best described as an iron(II)-peroxypterin complex (Figure 18a).[145,146] Since no intermediate has been directly observed to date, formation of this adduct may be rate-limiting. The putative Fe^{II}–O–O–pterin intermediate is then proposed to cleave heterolytically to form 4a-hydroxypterin (BH_3OH) and a reactive oxoiron(IV) species that carries out

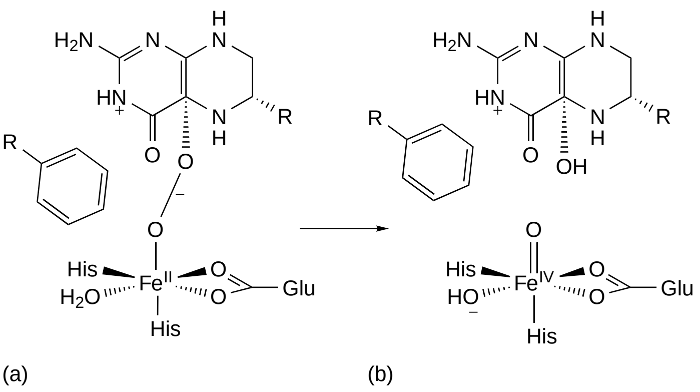

Figure 18 Key intermediates in the proposed mechanism for pterin-dependent hydroxylases

the electrophilic attack of the aromatic substrate (Figure 18b). This step is supported by the observation of the nearly quantitative incorporation of isotope from $^{18}O_2$ into both the amino acid and BH_3OH products.[142,147] Pterin-dependent enzymes are thus proposed to utilize an $Fe^{II}/Fe^{IV}{=}O$ couple, distinct from the formal $Fe^{III}/Fe^{V}{=}O$ couple associated with heme enzymes such as cytochrome P450 (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[148]

There is currently no consensus with respect to the mechanism of Fe–O–O–pterin adduct formation. Observation of an ^{18}O kinetic isotope effect for TyrH, $\Delta V/K = 1.017(2)$, coupled with the lack of solvent (H_2O, D_2O) isotope effects, indicates a significant O–O bond order change in the rate determining step.[149] Stepwise O_2 binding may occur initially at Fe^{II} to form an $Fe^{III}–O_2^-$ species that subsequently couples to BH_4, as favored by recent DFT calculations.[150] In this case, the metal ion plays a role in stabilizing incipient charge on the O_2 unit and mitigating the spin barrier, and a metal-independent reaction trajectory could not be found. Alternatively, O_2 attacks initially at BH_4 to form a pterin hydroperoxide,[149,151] paralleling the chemistry of metal-free flavin-dependent oxygenases,[152] with the metal center subsequently required for activation of the peroxo species. Experiments on the Glu280Lys mutant of PheH favor the latter option.[153] Despite the fact that the iron(II) center of this mutant enzyme remains 6-coordinate in the ternary complex, pterin oxidation activity is nevertheless retained and in fact is enhanced twofold. A third option may be the concerted addition of O_2 to both the metal center and pterin.

The next step in the mechanism is O–O bond heterolysis of the Fe^{II}–O–O–pterin intermediate to form an $Fe^{IV}{=}O$ species. Heterolysis is predicted by DFT calculations to be quite difficult for a tetrahedral iron(II) model,[154] but relatively facile for six-coordinate iron(II),[150] especially when assisted by protonation at the departing β-oxygen. Consistent with the weak ligand field, DFT calculations suggest a reactive oxoiron(IV) intermediate in a high-spin, $S = 2$ ground state.[150] This intermediate is postulated to attack a single carbon atom on aromatic substrates to form a 2,4-dienone intermediate, which subsequently tautomerizes to phenolic product. While this oxoiron(IV) species has not been experimentally observed, there is indirect evidence implicating such an electrophilic hydroxylating agent. Besides arene hydroxylation, the pterin-dependent enzymes can accommodate a number of substrate analogues and carry out sulfoxidation, epoxidation, and benzylic hydroxylation,[146] a reactivity pattern closely related to that associated with the $Fe^{IV}{=}O$ porphyrin radical intermediate of cytochrome P450 (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[148] Secondly, TyrH can hydroxylate a series of *para*-substituted phenylalanines with consistent rates of pterin oxidation, but with increasing degrees of uncoupling as substrate analogues become electron-poor.[155,156] Correlation of arene hydroxylation against the consistent pterin oxidation rate was observed using the standard Hammett σ parameter, yielding $\rho = -4.3(7)$ for tetrahydrobiopterin and $-5.6(8)$ for the 6-methyltetrahydrobiopterin cofactor analog; these values are consistent with an electron-deficient transition state produced by an electrophilic oxidant.[155] Thirdly, the hydroxylation of deuterated substrate by TrpH exhibits an inverse isotope effect that suggests a partially rate-limiting electrophilic substitution step in this specific instance.[157] Lastly, arene hydroxylation is often accompanied by a 1,2-hydrogen shift commonly referred to as an 'NIH shift', by which substrates labeled with hydrogen isotopes at the site of attack are converted to metabolites with isotope retention on an adjacent carbon (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[158] Such a shift is usually indicative of cationic intermediates associated with oxo atom transfer, forming epoxides or 2,4-dieneones.[150,157–159] An appropriate model system that mimics the step involving attack of an $Fe^{IV}{=}O$ moiety on an aromatic ring has been investigated in some detail,[160] and supports mechanistic notions discussed above.

8 RIESKE DIOXYGENASES

The *cis*-dihydroxylation of arenes catalyzed by Rieske (*see* ***Iron–Sulfur Proteins***) dioxygenases constitutes the first step in the biodegradation of aromatic molecules by soil bacteria and leads in two subsequent steps to the formation of catechols,[161–163] which are in turn degraded by the intradiol and extradiol-cleaving catechol dioxygenases discussed in Section 4. Furthermore, there is strong interest in these enzymes as biotechnological tools since the enzyme-catalyzed reactions are both stereo- and enantiospecific and arene *cis*-dihydroxylation is a novel transformation not observed thus far in synthetic organic chemistry.[164–167] Rieske dioxygenases are multi-component enzymes with an oxygenase component where O_2 activation and substrate dihydroxylation occur and a reductase component that mediates electron transfer between NAD(P)H and the oxygenase component. In the course of catalysis, both atoms of O_2 are incorporated into the *cis*-diol product (Figure 19).[161,167–170] Aside from *cis*-dihydroxylation, Rieske dioxygenases also catalyze a number of oxidations such as benzylic hydroxylation, desaturation, sulfoxidation, O- and N-dealkylation.[168,171] This large range of oxidative transformations indicates that Rieske dioxygenases may even be more versatile than the cytochromes P450 (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).

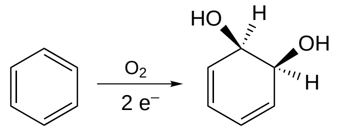

Figure 19 Rieske dioxygenase-catalyzed arene *cis*-dihydroxylation reaction

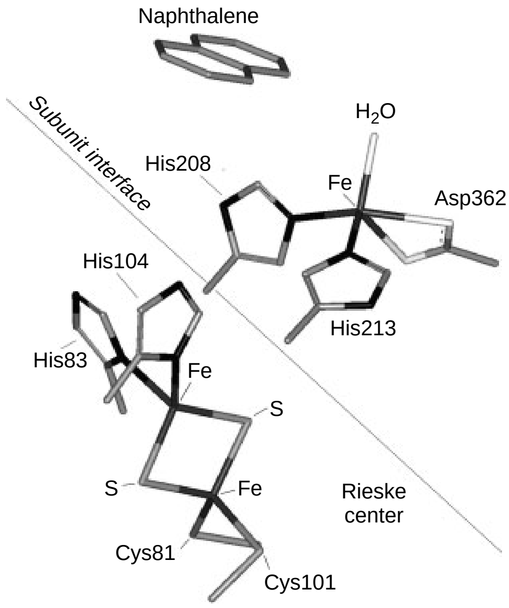

Figure 20 Crystal structure of the enzyme-substrate complex of naphthalene dioxygenase Fe·NDO·napthalene (1O7G.pdb)

There is thus far only one Rieske dioxygenase that is crystallographically characterized (Figure 20).[172–174] The structure of the oxygenase component of naphthalene 1,2-dioxygenase (NDO) from *P. putida*, the enzyme that catalyzes the formation of *cis*-(1R,2S)-1,2-dihydroxy-1,2-dihydronaphthalene from naphthalene[172] shows two metal centers, a mononuclear iron center where O_2 binding and activation takes place and a nearby Rieske-type Fe_2S_2 cluster (*see* ***Iron–Sulfur Proteins***), which delivers electrons to the mononuclear center in a controlled fashion during catalysis. These results confirm earlier notions derived from spectroscopic studies mainly on phthalate dioxygenase (PDO).[175,176] The mononuclear iron center of NDO is coordinated to two histidine residues (His208 and His213) and a bidentate aspartate (Asp362) (Figure 20),[172–174] occupying four sites of the metal center, again, in a variation of the 2-His-1-carboxylate facial triad.[60,61] A water molecule occupies a fifth coordination site, and there is an asparagine residue 3.7 Å from the iron in the vicinity of the sixth coordination site. The Rieske cluster with its characteristic $Fe_2S_2(Cys)_2(His)_2$ core is 12 Å away with His104 on the cluster connected to His208 on the monoiron center by hydrogen bonding to Asp205. Structures of the oxygenase component with bound naphthalene (Figure 20) or the substrate analogue indole are also available and show a substrate binding pocket nearby that orients the double bond to be attacked in position for substrate oxidation 4 Å away from the monoiron center.

Spectroscopic studies also provide insight into the coupling of substrate binding and the redox state of the Rieske cluster to changes at the mononuclear iron center in preparation for oxygen activation. MCD studies on PDO show that the iron(II) center is six-coordinate and becomes five-coordinate upon substrate binding.[176] This substrate-triggered change follows the general mechanistic paradigm for oxygen activation by iron(II) enzymes with 2-His-1-carboxylate active sites.[177] NO, an O_2 analogue, binds to the mononuclear iron(II) site of NDO and converts the EPR-silent high-spin iron(II) center into an EPR-active $S = 3/2\{\text{Fe-NO}\}^7$ center.[178] ENDOR studies of the NO adduct show that protons on the naphthalene substrate are dipolarly coupled to the paramagnetic center, indicating that the substrate remains in the crystallographically characterized binding pocket even after NO binding.[179,180] Furthermore the substrate is sensitive to the redox state of the Rieske cluster and undergoes an allosteric shift towards the mononuclear nonheme iron center upon reduction of the Rieske cluster.

An exciting recent development is the crystallographic characterization of O_2 adducts of NDO in the absence and in the presence of substrate, the first example for a nonheme iron enzyme.[173,174] The crystal structure of the reduced enzyme exposed to O_2 in the absence of substrate shows a side-on bound dioxygen moiety with Fe–O distances of 2.2 and 2.3 Å. The observed O–O distance of 1.4 Å suggests the reduction of O_2 to the peroxide level. The same experiment performed with crystals previously soaked in solutions of the substrate analogue indole and then exposed to O_2 shows an even more tightly bound side-on peroxo species with Fe–O distances of 1.8 and 2.0 Å and an O–O bond distance of 1.4 Å (Figure 21a). The Fe–O bond distances of the latter are in good agreement with Fe–O_{peroxo} bond lengths obtained from the EXAFS analysis for $[Fe(N4Py)(\eta^2\text{-}O_2)]^+$ (1.93 Å)[181] and from the crystal structure of a heme/copper complex with a μ-$\eta^1 : \eta^2$-peroxo bridge (1.89 and 2.03 Å).[182] The asymmetry of the bound dioxygen moiety in the enzyme structures on the measured Fe–O bonds suggests the strong possibility that it may be a side-on bound hydroperoxide. The observation of these side-on bound dioxygen intermediates in two crystal forms differs from an earlier observation by the same group of a dioxygen adduct in which one oxygen atom is bound to the metal center and the other to the C3 carbon atom of the substrate analogue indole.[173] This structure may be construed to be an intermediate subsequent to the initially formed side-on

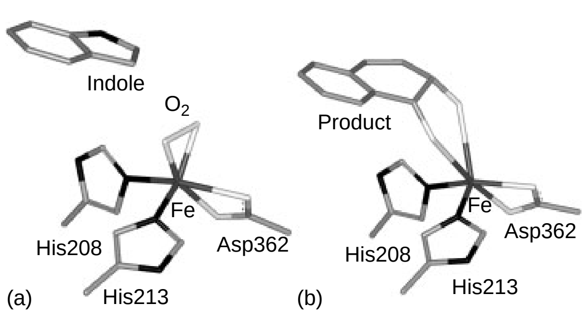

Figure 21 Structurally characterized intermediate species of NDO: (a) Fe·NDO·indole·O_2 (1O7N.pdb), and (b) Fe·NDO·product (1O7P.pdb)

bound dioxygen complex, demonstrating dioxygen attack on substrate. Lastly, the crystal structure of an enzyme-product complex demonstrates that the *cis*-dihydroxylated product coordinates the iron center as a bidentate ligand to the metal center (Figure 21b).[174] Product release occurs only after the two redox active iron sites (the mononuclear and Rieske centers) are reduced, allowing the enzyme to initiate another round of catalysis.

Although early studies on PDO have shown that the oxygenase and the reductase components form an essential complex for catalytic turnover,[183,184] recent studies on NDO[178] and benzoate 1,2-dioxygenase (BzDO)[185] demonstrate that the fully reduced oxygenase component alone is competent to activate O_2. In the absence of substrate, the fully reduced oxygenase reacts slowly with O_2 resulting in the autoxidation of the enzyme. The addition of substrate accelerates this reaction, producing nearly a single turnover of product *cis*-dihydrodiol. The rate of this reaction is in fact more than one order of magnitude faster than the overall catalytic turnover rate, suggesting that other steps control the overall kinetics. At this stage, both the monoiron center and the Rieske cluster are oxidized and the product can only be recovered from the enzyme via a procedure involving thermal denaturation and chemical extraction.[178,185] The tighter binding of the product diol at this stage is not surprising, given the expectation that the Lewis acidic iron(III) center should have a strong affinity for the diol oxygens. Product release could then be triggered by reduction of the oxygenase by the reductase and probably constitutes the rate determining step during catalysis.

The above observations can be considered together to assemble the following mechanistic sequence. The fully reduced enzyme binds the arene substrate to initiate the reaction. O_2 binding followed by electron transfer from the reduced Rieske cluster generates the side-on bound O_2 adduct shown. Studies on NDO with benzene as a substrate analogue[186] show that, the reduction of O_2 can be uncoupled from substrate dihydroxylation, and H_2O_2 is released with no benzene oxidation, presumably the result of protonation of a putative Fe^{III}–OOH intermediate. The fully oxidized NDO has also been shown to undergo a peroxide shunt (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***), catalyzing the single turnover oxidation of naphthalene with H_2O_2 to afford the corresponding *cis*-(1*R*,2*S*)-1,2-dihydroxy-1,2-dihydronaphthalene product.[187] Isotope labeling studies show almost full incorporation of the two oxygen atoms of the peroxide into the *cis*-diol product. Thus substrate oxidation can be brought about by an iron(III)-peroxo moiety or derivatives thereof.

From the above results, a mechanism for arene dihydroxylation can be formulated (Figure 22). Upon coordination of the substrate, dioxygen binds the iron(II) center in a side-on fashion. This Fe^{III}-η^2-O_2^- species is reduced and protonated to a side-on bound hydroperoxo iron(III) species. The Fe^{III}-η^2-OOH intermediate could then attack the substrate directly to form the (η^1-alkylperoxo)iron species found in an NDO crystal structure,[173] but the chemistry underlying this transformation is difficult to envision. The fact that the O–O bond remains intact suggests a nucleophilic attack of the substrate by the bound peroxide, but how this should come about is not clear. Alternatively, the Fe^{III}-η^2-OOH intermediate may undergo O–O bond cleavage and convert to an electrophilic HO–Fe^V=O species prior to substrate attack. Such a species may be akin to the high-valent *cis*-dioxometal species such as OsO_4, RuO_4 or MnO_4^- well known to effect *cis*-dihydroxylation of olefins.[188,189] The involvement of an

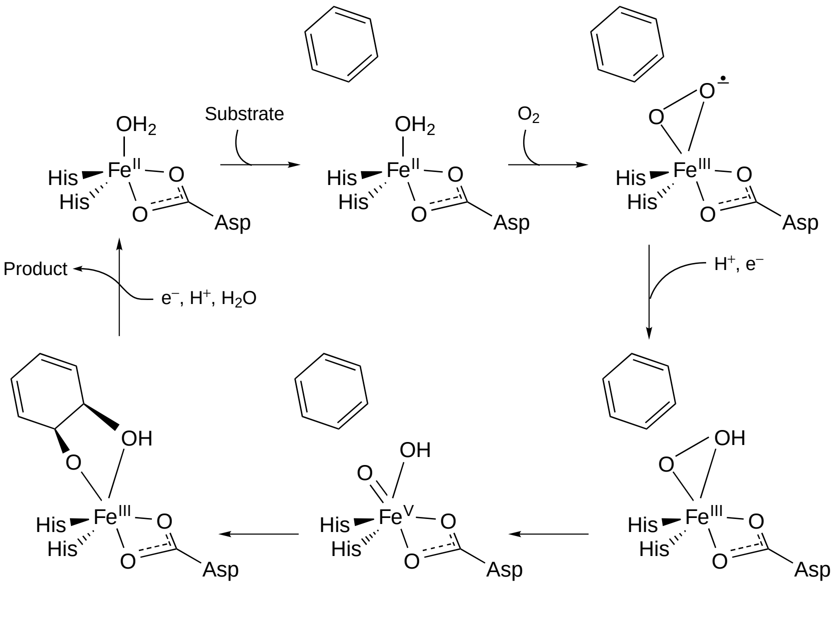

Figure 22 Proposed mechanism for Rieske dioxygenases

iron-oxo species in the catalytic mechanism may be implicated by the incorporation of $H_2{}^{18}O$ into the product. Indeed a small amount of oxygen from water (3–10%) is incorporated into the naphthalene *cis*-diol product in the peroxide shunt studies of Wolfe *et al*.[187] Furthermore Wackett *et al.* have found significant label incorporation from $H_2{}^{18}O$ (70%) in the oxidation of the substrate analogue indane by toluene dioxygenase to 1-indanol.[190] These results argue for the involvement of an intermediate that allows solvent to be incorporated into the product.

Insights have also been provided by the first examples of biomimetic iron complexes that catalyze olefin *cis*-dihydroxylation.[191,192] Using H_2O_2 as an oxidant, complexes exemplified by $[Fe^{II}(TPA)(CH_3CN)_2]^{2+}$ convert olefins stereospecifically to *cis*-diols (and epoxides). A Fe^{III}–OOH intermediate is observed at low temperature and an $HO–Fe^{V}{=}O$ oxidant is implicated by ^{18}O labeling experiments. These results support the mechanism proposed in Figure 22. Interestingly, introduction of 6-methyl substituents on TPA affords a catalyst that incorporates both oxygen atoms of H_2O_2 into the *cis*-diol product. These results reveal a rich reaction landscape that requires further exploration.

9 PERSPECTIVE

In the decade since the publication of the first edition of this encyclopedia, there has been a virtual explosion of X-ray crystallographic information on mononuclear nonheme iron enzymes involved in dioxygen metabolism. In many cases structures are now available for various states of the enzymes, providing a detailed picture of the interactions leading to oxygen binding. Significant progress has also been made in spectroscopic, kinetic, and biomimetic studies leading to the characterization of plausible reaction intermediates. Taken together, this body of information has furthered our understanding of how mononuclear nonheme iron centers activate dioxygen (or process superoxide). Prominent among these developments is the emergence of the 2-His-1-carboxylate facial triad as a recurring structural motif for the active sites of different classes of iron enzymes, demonstrating the versatility of this motif for dioxygen activation. Also significant is the recent characterization of the elusive nonheme $Fe^{IV}=O$ species common to the mechanisms of many of these iron enzymes. The crystallization and spectroscopic investigation of corresponding biomimetic oxoiron(IV) complexes are also providing new opportunities to gain insight into the nature of this key oxidant and how it reacts with substrates. Great strides have been made in the past decade, but a great deal more remains to be learned of how dioxygen is activated by this novel family of mononuclear, nonheme iron enzymes.

1 INTRODUCTION

Iron is an essential micronutrient (*see **Nutritional Aspects of Metals & Trace Elements***) but in order to obtain sufficient iron and then to handle it in a safe way, biological organisms have evolved complex transport proteins for iron. A major reason for this is that iron bound to low molecular weight ligands can be highly toxic owing to its ability to catalyze Fenton-type reactions, which produce free radicals, as in reactions (1) and (2) below.

$$Fe^{2+} + O_2 \longrightarrow Fe^{3+} + O_2^{\bullet -} \quad (1)$$

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^{\bullet} + OH^- \quad (2)$$

These free radicals can cause DNA damage and eventually lead to cell death. Another problem is that although iron is abundant in the environment, it is usually present in insoluble forms. Microorganisms and plants overcome this obstacle by a variety of iron uptake systems, which actively recruit iron and transport it back to the organism. Multicellular animals acquire iron through their diet, but still need mechanisms to absorb the iron from their digestive systems and transport it to its place of use. Proteins for iron storage are another common necessity, not only as a means of conserving a hard-won resource, but also to prevent oxidative damage; the latter is particularly important in organisms that lack a pathway for iron excretion, such as humans.

All iron transport and storage proteins share a common requirement: they need to keep the iron in a soluble and safe form to prevent Fenton chemistry as described by equations (1) and (2). Both types of proteins also need to bind iron tightly, and the transport proteins in particular need to be able to release the metal when required. In the present article we will concentrate on chemically well-characterized iron transport and storage proteins with a focus on their structural and mechanistic features. We shall consider proteins that transport heme as well as proteins that transport nonheme iron, recognizing, as Baker *et al.*[1] have noted, that there are common structural and mechanistic principles operating in such proteins. There are many other proteins involved in iron metabolism other than those we describe however. Many of the systems we discuss are controlled at the transcriptional or translational level by iron-responsive proteins, such as the ferric uptake regulatory protein (FUR) in bacteria and the iron-responsive element binding protein in eukaryotes (*see* ***Metalloregulation***). Iron trafficking with cells must also involve molecules apart from the proteins we have discussed, but despite chaperone proteins for other transition metal ions having been identified and well-characterized (*see* ***Metallochaperones & Metal Ion Homeostasis***), unambiguous identification of similar chaperone proteins for iron has not been reported.

2 FERRIC-SIDEROPHORE RECEPTORS

In times of iron deficiency, many bacteria and fungi release low molecular weight chelators called siderophores (*see* ***Iron Transport: Siderophores***). These molecules bind ferric iron tightly and the ferric-siderophore complexes are then transported into the cell by a system of uptake proteins. The first stage in the uptake process involves an outer membrane receptor specific to each siderophore. One of the best characterized of these receptors is FhuA,[2] the ferrichrome uptake receptor of *E. coli*, and we will describe this in detail. However, though other ferric-siderophore complexes are taken up by cells, and their iron released by systems similar to those of ferrichrome, their mechanisms may vary from those of ferrichrome in some respects. FepA[3] and FecA[4] are two of the outer membrane ferric-siderophore receptors that have recently been structurally characterized.

2.1 Structure of Fhua

FhuA has two domains that fold independently of one another[2] (Figure 1). The C-terminal domain has 22 antiparallel β-strands, which form a β-barrel that spans the outer

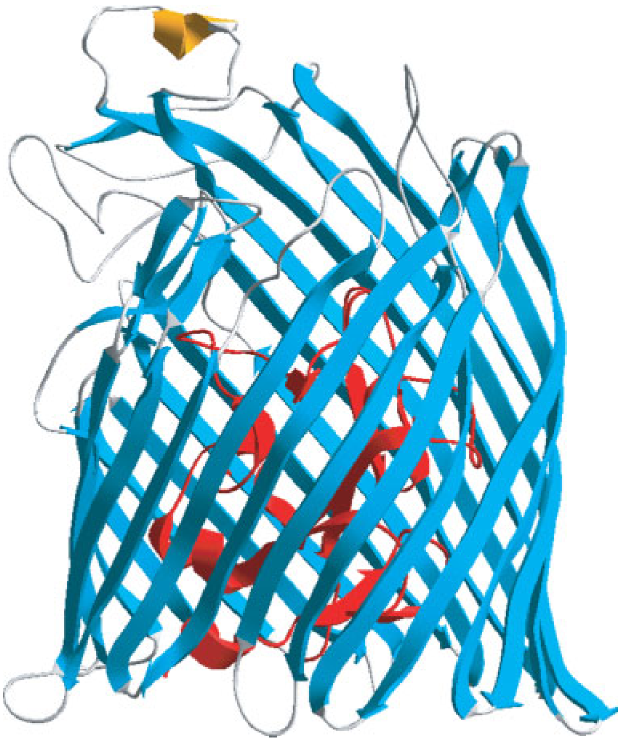

Figure 1 Crystal structure of apo FhuA from *E. coli*. The plug domain is shown in red. Figure created using pdb coordinates 1by3[2]

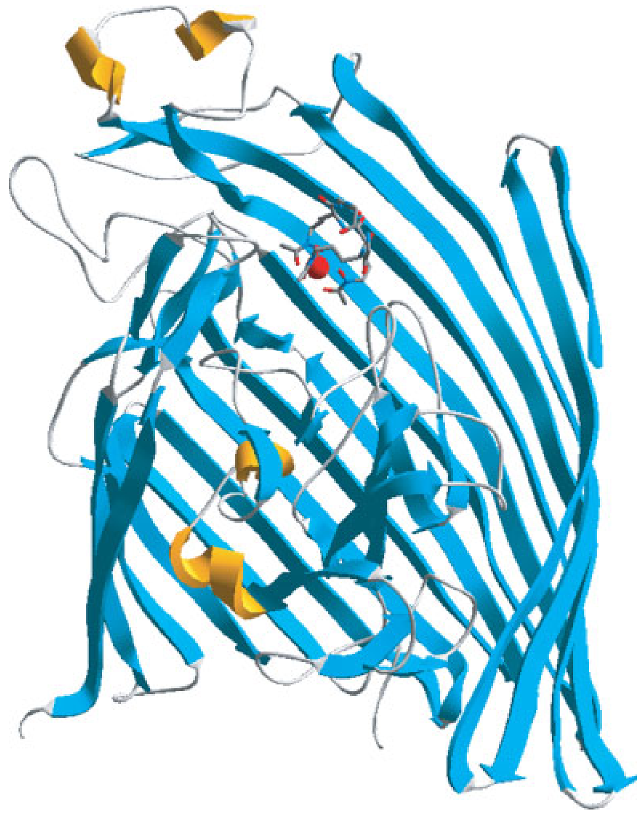

Figure 2 Ferrichrome bound to FhuA. The iron atom is shown as a red sphere, and part of the β-barrel has been removed for clarity. Figure created using pdb coordinates 1by5[2]

membrane. The N-terminal domain of the protein forms a plug, which is positioned within the β-barrel on the periplasmic side of the membrane. This plug domain consists of a mixed 4-stranded β-sheet interspersed with four α-helices. The outer membrane receptors for ferric citrate and ferric enterobactin, FepA, and FecA, respectively, have similar structures to that of FhuA,[3,4] and a β-barrel structure is present in all bacterial outer membrane proteins characterized to date.[5]

The crystal structure of FhuA bound to the iron ligand ferrichrome has also been determined.[2] This shows that the ferric-siderophore complex binds inside the barrel above the plug, forming hydrogen bonds and van der Waals interactions with residues within the plug domain and with the β-strands of the barrel (Figure 2).

2.2 Iron Transport Into the Cell

The N-terminus of the plug domain appears to be disordered.[2] This region contains the TonB box, a stretch of 7 residues that interact with the C-terminal domain of the periplasmic protein TonB. The TonB box has the consensus sequence (Asp or Glu)-Thr-(hydrophobic residue)$_2$-Val-(Ser or Thr)-Ala. The disorder in this region of FhuA means that the TonB box does not appear in the crystal structure, and it is likely to extend into the periplasm to allow binding of TonB, as seen for FepA.[3] TonB interacts with the ExbB-ExbD system, which allows the transfer of chemiosmotic energy from the cytoplasmic membrane to the TonB-dependent outer membrane receptor, driving transport of the ferric siderophore across the outer membrane. The ExbB-ExbD complex charges TonB with conformational energy and promotes its binding to the TonB binding epitope in the plug domain of FhuA. The stored energy is then transduced to FhuA, which drives a conformational change that reduces the ligand binding affinity and leads to the Fe(III)-siderophore complex passing through the outer membrane and into the periplasm. Chemical details of this passage are unclear and several possibilities have been discussed, including that the complex diffuses through an aqueous channel in the outer membrane formed by the β-barrel.[6] Recently, evidence has been provided from studies of amonabactin-mediated iron transport in *Aeromonas hydrophila* for a ‘shuttle’ mechanism in which free ferric siderophores interact with apo siderophores bound to their receptors and transfer iron to the receptor-bound molecule.[7] This attractive proposal may be the route by which other outer membrane receptors operate.

Once in the periplasm the Fe(III)-siderophore complex is bound by a specific protein, which in the case of ferrichrome

is FhuD. FhuD has a fold different from other periplasmic binding proteins, and although it is bilobal, the two lobes are connected by an α-helix rather than a flexible linker.[8] The reduced flexibility caused by this, coupled with hydrophobic contacts between the two lobes, appears to result in a smaller conformational change than that seen in the binding mechanisms of other periplasmic binding proteins.[8] The Fe(III)-siderophore complex binds in a negatively charged cleft between the lobes that has a localized positive region that interacts with carbonyls of the hydroxamate. There are fewer hydrogen bonds and hydrophobic contacts between FhuD and the siderophore than seen for FhuA, and this may contribute to the lower specificity of FhuD, which is able to transport other ferric hydroxamates in addition to ferrichrome, including coprogen and aerobactin.[8] Note that in both the FhuA and FhuD structures, ferrichrome binds to the protein through contacts with its organic component and not through coordination to the Fe(III) ion.

FhuD delivers the ferric-siderophore complex to the FhuBC complex in the cytoplasmic membrane.[8] FhuB is an intrinsic cytoplasmic membrane protein through which the iron complex can pass, driven by energy supplied by ATP hydrolysis catalyzed by the ATPase FhuC. Ferrous iron may be released from the hydroxamate via reduction by the reductase FhuF, which is loosely associated with the cytoplasmic membrane and, like FhuD, appears to have a lower specificity than FhuA and is active with coprogen and ferrichrome.[9]

3 ANIMAL TRANSFERRINS

Transferrins are Fe(III)-carrying proteins found in the bodily fluids of vertebrates and some invertebrates. The group includes serum transferrin and ovotransferrin, found in blood and avian egg white respectively, and lactoferrin, which is found in milk.[10] The transferrin family have a general bacteriostatic role in that iron is safely sequestered by the protein and is therefore unavailable to invading pathogenic bacteria. Pathogens have of course evolved methods to try and circumvent this problem; transferrin receptors have been identified on the outer membranes of bacteria such as *Neisseria meningitidis* and *Hemophilus influenzae*, thus allowing them to use host transferrins as an iron source.[11,12] Not only do *N. meningitidis* and *H. influenzae* scavenge iron from host transferrin but they also have transferrin-like iron transport proteins in their periplasms; which have been named Ferric Binding Proteins (Fbps).[13,14] We shall consider animal transferrins separately from Fbps because despite their evident similarities, there are distinct chemical differences between them.

Serum transferrin has a more specialized function than simply iron sequestration, transporting iron from sources of iron in the body (e.g. after absorption through the gut or degradation of redundant iron-containing molecules) to its point of use or storage.[15] There are numerous cell types with a high requirement for iron, such as immature erythroid cells, which synthesize hemoglobin in bone marrow, placental tissue, and rapidly dividing cells. All of these express particularly high levels of the transferrin receptor.[16] Transferrins are also able to bind other metal ions,[17] some of which (e.g. Al(III) and Ga(III)) may be physiologically important.

3.1 Structure

All the transferrins crystallized to date share a common structure,[18] an example of which is shown in Figure 3. The protein has two structurally homologous lobes of roughly 330 residues each, with a high sequence identity between them. Each lobe comprises two domains with a central mixed β-sheet surrounded by α-helices. Between the domains is a cleft in which the metal ion binding site contained in each lobe is situated. One ferric ion binds to each site, with a carbonate ion binding concomitantly with each metal.

The fold of the transferrin protein resembles those of microbial periplasmic binding proteins that transport small solute molecules (such as sugars, amino acids, and other metabolites) and Fbp.[18,20] These structural studies indicate an intriguing combination of divergent and convergent evolutionary relationships between animal transferrins and Fbps,[20,21] though these are beyond the scope of this article. They also suggest common features to their mechanisms of action; in particular, that a 'Venus fly trap' mechanism is in operation, whereby the apo protein adopts an open conformation that hinges closed upon binding iron. However, the observation of a closed conformation for some apo-lactoferrins suggests that in solution the apo protein is in equilibrium between its open and closed forms.[22] In this case, Fe(III) binding may then displace the equilibrium to the closed form.

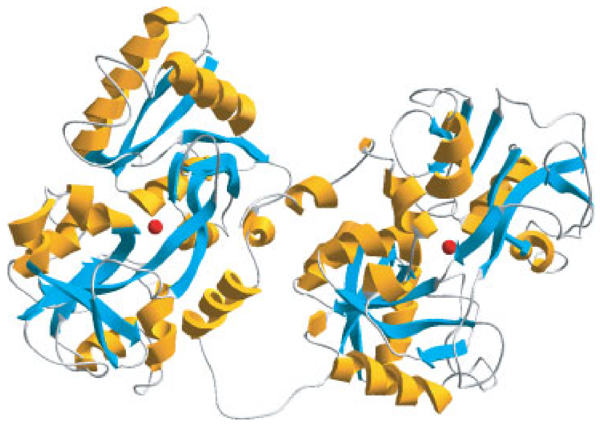

Figure 3 Crystal structure of rabbit transferrin. Bound iron atoms are shown as red spheres. Figure created using pdb coordinates 1jnf[19]

3.2 Iron Binding

The two iron-binding sites in most transferrins are similar to each other, with each consisting of two tyrosines, one aspartic acid and one histidine. In some transferrins, however, conservation of the binding site residues is reduced; for example, cockroach transferrin lacks the histidine in the N-lobe binding site, while several other invertebrate transferrins lack conserved binding site residues in the C-lobe. This may contribute to a lack of binding in the C-lobe of invertebrate transferrins.[23]

The charge on the bound ferric ion is balanced by the deprotonated tyrosine and aspartic acid residues, while the charge on the carbonate ion is balanced by binding to the positively charged arginine and the N-terminus of an α-helix.[24] This results in an overall charge-balanced complex in which the iron is ligated by two oxygens from the carbonate ion in addition to the protein ligands, leaving the metal in an octahedral environment. Though carbonate is the physiological anion, in vitro others, such as oxalate and nitrilotriacetic acid, can replace it.[25,26]

Using iron chelated to small ligands it has been shown that the carbonate ion binds to the protein first, attracted to a positively charged arginine residue close to the metal binding site, followed by the binding of the Fe(III)-chelate complex to the two tyrosine residues. A conformational change then takes place to close the protein over the bound iron, leading to loss of the chelator and completion of the interactions between the Fe(III) and its remaining amino acid ligands.[27] The carbonate anion forms a hydrogen bond network to the protein backbone (Figure 4), which helps stabilize the closed conformation of the iron-loaded protein.

Reported stability constants (*see* ***Stability Constants & their Determination***) for metal ion binding to transferrins are generally conditional association constants under specified conditions as there are many factors affecting their magnitudes: temperature, pH, bicarbonate concentration, and

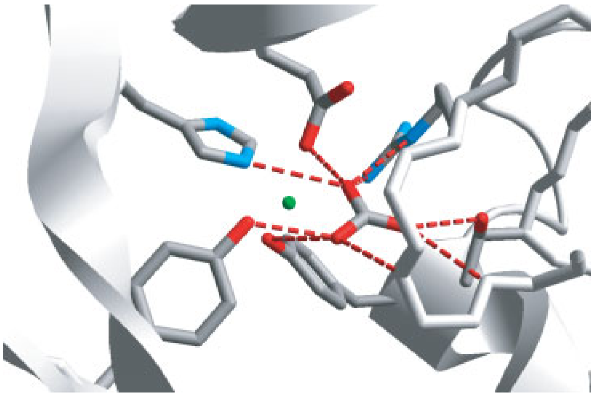

Figure 4 The iron-binding site of the transferrin N-lobe showing hydrogen bonds to the carbonate ion. The iron atom is shown as a small green sphere; and for clarity bonds involving the iron atom are not shown. Figure created using pdb coordinates 1jnf[19]

ionic strength among them.[17,28,29] A further complication with determining stability constants is that the properties of the metal ion donors are important and their association equilibria need to be considered in the analysis. Aisen *et al.*[28] showed that the two iron-binding sites on human serum transferrin had slightly different binding affinities for Fe(III), consistent with a small degree of negative cooperativity in iron binding. At 25 °C, pH 7.4 and 2×10^{-4} M $NaHCO_3$, the macroscopic association constants for Fe(III) binding to transferrin are $\geq 10^{20}\,M^{-1}$. The binding affinities of the two sites change their relative order under some conditions and kinetic factors are important, so that site loading varies greatly depending upon conditions.[28–30] For example, some iron donors preferentially load the N-lobe site and some the C-lobe site. Once loaded to produce monoferric transferrin, kinetic barriers inhibit the equilibrium distribution expected from consideration of the intrinsic site association constants.

The $Fe^{3+/2+}$ reduction potentials for holo-transferrin have been difficult to determine because of their low values and the need to take account of the dissociation of Fe(II) from diferrous-transferrin. This has been estimated[31] from the association constant for Fe(II) binding to transferrin at pH 7.4, $\sim 10^6\,M^{-1}$, which yields reduction potentials < -500 mV at pH 7.4 for the C-terminal and N-terminal sites of human serum transferrin, and probably more negative potentials at the lower pH present in the endosome where iron is released.[32,33]

It is not known whether other proteins are involved in loading transferrin with iron in vivo, though in vitro apo transferrin on its own can bind and oxidize ferrous iron rapidly.[34] A role for the copper-containing protein ceruloplasmin (*see* ***Copper Proteins: Oxidases***) has been suggested for iron loading of transferrin in vivo[35] as ceruloplasmin is known from studies of patients with aceruloplasminemia[36,37] and genetic disruption studies[38] to be involved in iron metabolism, catalyzes the oxidation of Fe(II), and no other function has been convincingly demonstrated for it.[39] However, there is no unambiguous physiological evidence pointing to such a role, though ceruloplasmin does form a complex with lactoferrin.[40]

3.3 Iron Transport Into the Cell and Release From Transferrin

As noted above, iron-loaded serum transferrin has the role of transporting Fe(III) to cells requiring it. Once it reaches a target cell, it binds to the transferrin receptor (TfR) on the cell outer surface. TfR is a disulfide-linked dimer that binds two transferrin molecules.[29] At neutral pH, apo transferrin does not bind to the transferrin receptor.[41] Once formed, the transferrin receptor complex becomes detached from the cell membrane and enters the cell enclosed in a clathrin-coated vesicle.[29] Uncoating of the vesicle generates an endosome in which the pH is lowered to 5.5, promoting release of iron. At this pH, the transferrin remains bound to its receptor,[41] and

is then returned to the outer surface of the cell. The external pH around the cell is slightly alkaline, generally around pH 7.4, and this greatly reduces the affinity of the complex and so the apo transferrin is released ready to pick up more iron in serum.

The transferrin receptor TfR may have a role in reduction of the transferrin-bound Fe(III) within the endosome. Iron leaves the endosome to enter the cytoplasm via the divalent metal ion transporter DMT1,[42] which only transports Fe(II), not Fe(III) (see Section 5). As noted above, the reduction potential of Fe(III) bound to transferrin not associated with TfR is less than $-500\,\text{mV}$, which is too low for reduction of the bound Fe(III) by physiological systems such as reduced pyridine nucleotides. However, as Dhungana *et al*. have shown,[43] the reduction potential of Fe(III)-transferrin bound to TfR is considerably higher at around $-300\,\text{mV}$, which puts it in the range for reaction with physiological reductants.

Protonation of the carbonate ion and its removal as a ligand from the bound Fe(III) occurs at an early stage in iron release from Fe(III)-Tf-TfR.[44] This is followed by protonation of the histidine residue, which further weakens iron binding. At this point in the mechanism, iron release from the N-lobe may be facilitated by a dilysine trigger.[45] Two lysine residues in the N-lobe lie very close to one another, such that charge repulsion ensures there is not enough room for both to be protonated without a change in their relative dispositions. One of the residues is thought to have a particularly low pK_a, and so would only become protonated when the pH is decreased to 5.5 within the endosome. The two positive charges then repel each other, opening the cleft in the N-lobe of the protein. The C-lobe of transferrin does not have these lysine residues and requires a lower pH to release bound iron in vitro.[46] Recently, mutagenesis experiments have helped to identify three residues in the transferrin C-lobe (K534, R632 and D634) that are implicated in iron release. These residues may act by destabilizing the iron bound conformation of the C-lobe; alternatively they could provide a binding site for iron chelators.[15] As with Fe(III) loading, however, the rates of Fe(III) release are influenced by the properties of any Fe(III) acceptor molecules present in addition to the intrinsic characteristics of the protein.[47] In vitro, polyphosphates promote Fe(III) release[48] but it is not known whether this is physiologically relevant. The possibility that iron is released from transferrin as Fe(II), discussed above, obviates the need for an Fe(III)-chelator within the endosome.

3.4 Spectroscopy

Studies of ferric transferrins with a wide range of spectroscopic methods have been reported but here we focus on their optical and EPR properties. Ferric transferrins are a salmon pink color, resulting from a weak Fe(III)-phenolate charge transfer absorption at 470 nm (for lactoferrin $\varepsilon = 2,070\,\text{L}\,\text{mol}^{-1}\,\text{cm}^{-1}$ per Fe),[30] which has been used to monitor iron binding to transferrins. Diamagnetic metals, such as Ga(III), Al(III) and Zn(II), do not produce an absorption band in the visible region of the spectrum on binding to apo transferrin, but, like Fe(III), they do perturb the spectrum in the region 220–290 nm as a result of the metal ions binding to tyrosines and perturbing their $\pi-\pi^*$ transitions. UV difference spectroscopy over this range has been a productive method for investigating metal binding.[17,49]

EPR spectra of the diferric species have been thoroughly investigated.[50] The two high-spin Fe(III) ions have an absorption at $g \sim 9.7$ and a three-line signal centered at $g \sim 4.3$. The complexity of these signals is a result of zero-field splitting of the electronic energy levels. In most high-spin Fe(III) systems, zero-field splitting is not understood in a quantitative way but this is not so for diferric transferrin, which is now routinely used as an EPR standard for quantitating $g \sim 4.3$ signals of nonheme iron systems.[50,51]

3.5 Synthetic Analogs

The search for synthetic analogs of ferric-containing transferrins has concentrated on reproducing spectroscopic properties of the protein. Prior to the X-ray structure determinations, various compounds were synthesized based on sporting interpretations of the spectroscopic data for diferric transferrin. Powell[52] has reviewed these noting that none reproduced the coordination sphere of Fe(III) in transferrin and all left 2 trans sites open for coordination by the synergistic anion while transferrin provides two cis sites for this. Subsequent to the X-ray structure determinations, a compound has been described[53] in which the Fe(III) is octahedrally coordinated by O and N ligands, including phenolate and monodentate carboxylate, and in ethanol has a similar visible absorption spectrum to that of transferrin ($\lambda_{max} = 494\,\text{nm}$, $\varepsilon = 1340\,\text{M}^{-1}\,\text{cm}^{-1}$ per Fe) suggesting that the electronic environment of the Fe(III) resembled that of transferrin.

4 MICROBIAL TRANSFERRIN-LIKE PROTEINS

As noted in Section 3, some pathogenic bacteria have transferrin receptors on their outer membranes to acquire diferric transferrin from their host. These outer membrane receptors extract the iron from the transferrin and transport it into the periplasm where it is picked up by the periplasmic ferric binding proteins (Fbp), which carry the iron to a transmembrane protein in the inner membrane that conveys it into the cytoplasm.[54] A considerable amount of chemical and structural information has been gathered for Fbp, which is sometimes referred to as bacterial transferrin in recognition of its similarities with animal transferrin.[55]

4.1 Structure of Fbp and Its Fe^{3+} Binding Site

Fbp is about half the size of transferrin and has the appearance of a single lobed transferrin-like protein: not only does the polypeptide fold into a bidomain $\alpha\beta$-structure similar to that of transferrin (Figure 3), with a central mixed β-sheet surrounded by α-helices, but also the fold creates a single iron-binding site between the two domains. The amino acid ligand set for the bound Fe(III) of *N. gonorrhoeae* and *H. influenzae* Fbp is the same as provided by transferrin; namely, two tyrosinates, a carboxylate and a histidine. However, despite the similarity in overall fold and Fe(III) binding site, the sequence positions of the metal ion ligands are very different suggesting that the Fe(III) binding sites have evolved in a convergent fashion.[21] As with animal transferrin, Fe(III) binding to *N. gonorrhoeae* and *H. influenzae* apo-Fbp causes a switch from an open to a closed structure. In the apoprotein, the two domains are rotated relative to their positions in the closed Fe(III)-Fbp structure and some of the Fe(III) ligand residues are too far apart to make an effective metal ion binding site.

Tight binding of Fe(III) to Fbp requires a synergistic anion, which is likely to be phosphate in vivo for *N. gonorrhoeae* and *H. influenzae* Fbp, as their iron-containing Fbp's are isolated with bound phosphate.[55] A bound H_2O completes the octahedral coordination of Fe(III). Other anions, including citrate and oxalate, can bind to the Fbp-bound iron,[55] and in the H9Q mutant of *H. influenza* Fbp the bound Fe(III) is coordinated by tetradentate EDTA located at the site normally occupied by phosphate.[56] Thus, it is possible that multiple forms of Fbp differing in the identity of the bound anion occur under physiological conditions. Dhungana *et al.*[55] propose that variable anion binding may play a role in iron release in vivo. An indication of the scope for this is provided by a comparison of citrate and phosphate binding to Neisserial Fe(III)-Fbp. These have effective association constants (for reaction 3) at pH 6.5 of 1.4×10^{17} for citrate and $4.2 \times 10^{18}\,M^{-1}$ for phosphate, but significantly different $Fe^{3+/2+}$ redox potentials of -191 and -300 mV, respectively. Dhungana *et al.*[55] suggest that the exchange of bound anions modulates the redox potential and may lead to the reduction of the bound iron to Fe(II), which is readily lost from Fbp.

$$Fe^{3+}{}_{aq} + Fbp + X^{n-} \longrightarrow Fe^{3+}\text{-}Fbp(X^{n-}) \qquad (3)$$

A comparison of Fe(III) binding characteristics of animal transferrins and Fbp is revealing about structural influences on their iron chemistries. Though Fe(III)-Fbp binds many anions, binding of carbonate at pH 6.5 has not been detected in vitro.[55] Presumably this is because the anion binding site adjacent to the Fe(III) binding sites is configured for phosphate rather carbonate. Partly as a consequence of the anion exchange, the redox potential of Fe(III)-Fbp(phosphate) is ~200 mV more positive than that of Fe(III)-Tf(carbonate), though the greater solvent exposure of the Fbp site as compared to the transferrin site has also been suggested to be an important contributing factor to this difference.[55]

P. haemolytica Fbp has significantly different spectroscopic properties from other Fbp's, with bound Fe(III) having an absorbance of 419 nm, blue-shifted from the ~480 nm usually observed for Fbp.[57] The X-ray structure of apo-Fbp from *P. haemolytica* suggests an explanation for this.[58] Although the protein did not contain bound Fe(III) it did contain two bound formate ions and was in a closed rather than open conformation. This led Shouldice *et al.*[58] to propose that the Fe(III) binding site in this Fbp consists of three tyrosines, the two formate ions and a glutamine.

4.2 Multinuclear Oxo-metal Clusters and Fbp

X-ray structures of wild-type *N. gonorrhoeae* Fbp[59,60] and mutant forms of *H. influenzae* Fbp[61] have been described in which multinuclear oxo-metal clusters are bound to the protein. These surprising results are informative about aspects of the Fbp structure and formation of oxo-metal clusters on a protein surface, but it is not clear whether they have any physiological relevance. Sadler and coworkers present a case for this,[59,60] noting that the outer membrane transport protein FecA passes diferric dicitrate into the periplasm[4] and so at least one dinuclear iron complex is available to Fbp.

The polynuclear Fe(III) clusters are bound to the two tyrosines in the conventional mononuclear Fe(III) site, Y195 and Y196, but are not bound to other amino acid residues. Trinuclear and tetranuclear clusters were observed for the H9A and N175L mutants of *H. influenzae* Fbp, respectively, and with *N. gonorrhoeae* Fbp, trinuclear clusters were seen though the structural details of these clusters varied over the different molecules in the unit cell. The crystals of *N. gonorrhoeae* Fbp containing polynuclear iron were obtained using crystals of apo-Fbp to seed iron-containing solutions. Since the apo-Fbp crystallizes in an open conformation, the question remains as to whether the formation of the polynuclear iron cluster is a consequence of crystal packing forces constraining the molecule into the open form. Shouldice *et al.*[61] note that the *H. influenzae* mutant Fbp's in which the iron-binding site residues were systematically substituted appear to be locked into the open conformation, suggesting that this is the preferred conformation for Fbp with the Fe(III) ligating residues playing a key role in closure of the structure. They then suggest that the open structure of Fbp provides a surface on which the formation of polynuclear clusters takes place. This is similar to the proposal of Malone *et al.*[62] regarding protein-template-assisted formation of polynuclear iron clusters on the surface of mutant bacterioferritins (see Section 7.8).

5 PROTEIN-MEDIATED ABSORPTION OF DIETARY IRON

Iron absorption from the mammalian gut takes place mainly in the duodenum and upper ileum. The inside of the intestine is lined with villi, the tips of which are coated with mucosal cells that provide the pathway for iron to gain access to the bloodstream. Heme iron is more readily absorbed than nonheme iron,[63] because heme does not bind most of the dietary chelators that interfere with absorption of nonheme iron. However, the mechanisms for heme absorption have not yet been fully established. Once inside the cell, the porphyrin ring is degraded and the ferrous iron produced is released into the intracellular iron pool. Nonheme iron appears to be transported to the labile iron pool within the mucosal cell via reduction by a membrane-bound ferric reductase, the diheme duodenal cytochrome *b* (Dcytb),[64] and transfer of ferrous iron to DMT1, previously called Nramp2 and DCT1.[65] This is an integral membrane protein that facilitates the proton-coupled transport of divalent cations across the cell membrane. Evidence for the involvement of DMT1 in iron acquisition comes from a natural mutation in DMT1 in some rodents, which causes microcytic anemia associated with defective iron absorption from the intestine.[65] This mutation (G195R) does not directly affect iron binding, but three negatively charged residues (D86, D192, and E299) that are highly conserved within the Nramp family have been identified by mutagenesis as being essential for cation transport.[66] Two further conserved residues, H267 and H272, are also involved in cation transport but appear to mediate a pH-dependent conformational change in the protein rather than directly binding metals.[66]

Once inside the mucosal cell, iron then has to be transported across the membrane to serum transferrin. This appears to take place via the Ireg1 transporter protein (also known as ferroportin 1 or MTP1).[67] Ireg1 is a transmembrane protein located at the basolateral membrane of the cell that has been shown to be involved in iron uptake. Oxidation of Ireg1-bound ferrous iron and its release to transferrin is likely to be enhanced by the membrane-bound multicopper ferroxidase hephaestin. This protein is 50% identical to ceruloplasmin, a soluble protein identified as having a possible role in iron loading of transferrin (*see* ***Copper Proteins: Oxidases***).[35] Mutation of hephaestin in mice leads to a build up of iron in duodenal cells and overall iron deficiency in the body.[68]

6 OTHER IRON TRANSPORT SYSTEMS

6.1 FeoABC

In conditions where a lack of oxygen stabilizes ferrous iron, the metal can be directly transported into some bacterial cells, in contrast with aerobic environments where iron is mostly present as insoluble ferric species. *E. coli* uses the FeoABC system, which comprises FeoB in the cytoplasmic membrane and two smaller proteins, FeoA and FeoC, with unknown functions. The system can use both ferrous and ferric iron as a source, although ferric ions need to be reduced before they can be transported. FeoB is also used by *Helicobacter pylori*[69] and *feo* genes are present in *Salmonella typhimurium*.[70] Both *E. coli* and *S. typhimurium* can also transport ferrous iron using the CorA protein,[71] which is a transporter of various divalent metal ions including Co(II), Mg(II), Mn(II) and Ni(II) in addition to Fe(II).

6.2 Iron Transport in Yeast

There are two main iron transport systems in *Saccharomyces cerevisiae*, one predominant under aerobic conditions and a lower affinity system utilized under anaerobic conditions.[29] In the high affinity system, which is more selective and more tightly regulated, ferric iron is first reduced to ferrous by outer membrane ferric reductases, and is then bound by the Fet3p-Ftr1p complex. Fet3p is a multicopper ferroxidase with structural and functional similarities to ceruloplasmin, although it has a higher level of ferroxidase activity (*see* ***Copper Proteins: Oxidases***).[29] Ftr1p is a permease with 6 transmembrane domains, possesses residues that suggest a potential iron-binding site, and is believed to allow iron to pass through it into the cell.[29] The low affinity pathway involves the integral membrane protein Fet4p, which appears to be another plasma membrane permease.[29] This protein can also transport other divalent transition metal ions including Cu(II), Mn(II) and Cd(II).

7 FERRITINS

The majority of organisms need a method for iron storage that protects against metal toxicity but retains bioavailability. A widespread solution to this problem is ferritin, found in almost all bacteria, plants and animals.[72] These proteins have a high capacity for storing iron, with space for up to 4,500 ferric ions per protein molecule as the mineral ferrihydrite.[73] The potential capacity for storing Fe(III) is even greater if the mineral form is different[74] though there is no compelling evidence for naturally occurring mineral cores other than ferrihydrite or amorphous phases.

7.1 Structure

The structures of several members of the ferritin family have been solved, and show a high level of conservation. Ferritin subunits, with a molecular weight of $\sim$20kDa, are four-helix bundles with a fifth short helix at the C-terminal

end of the protein chain. These subunits assemble to form a 24-meric, roughly spherical hollow shell with an outer diameter of ~120Å and an inner diameter of ~80Å (Figure 5). *Listeria innocua* ferritin, which is dodecameric, was thought to be an exception to the normal 24-meric ferritin structure but this protein is now recognized to be a member of the Dps family and will be discussed further below.

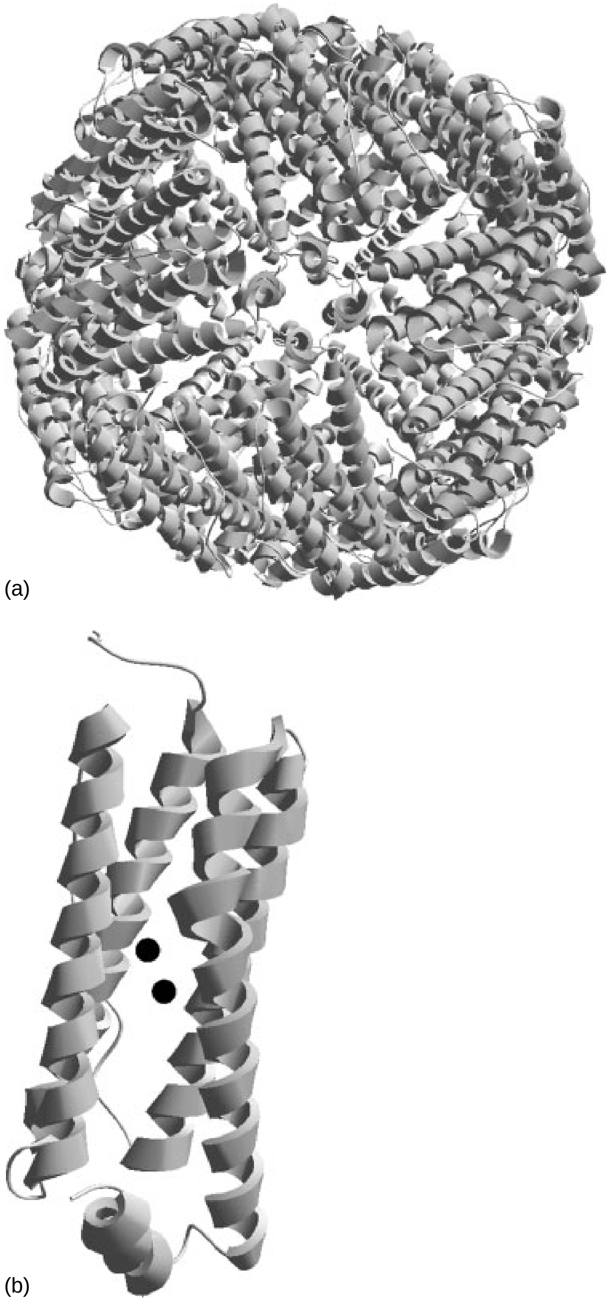

Figure 5 (a) Crystal structure of bacterioferritin from *E. coli* showing the 24-meric structure characteristic of the ferritin family. Figure created using pdb coordinates 1bfr.[75] (b) shows subunit monomer of human H-chain ferritin, with iron-binding site marked with black spheres. Figure created using pdb coordinates 2fha[76]

Mammalian ferritins are heteropolymers of H- and L-chains. These subunits are very closely related, with an α-carbon rmsd of 0.5 Å and ~55% sequence identity;[76] conservation of primary sequence rises to 79% when considering those residues responsible for intersubunit interactions.[77] Subunit assembly appears to take place via partially structured monomers associating to form fully structured homodimers, which then aggregate further. Upon chemical denaturation and refolding, heterodimers are rarely observed.[72,78]

Ferritins have eight channels located at the threefold symmetry axes and six channels at the fourfold axes. The threefold channels are often hydrophilic and the sixfold channels hydrophobic, though this polarity difference is not conserved. This may have important mechanistic consequences that are still being explored, as it appears that iron accesses the protein cavity via the hydrophilic channels.[72] The hydrophobic channels could act as the pathway for protons to be released from the protein cavity, possibly with water molecules in the channel acting as a proton wire.[79] Bacterioferritin and nonheme bacterial ferritin have extra channels located between the three- and fourfold axes. These B channels have clusters of negative charge and are large enough to allow iron atoms into the protein cavity.[80]

7.2 Oxidation of Ferrous Iron by H-chain Ferritins

Each ferritin H-chain subunit possesses a conserved dinuclear iron site known as the ferroxidase center, which catalyzes iron oxidation. Residues E27, E61, E62, H65, and E107 act as metal ligands while residues Y34 and Q144 form hydrogen bonds (the numbering refers to the human H-chain sequence) (see Figure 6).

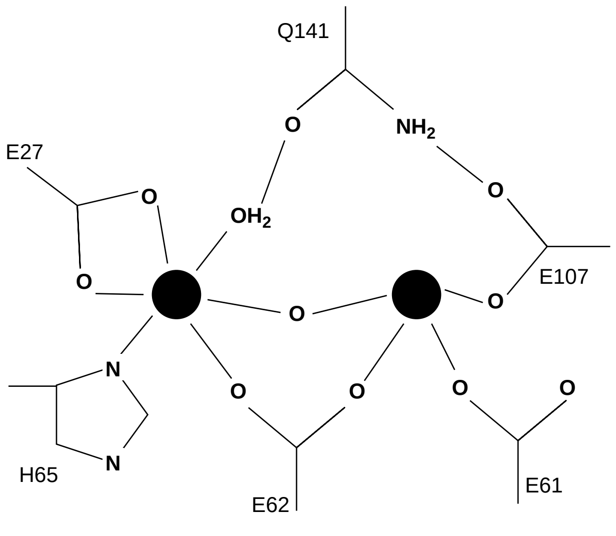

Figure 6 Schematic model of the human H-chain ferroxidase center based on the X-ray structure of Tb(III)-containing ferritin[81]

Ferrous iron binds to H-chain ferritin with the release of $\sim 0.25H^+$ per Fe(II) ion.[82] Iron oxidation then takes place via a combination of three pathways, with the proportions of each dependent on the amount of iron added. At low iron loading ($<$50 Fe per H-chain homopolymer, that is, less than required to saturate the ferroxidase centers) the dominant reaction is at the ferroxidase center (equation 4):

$$2Fe^{2+} + O_2 + 4H_2O \longrightarrow 2FeOOH_{(core)} + H_2O_2 + 4H^+ \quad (4)$$

The oxidized iron travels from the ferroxidase center to the core, thus regenerating the ferroxidase center for further reactions. When large amounts of iron are added ($>$800 Fe per protein), following oxidation of the first two ferrous ions per subunit an autooxidation reaction catalyzed by the core surface takes over and becomes the predominant mechanism (equation 5):

$$4Fe^{2+} + O_2 + 6H_2O \longrightarrow 4FeOOH_{(core)} + 8H^+ \quad (5)$$

When intermediate-sized additions are made (100–500 Fe per molecule), some of the hydrogen peroxide produced in reaction (4) is used to oxidize ferrous iron in a hydrogen peroxide/iron detoxification reaction (equation 6):

$$2Fe^{2+} + H_2O_2 + 2H_2O \longrightarrow 2FeOOH_{(core)} + 4H^+ \quad (6)$$

The result of this is that the majority of the hydrogen peroxide produced by reaction (4) goes undetected.[83]

During the ferroxidation reaction, a blue color with an absorption maximum of 650 nm appears. This persists in oxygen-limited conditions and decays as iron oxidation proceeds.[84] In frog H-chain ferritin, resonance Raman studies indicate a similar absorption is associated with an Fe(III)-tyrosinate.[85] Harrison and Treffry[86] have considered these and other studies and attribute the transient color to formation of a μ-1,2-peroxodiferric intermediate, which decays to a more stable μ-oxodiferric species as occurs in methane monooxygenase, ribonucleotide reductase, and model compounds.[87] Protein radicals distinct from reactive oxygen species have been observed that have been attributed to damage caused by Fenton chemistry.[88]

The two iron-binding sites at the dinuclear ferroxidase center are not identical. Mutagenesis of residues E27 (in site A) and E107 (site B) shows that site A can bind iron independently but requires site B for iron oxidation. In contrast, iron binding in site B is greatly decreased in the absence of site A, whereas oxidation is unaffected.[89]

7.3 L-chain Ferritin

In L-chain subunits, the ferroxidase center present in the H-chain is absent; the space occupied by it in H-chain ferritin has a salt bridge between K62 and E107 that stabilizes the protein. Nevertheless, L-chain homopolymers can accumulate Fe(III) particles through oxidation of Fe(II) at sites different from the intra-subunit ferroxidase centers of H-chain ferritins. These sites involve glutamic acid residues 53, 56, 57 and 60, and face the inner cavity of the molecule.[90,91] Because ferritins rich in L-chains oxidize iron more slowly than H-chain ferritins, they form iron particles of greater average size, crystallinity, and magnetic ordering.[77]

H- and L-chains have complementary roles in iron uptake, with heteropolymers having a higher ferroxidase activity per H subunit than H-chain homopolymers. This is because L-chain subunits bind ferric iron with a higher affinity than H-chains, thus promoting the regeneration of the ferroxidase center.[92] The rate of iron oxidation increases with increasing H-chain content up to a maximum of $\sim$35%, above which the rate-limiting step changes from ferroxidation to nucleation.[78] Heteropolymer composition varies according to the tissue of origin: organs which accumulate iron, such as the liver and spleen, have a high L content (up to 90%) to maximize storage capacity, while organs with a greater requirement for rapid iron detoxification such as the heart and brain can be two thirds H-chain.[77]

7.4 Nonheme Bacterial Ferritins

Bacterial H-chain ferritins are similar to their animal ferritin counterparts, though they are usually considered separately from these.[72] It is not clear whether the native proteins are heteropolymers or not as most of the chemical and structural studies have been carried out with recombinant protein. As-isolated proteins tend to have high levels of phosphate associated with the iron, resulting in an amorphous core structure.[93] Ferritin from *E. coli*, EcFtnA, has a dinuclear ferroxidase site that corresponds to that of H-chain ferritin, with one difference: residue E61 in human H-chain ferritin is replaced as a metal ligand by E130. EcFtnA also has a third iron-binding site, site C, on the inner surface of the protein cavity. This site shares residue E130 with site B and has E49 and E126 as additional metal ligands (Figure 7).[94] It is not essential for ferroxidase activity, as mutagenesis of site C residues results in only a slight reduction in oxidation rate. Although a third metal binding site has been suggested for human H-chain ferritin following crystallization using Tb(III), this is in a different position from the EcFtnA site C and has not been shown to bind iron.[81]

Oxidation of iron by EcFtnA produces a blue-colored intermediate with an absorption maximum at 650 nm and a shoulder at 370 nm.[86] This intermediate in human H-chain ferritin corresponds to a diferric peroxo species and is likely to be the same for EcFtnA, as mutation of Y24 has indicated that it cannot be an iron-tyrosinate.[95]

7.5 Bacterioferritins

Another member of the ferritin family found in bacteria is bacterioferritin (BFR). BFR has the same 24-meric

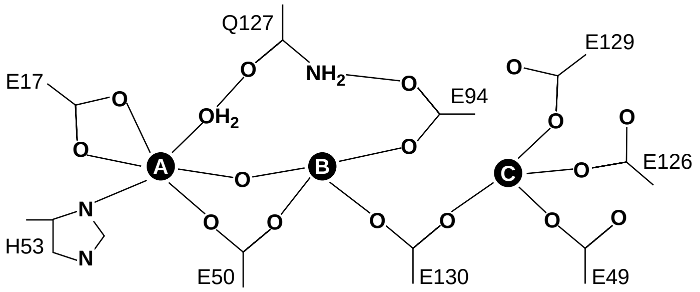

Figure 7 Schematic model of EcFtnA ferroxidase center including site C based on crystal structure[94]

three-dimensional structure as the mammalian ferritins described above, but it differs from other ferritins in containing up to 12 heme groups per molecule[96,97] bound at the interface between pairs of monomers (Figure 8), with each heme iron ligated by a methionine residue from each subunit (Met52).[75,98,99] In most characterized BFR proteins the heme macrocycle is protoporphyrin IX but in *Desulfovibrio desulfuricans* BFR it is coproporhyrin III.[100] The heme groups of *E. coli* and *A. vinelandii* BFR have been shown not to play a part in oxidative aerobic iron uptake, and their function may be in iron release or electron storage.[96,99,101]

As with H-chain ferritins, the three-dimensional structure of BFR results in channels through the protein at the symmetry axes. However, while the hydrophilic threefold channels in bacterioferritin are similar to those in ferritin, the BFR fourfold channels are hydrophilic rather than hydrophobic in character.[72,80]

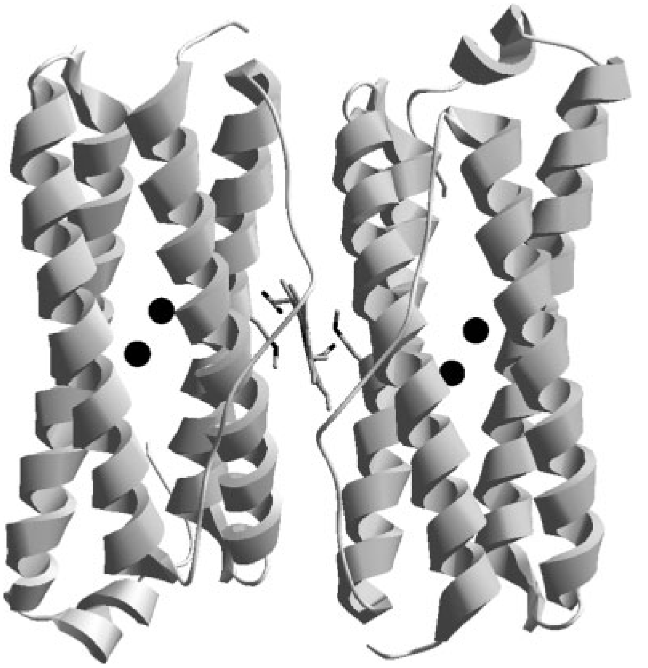

Figure 8 The structure of the BFR subunit dimer showing heme bound at monomer interface by M52 residues. The iron atoms in the ferroxidase centers are shown as black spheres. Figure created using pdb coordinates 1bcf[75]

The residues that make up the bacterioferritin ferroxidase center also differ from those seen in H-chain ferritins. Although there are differences between mammalian and nonheme bacterial ferritins in the individual residues used to ligate the iron, H-chain ferroxidase centers have four glutamate residues, one histidine, and a bridging glutamine that interacts with metal ions indirectly via a hydrogen bonded water molecule. The BFR ferroxidase center, in contrast, more closely resembles the di-iron sites of proteins such as methane monooxygenase and ribonucleotide reductase (*see* ***Iron Proteins with Dinuclear Active Sites***). It has four glutamate residues, one of which replaces the bridging glutamine, and Glu130 in EcFtnA is replaced by an additional histidine (Figure 9). Although the bacterioferritin ferroxidase center is more symmetrical than those in H-chain ferritins, the surrounding residues induce an element of asymmetry in the BFR center. This leads to nonequivalence in the two iron sites. Mutagenesis of E18 in site A abolishes iron uptake, giving iron oxidation rates similar to those of autooxidation, while mutagenesis of E94 (the corresponding residue in site B) results in a much less dramatic reduction in activity.[102] Similar effects are seen for the histidines. A third iron site similar to site C of EcFtnA has not been described for BFR.

A significant difference between BFR and H-chain ferritins is the mechanism of iron uptake and core formation. In H-chain ferritins, initial iron uptake takes place by ferrous iron being oxidized at the ferroxidase center and moving into the core, and once a sizeable core has been established, autooxidation at the core surface takes over from the ferroxidase center reaction (see Section 7.2). In BFR, iron uptake takes place in three distinct phases.[103] Phase 1 is the binding of two ferrous ions per ferroxidase center (48 per protein). Phase 2 corresponds to rapid oxidation at the ferroxidase center according to reactions (7) and (8), where z represents the charge on the protein.[51,102–104]

$$[Fe^{II}{}_2\text{-P}]^z + O_2 + H_2O \longrightarrow [Fe^{III}{}_2O\text{-P}]^z + H_2O_2 \qquad (7)$$

$$[Fe^{II}{}_2\text{-P}]^z + H_2O_2 \longrightarrow [Fe^{III}{}_2O\text{-P}]^z + H_2O \qquad (8)$$

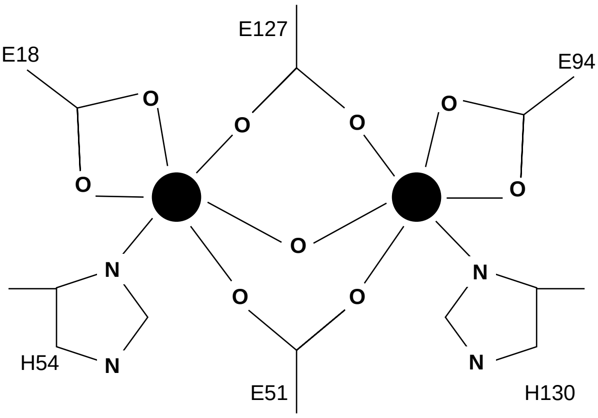

Figure 9 Schematic model of BFR ferroxidase center based on the crystal structure of iron-bound BFR from *D. desulfuricans* (EcBFR numbering). The bridging ligand, shown here as a μ-oxo group, cannot be determined in the structure but there is sufficient electron density for a μ-oxo, μ-hydroxo, H_2O and even peroxo group[100]

The overall ferroxidase reaction is therefore reaction (9) below:

$$2[\mathrm{Fe^{II}}_2\text{-P}]^z + O_2 \longrightarrow 2[\mathrm{Fe^{III}}_2\mathrm{O}\text{-P}]^z \qquad (9)$$

Note that reaction (9) indicates a pairwise reaction within subunit dimers rather than individual ferroxidase centers reacting separately. Although reaction (7) indicates the formation of hydrogen peroxide, no diferric peroxo intermediate has been observed for BFR. This may be because such a species is not formed, or, more likely, because such an intermediate is too short lived or has too low an extinction coefficient to be detected.[86]

Following reaction (9), the ferric iron remains at the ferroxidase center as a μ-oxo bridged species instead of moving into the core and thus regenerating the ferroxidase center. The addition of more than 48 ferrous ions per protein saturates the ferroxidase reaction and any further iron is oxidized within the core (phase 3). This process is significantly slower than phase 2. Core formation occurs according to reaction (10) below.

$$4Fe^{2+} + O_2 + 6H_2O \longrightarrow 4[FeOOH] + 8H^+ \qquad (10)$$

Although reaction (10) takes place after the ferroxidase center has been filled, experiments involving blockage of the BFR ferroxidase centers with zinc in BFR containing a significant ferric core show that the ferroxidase center is required throughout core formation.[102,105] However, the rate of core formation is linked to the core surface area, indicating a role for the core surface in the phase 3 reaction. This has led to the proposal that in phase 3 ferrous iron binds at the growing mineral surface, or to acidic residues on the inner surface of the protein, becoming oxidized to Fe(III) with the electrons from this oxidation passing through the core to the ferroxidase

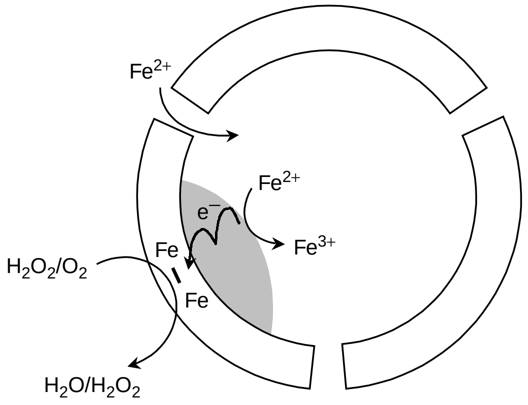

Figure 10 Schematic model of BFR core formation mechanism

center, which becomes reduced. The ferroxidase center iron is then reoxidized by molecular oxygen according to reaction (9) above. Thus the core surface is the site of iron oxidation but not oxygen reduction.[105] This reaction mechanism is illustrated in Figure 10.

7.6 Iron Release from Ferritins

Iron can be removed from ferritin containing Fe(III) by Fe(III) chelators or, following reduction, by Fe(II) chelators.[106–108] Rapid iron release results from reduction of the core in the presence of a ligand; reduction alone does not lead to iron release. For example, at pH 7 thioglycollic acid removed ~5% of the core iron after a 10 min incubation, and reduced flavin mononucleotide removed ~25% after only a 2.5 min incubation. Moreover, Fe(III) chelators, such as EDTA, 1,10-phenanthroline and desferrioxamine B, removed only a small fraction ($\leq$10%) of the iron of horse spleen ferritin after 24 hr at pH 7 and this, coupled with calculations of iron turnover in cells synthesizing heme, is generally taken to indicate that the release of Fe(III) is not physiologically significant.[106,108] This suggests that the core contains Fe(II) in vivo or that iron release involves the prior reduction of core iron. The physiological significance of such experiments is open to question however, as the iron acceptor molecules and any reductants employed are rarely physiologically relevant. Proteins involved with intracellular trafficking of iron in bacteria have been reported, such as YggX in *Salmonella enterica*[109,110] and Bfd in *E. coli*,[111,112] making this a topic ripe for revisiting with these proteins in place of the normal iron acceptors.

The mechanism of the reductive iron release has not been fully characterized but several lines of evidence point to small reductants and chelators remaining outside the protein shell during reaction[107,113,114] with the rate-limiting step for Fe(II) release being long-range electron transfer (*see* ***Long-range Electron Transfer in Biology***) into the core across the protein shell.[101,111] If correct, this implies that Fe(II) migrates

through the protein shell faster than electrons. Nevertheless, iron passage through the shell is relatively slow with a rate that is influenced by the structural dynamics of the channels though the protein shell by which iron enters and leaves the cavity.[115]

7.7 Redox Properties of Ferritins

Rapid iron uptake or release by ferritins to form, or breakdown, a Fe(III) core involves redox reactions, as discussed in previous sections. The present section summarizes data regarding measurement of redox properties not involving iron release or uptake.

The reduction potentials of the core iron of *A. vinelandii* and horse spleen ferritins have been determined electrochemically to be $-420 \pm 20\,\text{mV}$ and $-190\,\text{mV}$, respectively, at pH 7.[116,117] The former potential was invariant over the pH range 7.0–9.0 while the latter potential decreased with increasing pH. The $Fe^{3+/2+}$ reduction potential at pH 8 of the heme of *A. vinelandii* ferritin is $-475\,\text{mV}$ in the presence of the core and $-225\,\text{mV}$ in its absence.[116] Since magneto-optical spectroscopic properties of the heme are not affected by the core this shift in potential has been ascribed to a core electrostatic field effect.[118]

Horse spleen apoferritin undergoes additional redox reactions with an overall stoichiometry of 4.0–7.1 electrons/24-mer at a midpoint reduction potential of $-310\,\text{mV}$.[119] This potential was invariant over the pH range 6–9 showing that H^+ uptake or release does not accompany the redox process. The identity of the group(s) giving rise to these processes has not been established but studies with recombinant H- and L-chain ferritins suggest that the formation of protein-bound organic redox centers involves the H-chain, but only when it is associated with L-chain in heteropolymers.[120] Since this study found that the W93F H-chain mutant was redox-inactive, it appears as if W93 is required for this activity.

The polynuclear iron cores of reduced horse spleen ferritin and *A. vinelandii* ferritin can be oxidized by a variety of proteins via long-range electron transfer across the protein shell.[113,121] The rates for horse spleen ferritin varied from $<0.2\,M^{-1}\,s^{-1}$ for metmyoglobin to $1.1 \times 10^3\,M^{-1}\,s^{-1}$ for horse ferricytochrome *c*. None of the reported interprotein electron transfer studies with ferritins are physiologically significant because nonphysiological partner proteins were used, and it will be interesting to see this kind of study extended to bacterioferritin reacting with proteins like YggX[109,110] and Bfd.[111,112]

7.8 Physicochemical Characteristics of the Nonheme Iron Cores of Ferritins

There are a variety of types of ferritin nonheme iron core, ranging from the highly ordered cores of horse spleen ferritin to the amorphous cores of bacterioferritins.[72] As noted earlier, the central cavity of ferritin has a sufficient volume to accommodate 4,500 iron atoms as $Fe_2O_3{\cdot}9H_2O$, though ferritins are rarely isolated fully loaded.[73] Mature horse spleen ferritin generally has 1,000–3,000 iron ions per molecule and bacterioferritins are usually isolated with only 800–1,500 iron ions per molecule,[122] even though their mean core sizes determined by electron microscopy are not too different from those of animal ferritin.[123,124] This is one indication that the density of ferritin cores differ markedly. This difference in core morphology is often associated with the phosphate content of the core, a high phosphate content being correlated with an amorphous core,[124] and indeed, the phosphate content of ferritin is generally low, with the phosphate located at the surface of the core,[125] while native bacterioferritins have a greater phosphate content, suggesting that bacterioferritin may have a role as a phosphate store.[107,126]

There is a lack of precise structural information for ferritin cores because while preparations of iron-containing ferritins may be monodisperse with regards to their protein components they are polydisperse in their core components as a result of the high symmetry of the inner surfaces bordering their central cavities. A consequence of the polydisperse nature of the cores is that in crystals of ferritin, though the protein shell is ordered the iron-containing core is not.[72,73] Consequently, the structure of the core mineral has not been determined by X-ray crystallography, and complete structural characterization of intact ferritins may not be possible. For this reason, stabilized subunit dimer forms of ferritins have been made by site-directed mutagenesis. Fe(III)-binding properties of two of these engineered proteins, the E128R/E135R mutant bacterioferritins from *E. coli* and *Rhodobacter capsulatus*, have been described.[62] They both acquire polynuclear Fe(III)-containing particles on their surfaces that are resistant to rapid removal by chelating agents, and thus they may represent a way forward for determining structural features of the core iron.

EXAFS studies of *A. vinelandii* bacterioferritin have shown that there are fewer Fe–Fe contacts in the mineral core than occur with native horse ferritin, and those that do occur are at a greater interatomic distance.[127] Moreover, the EXAFS data showed that the core iron of bacterioferritin had 5 to 6 phosphorus atoms no more than 3.17 Å distant, thus supporting a model for the core of an amorphous Fe(III)-phosphate complex in which some of the phosphate bridges Fe(III) ions and some of it is nonbridging.

The generally accepted structure for the crystalline iron core of ferritin is the ferrihydrite structure proposed by Towe & Bradley.[128] This consists of oxygen layers with iron in octahedral sites between the layers. Ford *et al*.[73] and Powell[74] have summarized the evidence in support of this model for ferritin, which includes electronic spectroscopic data and EXAFS measurements confirming the presence of six-coordinate Fe(III) and indicating that four-coordinate Fe(III) is present, if at all, at low levels only. This latter point is important because the X-ray powder diffraction patterns of

air-dried ferritin cores can be adequately fitted with both the Towe & Bradley model and with a model containing both tetrahedrally and octahedrally coordinated Fe(III);[73] and because the Towe & Bradley model itself is not accepted by all workers for the structure of ferrihydrite.[129] Moreover, as Powell notes,[74] even in the crystalline native ferritin cores there is disorder which makes their characterization difficult. This is one of the reasons so much effort has been expended on synthetic analog studies of ferritin cores (see Section 7.9).

Reconstitution experiments with apoferritins from animal and bacterial sources, whose native iron-loaded ferritins had crystalline and amorphous cores respectively, have been informative in showing that the core morphology is not determined by the protein shell. For example, Baaghil *et al.*[105] and Mann *et al.*[130] were able to form crystalline cores in bacterioferritins, and Rohrer *et al.*[127] formed cores of iron-phosphate in horse spleen ferritin with fewer short range Fe–Fe distances than in the native cores. Thus it appears that the composition of the medium within which the ferritin cores are laid down, particularly the phosphate content, influences strongly the nature of the core. This is consistent with the role of phosphate as an iron oxide chain terminator.[126]

^{57}Fe Mössbauer spectroscopy has been widely employed to study ferritins.[116,124,130] The spectra of the ferric cores are temperature dependent and consist of a quadrupole-split doublet at high temperature and a magnetically split sextet at low temperature. Two general cases have been observed. In the first, the magnetic ordering temperature (T_{ord}) is greater than the blocking temperature (T_B), and in the second, $T_B > T_{ord}$. Proteins in the former class, exemplified by horse ferritin with a T_B of $\sim$40 K, exhibit superparamagnetic behavior. The latter class of ferritins, illustrated by *Pseudomonas aeruginosa* bacterioferritin,[131] with a $T_B > 3$ K and a $T_{ord} < 3$ K, does not show superparamagnetic behavior. The presence of superparamagnetism appears to be correlated with both the size and degree of crystallinity of cores; the higher the magnetic anisotropy barrier the greater T_B is. Hence at constant K, a higher T_B indicates a greater particle volume, and hence a greater crystallinity. Thus ^{57}Fe Mössbauer spectra are consistent with electron microscopic data indicating that the cores of bacterioferritin are largely amorphous while those of mammalian ferritins are largely crystalline. Magnetic circular dichroism spectra of amorphous bacterioferritin and crystalline ferritin cores are also consistent with this.[132]

EPR data also reveal a difference between the ferritin and bacterioferritin cores. At high temperatures the latter yield a broad signal with $g \sim 2$ and at 4 K are EPR silent,[118,133] while the former give signals at high temperatures at $g \sim 6$ and $g \sim 2.2$ that are lost at 4 K.[134,135] The origin of the bacterioferritin signal is not certain but since bacterioferritin cores of 800 iron atoms per 24-mer and 24–68 iron atoms per 24-mer have similar EPR characteristics which are absent from core-free protein, the signal must arise from the core particle.[118] The signal appears to be reporting the relaxation characteristics of the core and may arise either from uncompensated spins or, more likely, from uncoupled spins since the exchange coupling temperature is below 4 K. It has been assumed that the ferritin EPR signals originate from the uncompensated electron spins of the antiferromagnetically ordered cores[135] and if this is so there should be a correlation between the EPR and Mössbauer data. This appears to be the case for animal ferritin, which Mössbauer indicates is magnetically ordered at 4 K.

7.9 Synthetic Analogs of the Polynuclear Clusters of Ferritins

A variety of approaches have been adopted in attempts to obtain analogs of crystalline ferritin cores but, as Powell has pointed out,[74] uncertainty over the structure of the ferritin core itself complicates this field. The earliest synthetic approach was that of Spiro *et al.*,[136] who obtained citrate-coated spheres of polymeric iron hydroxide by hydrolysis of ferric citrate. Though the early characterization of these spheres indicated they might be good models for ferritin,[137] the difficulty in obtaining reproducible samples, and the lack of structural information, has led to greater efforts being put into other approaches.

One of these approaches is the formation of polysaccharide iron complexes[138–140] (PIC), such as Niferex, a compound used in the treatment of iron deficiency anemia. PICs are formed by neutralization of $FeCl_3$-containing carbohydrate solutions with base. Mineral particles of roughly the same size as ferritin cores can be made. These contain iron in an octahedral environment coordinated to oxygen. However, the long-range order of the polynuclear iron core is closer to that of akaganéite rather than ferrihydrite.[140]

Addition of base to aqueous solutions of Fe(III) in the presence of the ligand $N(CH_2COOH)_2(CH_2CH_2OH)$ ('heidi'), produced 19-iron and 17-iron species, neither of which have a 3-D framework of Fe(III) ions. These species contain close-packed iron hydroxide cores bound, via oxide and hydroxide bridges, to Fe(III) located on the inner surface of the heidi coat.[74,141] The inner core, which is common to both Fe_{17} and Fe_{19} compounds and consists of an $[Fe_7(\mu_3\text{-OH})_6(\mu_2\text{-OH})_4\{(\mu_3\text{-O})Fe\}_2]^{13+}$ unit, derives from a portion of an infinite 2-D $[Fe(OH)_2{}^+]_n$ framework. This suggests that the ligand shell, $[Fe_{10}(heidi)_{10}(H_2O)_{12}(\mu_3\text{-O})_4(\mu_2\text{-OH})_4]^{12-}$, traps the iron in an unusual, for Fe(III), hydroxide mineral structure, and poses the question of whether the core of ferritin is a similarly 'trapped' structure.[74]

An alternative approach is to use nonaqueous synthetic routes to achieve tight control of any hydrolytic processes taking place. Many species have been prepared this way including Fe_3, Fe_4, Fe_6, Fe_8, Fe_{10}, Fe_{11} and Fe_{16} iron-oxo compounds.[52,142–145] Though the compounds produced via this route have an intriguing set of structures and properties, it is not clear that they are good models for the ferritin

core since most are not close-packed structures. However, they may be relevant to the early stages of nucleation and core formation. The most relevant compound produced from nonaqueous solutions, and the only characterized poly iron-oxo complex with a 3-D close-packed structure, is $[Fe(III)_4Fe(II)_8(O)_2(OCH_3)_{18}(O_2CCH_3)_6(CH_3OH)_{4.67}]$. This compound was prepared by Taft *et al.*[146] by controlled oxidation of a methanol solution of Fe(II) and $LiOCH_3$. The central distinction between this compound and that of the heidi complexes is that the former only contain μ_3-oxo ligands and μ_4, or greater, are needed to form a 3D lattice. The Fe_{12} compound of Taft *et al.* contains μ_6-oxo ligands.

8 Dps

Another protein able to sequester iron in a mineral core is Dps, a member of the ferritin superfamily. The name Dps comes from DNA-binding protein from starved cells,[147] but although some Dps (for example, those from *E. coli* and *Synechoccus* sp.[147,148]) do bind DNA nonspecifically, others such as those from *Campylobacter jejuni* and *Agrobacterium tumefaciens* have no DNA-binding activity.[149,150] These proteins retain the ability to protect DNA from damage via reactions with hydrogen peroxide.

Those Dps proteins that bind DNA do so nonspecifically via positive residues at the N-terminus of the protein. When a cell is under prolonged stress, Dps cocrystallizes with DNA in vivo.[147] This process is favored because it occurs spontaneously and does not deplete the cell's ATP levels. The formation of a multilayered complex provides a physical barrier around the DNA in addition to the hydrogen peroxide detoxification that accompanies iron oxidation.[147]

In addition to the ferritin from *L. innocua* already mentioned, a variety of proteins show structures and iron assimilation activities similar to Dps, although they do not bind DNA. These include the Dpr (Dps-like peroxide resistance) protein from *Streptococcus mutans*,[151] Dlp from *Bacillus anthracis*[152] and the neutrophil-activating protein from *Helicobacter pylori*, HP-NAP.[153]

8.1 Structure

Dps subunits have a molecular weight of ~17kDa and a four-helix bundle structure very similar to that of ferritin. The subunits are assembled into dodecamers (Figure 11), again giving a roughly spherical shell surrounding a central cavity with an internal diameter of 45 Å (compared to the 80 Å internal diameter of ferritin).[154] This means that the Dps cavity has a volume approximately one fifth to one sixth the size of ferritin. The protein has tetrahedral symmetry, resulting in two different pores associated with each of four threefold axes. Four of these pores are hydrophobic and, by analogy with ferritin, may provide a route for exiting protons. The remaining four acidic pores correspond to the threefold channels in ferritin and so could be the point of entry for ferrous iron.[154]

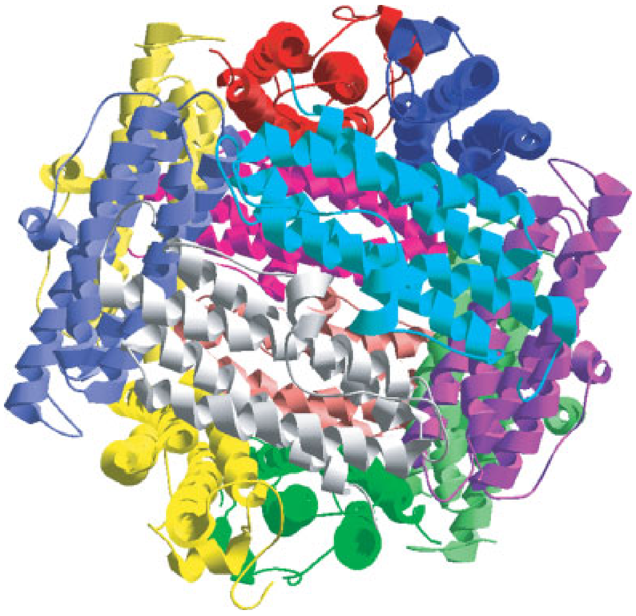

Figure 11 The X-ray structure of Dps from *E. coli* showing its 12-meric structure. Figure created using pdb coordinates 1dps[154]

8.2 Iron Uptake

Dps has ferroxidase activity and has 12 ferroxidase centers, two situated at each subunit dimer interface. The iron ligands are donated from both subunits; H31, H43 and E47 from one subunit and D58 and E62 from the other. The iron-bound ferroxidase center of the Dps from *Bacillus brevis* is shown in Figure 12.

Two ferrous ions bind per Dps subunit with the release of one proton per iron. The oxidation reaction takes place according to reaction (11) below:

$$Fe^{II}\text{-}P + H_2O_2 + H_2O \longrightarrow Fe^{III}{}_2O(OH)\text{-}P + 3H^+ \qquad (11)$$

Hydrogen peroxide is the preferred oxidant, which accounts for the ability of Dps to protect DNA from the effects of hydrogen peroxide; the rate of oxidation using molecular oxygen is little different from that of autooxidation.[156]

At higher iron concentrations, a ferrihydrite core is deposited, up to a maximum of 500 ferric ions per protein. This mineralization reaction occurs via reaction (12) below.

$$2Fe^{2+} + H_2O_2 + 2H_2O \longrightarrow 2FeOOH_{core} + 4H^+ \qquad (12)$$

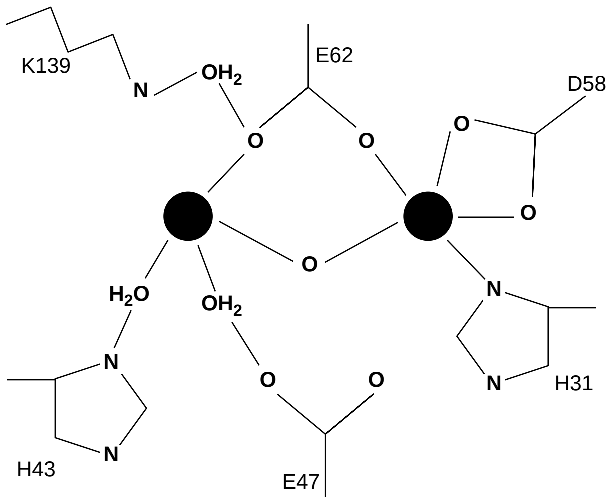

Figure 12 Schematic model of Dps binding site based on the X-ray structure of iron-bound Dps from *B. brevis*[155]

The mechanism of iron oxidation and core formation in Dps differs from that of ferritin and bacterioferritin in that the rate of mineralization is faster than oxidation at the ferroxidase center; in *L. innocua* ferritin and *E. coli* Dps core formation is 60% faster than the ferroxidation reaction.[156]

Fe(III) at the ferroxidase center of Dps has a very high extinction coefficient (~30 000 $M^{-1}\,cm^{-1}$, as contrasted with ~2000 $M^{-1}\,cm^{-1}$ for ferric iron in the bacterioferritin ferroxidase center). This high value, which shows a gradual decrease as the ferroxidase center empties, may be due to the presence of more than one bridging group between the ferric ions.[156] The Dps from *B. brevis* has been crystallized with some iron remaining at the ferroxidase centers, although the two binding sites are not equally occupied. This crystal structure shows the two metal ions linked by a μ-oxo bridge and a water molecule (Figure 12).[155]

9 HEMOSIDERIN

Hemosiderin was the first form of iron storage protein to be identified. It is the chief form of stored iron in animals suffering from iron overload but is also a nonpathological form of storage in many birds and animal species. The protein content of hemosiderin varies, but it appears to be composed of degradation products of ferritins. It is water-insoluble and has a molecular mass greater than 4,000 kDa. It has a high iron-to-protein ratio with the iron in a mineral form, although mineralization varies depending on the pathology of the source. In nonpathological hemosiderin, the iron is mainly in the form of ferrihydrite, as seen for ferritins and frataxin, whereas in genetic hemochromatosis and thalassemia (*see* ***Metal-related Diseases of Genetic Origin***) it is present mainly as amorphous ferric oxide and goethite, respectively. It is not clear how these different cores are formed, although hemosiderin from sources with genetic hemochromatosis often has high levels of phosphate associated with the iron, which may contribute to the amorphous nature of the core.[157] In overloaded liver tissue, studies have shown that hemosiderin is composed mainly of denatured H-chain ferritin. This is possibly due to L-chain ferritin having greater stability, as discussed earlier.[158]

10 FRATAXIN

Although a ferritin has been identified in some mammalian mitochondria, the role of the mitochondrion in the synthesis of heme and iron–sulfur clusters means that this organelle requires a more widespread way of controlling iron homeostasis, and this is where frataxin, a 14 kDa protein found in most eukaryotes, plays a role. A reduction in frataxin levels in humans causes the recessive neurodegenerative and cardiodegenerative disease Friedreich's ataxia. The wide-ranging effects of the disease are due to the broad distribution of the protein, with particularly high expression in the heart, cerebellum, and spinal cord.[159] Patients with the condition have been found to have increased iron deposits, with a resulting hypersensitivity to oxidative stress, as well as reduced synthesis of iron–sulfur cluster proteins. Deletion of the protein in yeast causes similar biochemical effects.[159]

The structure of the human frataxin monomer is an $\alpha\beta$ sandwich with a 7-stranded antiparallel β-sheet and 2 α-helices (Figure 13). A cluster of conserved acidic residues on the protein surface forms a large anionic patch that is likely to provide a site for iron nucleation. Frataxins from

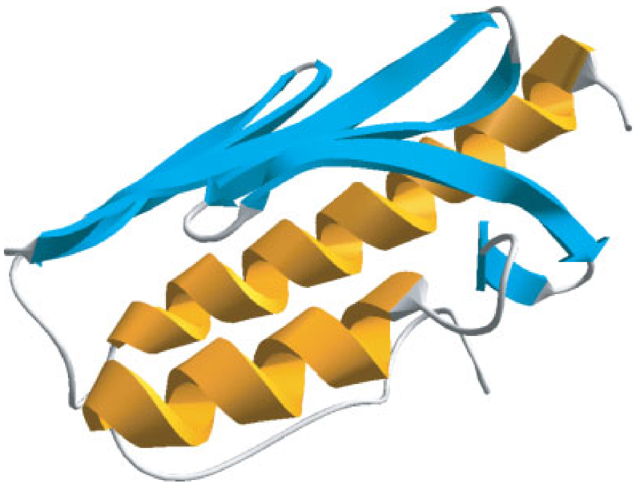

Figure 13 The X-ray structure of human frataxin. The figure was created using pdb coordinates 1ekg[160]

other organisms, including yeast, are predicted to have similar structures.[160]

The coupling between assembly of monomers and Fe(II) oxidation is complex and may be different for frataxin from different sources. A further complication is that the aerobic oxidation of Fe(II) in yeast frataxin is sufficiently slow that in vitro it stabilizes Fe(II) against autooxidation, and under some conditions a 40:60 mixture of Fe(II) and Fe(III) is retained by the protein.[161] Iron binding by human frataxin is faster than with yeast frataxin but the resulting mineral cores are identical; and when human frataxin is expressed in yeast cells grown under iron-rich conditions, roughly 50% of the mitochondrial iron is retained as a complex with frataxin (with iron levels of 5 per monomer).[159] We consider further aspects of yeast and human frataxins separately as they appear to have significantly different properties.

10.1 Yeast Frataxin

At low iron concentrations of Fe(II) (up to 0.5 per monomer), monomers of yeast frataxin are activated to assemble by a combination of ferrous iron and molecular oxygen. Iron oxidation occurs according to reaction (13) below:

$$2Fe^{2+} + O_2 + 2H^+ \longrightarrow 2Fe^{3+} + H_2O_2 \qquad (13)$$

Although this reaction produces hydrogen peroxide, less than 2% of the expected amount can be detected, because most of the peroxide goes on to react with the protein in reactions separate from iron oxidation.[162] At higher concentrations of Fe(II) (up to 1.5 ferrous iron per monomer), autooxidation begins to take over as in reaction (14):

$$4Fe^{2+} + O_2 + 4H^+ \longrightarrow 4Fe^{3+} + 2H_2O \qquad (14)$$

During reactions (13) and (14), the frataxin monomers link to form trimers.[162] These trimers have negatively charged inner surfaces that promote nucleation of the polynuclear iron mineral. As iron concentrations increase further and iron crystallites at the nucleation centers grow, the mineral components of the protein bind to each other, linking the protein trimers pairwise. These ultimately form 48-mers with a molecular weight of 840 kDa, although 96-mers have been observed. These protein aggregates contain up to 50 iron ions per monomer that X-ray absorption spectroscopy indicates is in a ferrihydrite core similar to those found in ferritins, although they are less ordered and much smaller than mammalian ferritin cores.[162–164]

Iron oxidation and trimer formation appear to be linked, as no iron-containing monomers have been observed for yeast frataxin. Trimers do not form under anaerobic conditions in the presence of Fe(II)[162] or following the addition of other divalent metal ions or Fe(III),[161] and the removal of the tightly bound Fe(III) using EDTA causes the protein to disassemble into monomers. Given the stoichiometry of the ferroxidation reaction and the low concentrations required to saturate ferroxidation, it has been suggested that a dinuclear iron site is formed between three monomers.[162]

10.2 Human Frataxin

Expression of human frataxin in *E. coli* gives a mixture of preassembled aggregates of ~1MDa and rod-shaped polymers of these, which can accommodate roughly 7–10 Fe per monomer.[159] The same protein expressed in *S. cerevisiae* forms a mixture of monomers and higher molecular weight (>600 kDa) aggregates. In contrast to yeast frataxin, treatment of these monomers with Fe(II) in an aerobic environment results in minimal aggregation (less than 10%). Although the observed preassembly may be an artifact due to overexpression, the aggregates formed are soluble and remain active in accumulating iron. They are also less prone to degradation than monomers. A similar distribution of monomers and higher molecular weight aggregates are also observed in native samples taken from mouse heart.[159]

11 HEMOPEXIN

Following degradation of heme-containing proteins, free heme is released into the extracellular environment. Although the iron is bound in the porphyrin ring, this is not enough to protect the organism from the potentially toxic effects of iron catalyzed Fenton-type reactions and, in addition, free heme provides a good source of iron to pathogenic bacteria. Mammals minimize these problems by the production of hemopexin, a serum protein that binds one heme per molecule with high affinity (K_d <1pM) as a low-spin bis-histidyl complex.[165] This process of heme recycling therefore not only protects the organism from the deleterious effects of free iron but has the additional benefit of enabling the iron within the heme to be reused.

Hemopexin is a 40 kDa protein divided into two domains with a high level of homology between them (25% amino acid sequence identity). Both domains are four-bladed β-propellers linked by a 20-residue hinge region (see Figure 14), with the bound heme in a pocket between the domains that is formed by the linker region. H213 from the linker and H266 from the C-terminal domain bind the heme. Although the N-terminal domain does not bind heme in the intact protein, the separated domain prepared by proteolytic cleavage of the intact protein does bind heme and in this case too, the heme binds as a low-spin bis-histidyl complex, though the identity of the heme ligands have not been determined.[165–167] Probably because the heme binding site involves the flexible linker peptide, heme binding to intact hemopexin induces a conformational change in the protein that apparently facilitates receptor binding.[165,168]

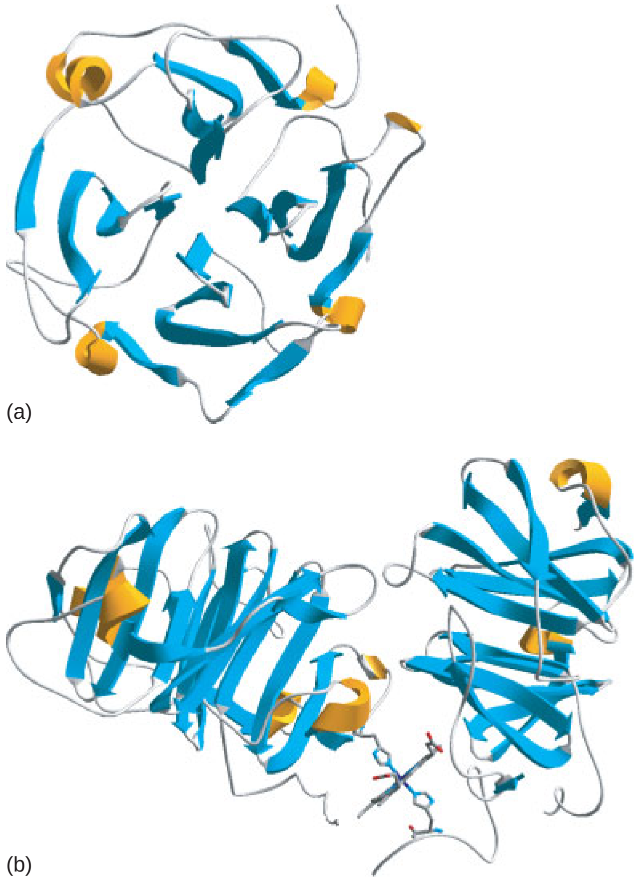

Figure 14 (a) The X-ray structure of heme-bound rabbit hemopexin. (b) shows the β-propeller structure of individual domains. The figure was created using pdb coordinates 1qhu[168]

Hemopexin delivers heme to specific cells, chiefly in the liver, by a mechanism involving receptor-mediated endocytosis similar to that employed by diferric transferrin.[165] Heme-loaded hemopexin binds to a specific receptor on the cell surface, with the hemopexin C-terminal domain promoting interactions between the two proteins. Following endocytosis, the heme is released from hemopexin in the low-pH environment of the endosome. At this point, the heme is released and the porphyrin ring degraded via heme oxygenase. At the same time, downregulation of transferrin receptors and induction of ferritin synthesis occurs as a protective mechanism to prevent cell damage from the released iron.[169]

12 HEMOPHORES

In addition to siderophores, pathogenic bacteria possess a range of other mechanisms to acquire iron from their host. Specific transferrin or lactoferrin receptors on the outer membrane allow iron to be removed from the host protein and transported into the cell, although the mechanism for this process is as yet unclear. Proteases and cytolysins may be released into the host by bacteria, and these enzymes then release hemoglobin from erythrocytes. This hemoglobin, or the free heme, can be transported into the bacterial cells by heme uptake systems with specific outer membrane receptors. Also, some pathogens secrete extracellular proteins called hemophores, which bind free heme and return it to the bacteria in a similar kind of uptake pathway to siderophore-mediated acquisition of nonheme iron. A well-characterized example of a hemophore is the HasA protein.

HasA has been identified in *P. aeruginosa*,[170] *P. fluorescens*,[171] *Yersinia pestis*[172] and *Serratia marcescens*.[173] It is a 19 kDa protein with no sequence homology to other known heme proteins. It binds free heme tightly and can remove it from hemoglobin, a property it shares with hemopexin. The mechanism by which HasA removes heme from hemoglobin is unclear; it does not form a stable complex with hemoglobin so there may be formation of a transient protein complex or alternatively binding may be due to a higher affinity of HasA for heme following diffusion of heme out of hemoglobin.[174]

The crystal structure of heme-loaded HasA has been determined, and reveals an $\alpha\beta$ protein that does not resemble any known structure (see Figure 15). The heme molecule is located between the α and β regions of the protein and is exposed to the bulk solvent. The heme iron is ligated by His32 and Tyr75, although His32 is not essential for in vitro heme binding. Numerous hydrophobic and stacking interactions with the porphyrin ring provided by surrounding residues in the heme pocket help contribute to the high binding affinity

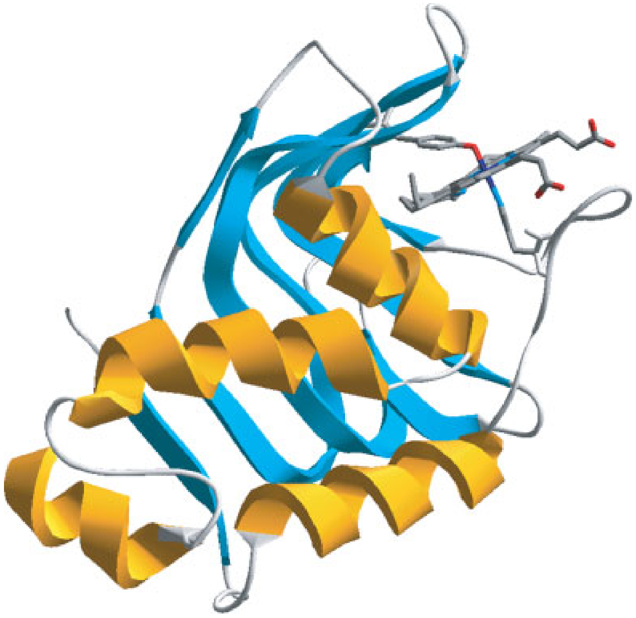

Figure 15 The X-ray structure of HasA from *S. marcescens* showing heme ligated by Y75 and H32. The figure was created using pdb coordinates 1b2v[176]

of the protein for heme. Another histidine residue, His83, stabilizes the iron-phenolate bond via hydrogen bonding and holds the tyrosine residue in an optimal orientation for heme binding. When Tyr75 is removed, His83 appears to be able to act as a replacement iron ligand.[175]

Once loaded with heme, HasA delivers it to its outer membrane receptor, HasR. This is able to take up heme directly, but the addition of HasA greatly increases its efficiency. Like uptake of many ferric-siderophore complexes, entry of heme into the cell via HasR requires the TonB-ExbB-ExbD system, although formation of the HasA-HasR complex is independent of TonB. Two regions of HasA (residues 51–60 and 95–107) bind HasR independently of each other, with a high enough affinity that the deletion of one region does not prevent complex formation. This has led to a suggested scheme in which the two regions, which fall either side of the ligating tyrosine, bind to HasR and then move apart, opening the heme pocket and destabilizing the heme-protein contacts.[177] Another factor affecting heme uptake by the cell is that apo and heme-loaded HasA bind the HasR receptor with apparently similar affinities; experiments using a mixture of radiolabelled and unlabelled HasA indicate that the proteins do not exchange. This raises the question of why the receptors do not become saturated with apo HasA once the heme has been delivered. One possibility is that heme-loaded HasA transfers heme to receptor-bound apo HasA, a mechanism we have already encountered in this article for some siderophore-receptor systems.[174]

CV = cyclic voltammetry; Fd = ferredoxin; HP = high potential iron–sulfur protein; IRP = iron regulatory protein; LS_3 = 1,3,5-tris((4,6-dimethyl-3-mercaptophenyl)thio)-2,4,6-tris(p-tolylthio)benzene (3-); Rd = rubredoxin; SCE = standard calomel electrode; tibt = 2,4,6-triisopropylphenyl; Tp = tris(pyrazolyl)hydroborate (1-).

1 INTRODUCTION

Iron–sulfur clusters appear in a great many proteins as both electron-transport and enzymatic sites (*see* ***Iron–Sulfur Proteins***); for this reason there has been great interest for 30 years in the development and understanding of iron–sulfur model complexes. Both structure and properties of synthetic analogs of 1-, 2-, 3-, and 4-iron protein active sites have been studied extensively.[1] This article will address the structural and chemical properties, synthesis, and catalytic activity of these synthetic analogs, as compared to the native protein-bound iron–sulfur cores.

In general, iron–sulfur clusters are coordinated to native proteins via cysteine thiolate bonding, often in a Cys-X-Y-Cys motif (X, Y = nonsulfur containing amino acids). In clusters with more than one iron atom, μ_2- or μ_3-sulfur linkages connect the iron atoms within the cluster. At the active site of proteins, iron–sulfur clusters perform a variety of functions, including electron transport and enzymatic activity.

2 RUBREDOXIN MODEL COMPLEXES

The active site of rubredoxin (Rd), (**1**) (Figure 1), consists of one Fe ion tetrahedrally coordinated by four cysteine thiolate ligands. The iron core serves as the electron-transport site of rubredoxin proteins.

2.1 Synthesis

The common synthetic route for Fe^{II} simple model complexes is shown in reaction (1).

$$FeCl_2 + 4RS^- \longrightarrow [Fe(SR)_4]^{2-} + 2Cl^- \quad (1)$$

Controlled oxidation by dioxygen or other means can provide the oxidized Fe^{III} complex. However, the $[Fe(SR_4)]^-$ complexes are often not stable. A ligand exchange reaction, (2), provides an elegant solution to the problem,[2] presumably because the phenolate stabilizes the Fe^{III} ion through the course of the synthesis. These methods have been widely used to create a large set of oxidized and reduced Rd model complexes for study.

$$[Fe(OC_6H_3\text{-}2,6\text{-}Me_2)_4]^- + 4RSH \longrightarrow [Fe(SR)_4]^- + 4\ 2,6\text{-}Me_2C_6H_3OH \quad (2)$$

2.2 Structures

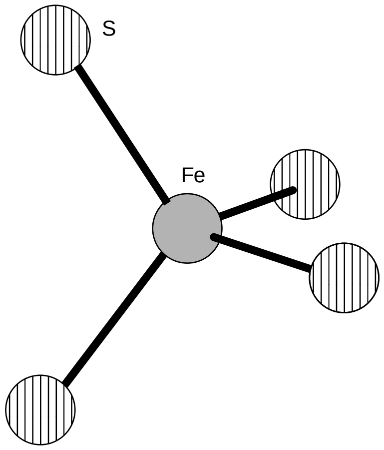
The structure of the $[Fe(RS)_4]$ core is shown in Figure 1. Bond lengths and angles for both typical rubredoxin and rubredoxin analogs are consistent, with typical ranges of Fe^{III}–S = 2.25–2.31 Å and Fe^{II}–S = 2.29–2.39 Å for both protein-bound [1Fe] clusters and synthetic analogs, as shown in Table 1. The iron sites in these proteins and model compounds exhibit distorted tetrahedral symmetry, generally following a D_{2d} symmetry tetragonally compressed along the S_4 axis. The sum of structural data indicate that distortions within the enzyme core are imposed by the surrounding protein, and are not unlike crystal packing forces in the synthetic model compounds.

2.3 Properties and Biochemical Activity

The essential redox reaction in both protein active sites and in the model complexes is the reduction of the Fe^{III} ion, as shown in reaction (3).

$$[Fe(SR)_4]^- + e^- \longrightarrow [Fe(SR)_4]^{2-} \quad (3)$$

Within the natural clusters, the redox potential is highly dependent on protein environment and on solvent effects, including electrostatic interactions (such as hydrogen bonding), pH, and ionic strength. The potentials for this



(**1**)

Figure 1 The Rd active site

couple in synthetic analogs also exhibit expected shifts owing to chemical environment. Most native rubredoxin proteins exhibit a reduction potential of 0.10 to −0.10 V versus SCE, while model complexes exhibit a considerably more negative range, in most cases −0.11 to −1.11 V versus SCE. Table 2 shows reduction potential and Mössbauer shift of selected rubredoxin analogs. Of course, deviations between protein properties and synthetic analog properties imply the influence of the protein environment and may provide direction for the elucidation of protein effects.

Figure 2 The [2Fe-2S] cluster

These include atomic spectral patterns, vibrational modes, bond covalency, and ground- and excited-state assignments consistent with the spin state and bonding structure.

Simple [1Fe] model complexes have been shown to catalyze the oxidation of mandelate to methylbenzoylformate, benzhydrol to benzophenone, and benzoin to benzil.

3 [Fe_2S_2] MODEL COMPLEXES

The $[Fe_2S_2]^{2+}$ core, (**2**) (Figure 2), appears in plant-type (chloroplast) ferredoxins (Fd) and in Rieske proteins.[9] In ferredoxins, the $[Fe_2S_2]^{2+}$ core is ligated with thiolate from Cys residues, while in Rieske proteins, the thiolates ligating one of the iron atoms are substituted with imidazole ligands from His residues.

3.1 Synthesis

The four reactions shown below are the principal methods of synthesizing [Fe_2S_2] complexes.[1,10,11]

$$2FeCl_3 + 4RS^- + 2HS^- + 2MeO^- \longrightarrow [Fe_2S_2(SR)_4]^{2-} + 6Cl^- + 2MeOH \quad (4)$$

$$2FeCl_3 + 8RS^- + 2S \longrightarrow [Fe_2S_2(SR)_4]^{2-} + 2RSSR + 6Cl^- \quad (5)$$

$$2[Fe(SR)_4]^{2-} + 2S \longrightarrow [Fe_2S_2(SR)_4]^{2-} + RSSR + 2RS^- \quad (6)$$

$$2[Fe(SR)_4]^{-} + 2S \longrightarrow [Fe_2S_2(SR)_4]^{2-} + 2RSSR \quad (7)$$

Typical ligand substitution reactions are as follows:[1]

$$[Fe_2S_2(SR)_4]^{2-} + 4R'SH \rightleftharpoons [Fe_2S_2(SR')_4]^{2-} + 4RSH \quad (8)$$

$$[Fe_2S_2X_4]^{2-} + 4RS^- \longrightarrow [Fe_2S_2(SR)_4]^{2-} + 4X^- \quad (9)$$

3.2 Structures

Figure 2 shows the structure of the [Fe_2S_2] core. All clusters of this type contain an Fe_2S_2 rhomb which is planar or with small nonplanar deviations from D_{2h} symmetry.[12–14] Protein clusters tend toward longer Fe–Fe distances, while most model complexes fall within a small range of Fe–Fe = 2.69–2.71 Å. The trend in Fe–S distances is not as clear-cut; overall, however, the synthetic analogs accurately reflect the important structural features of the active sites of native oxidized ferredoxin proteins, as shown in Table 3.

3.3 Properties and Biochemical Activity

Ferredoxins and Rieske proteins employ a $(Fe^{III})_2/Fe^{III}Fe^{II}$ redox couple for biological electron transfer reactions. Within the protein, the two iron atoms are rendered inequivalent, even in the fully oxidized $(Fe^{III})_2$ state, by the surrounding protein environment. Within a synthetic cluster, however, both iron atoms are typically equivalent, as may be expected from the symmetry of the overall complex. Table 4 shows reduction potentials for selected analog clusters.

In proteins, the redox couple operates at $E'_o \approx -0.42$ V versus SHE.[17] As with Rd-analog clusters, the redox couple in the synthetic analogs operates at a considerably more negative potential, but again can be significantly positively shifted by intramolecular N–H···S hydrogen bonding.[12] It is interesting to note that a 20-peptide artificial miniprotein has been designed and synthesized which exhibits a potential similar to that of native spinach Fd.[18]

Synthetic [Fe_2S_2] clusters have also shown catalytic activity. During redox, the cluster is particularly labile, and facile ligand swapping occurs under these conditions. It has

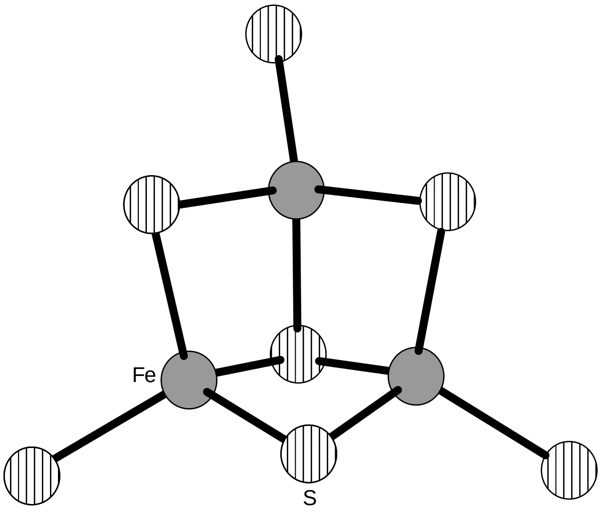
also been found that these clusters can stabilize radicals in processes that occur via free-radical pathways. Redox reactions with the synthetic cluster have been used to oxidize alcohols and keto alcohols, and to reduce ketones, alkenes, alkynes, and CO_2.

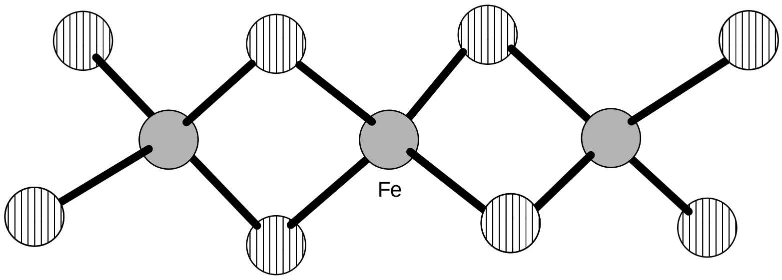
4 $[Fe_3S_4]$ MODEL COMPLEXES

The trinuclear $[Fe_3S_4]$ site has been described as either a linear cluster, (**3a**) (shown in Figure 3), or cuboidal cluster, (**3b**) (shown in Figure 4), and models of each have been prepared and studied. It is unclear whether the linear cluster is present in functioning proteins in vivo, but it has been claimed in vitro in various sources, including a number of bacterial proteins and in human iron regulatory protein 1 (IRP-1) (*see* ***Metalloregulation***).[19–23] Only one cuboidal cluster has been successfully synthesized and studied.[24,25]



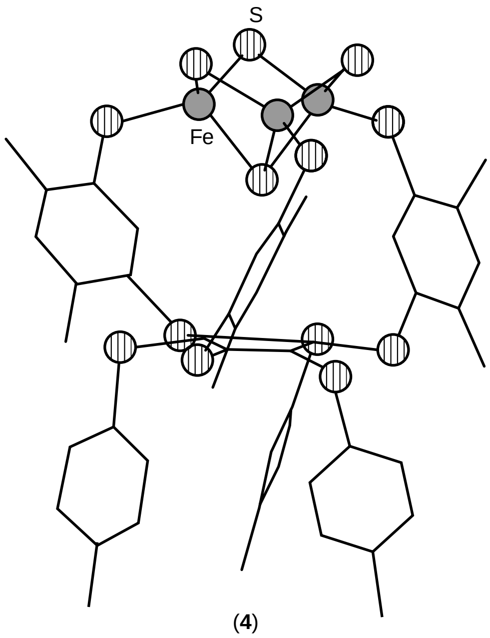
(**3b**)

Figure 4 The cuboidal $[Fe_3S_4]$ cluster



(**3a**)

Figure 3 The linear $[Fe_3S_4]$ cluster



(**4**)

Figure 5 $[Fe_3S_4(LS_3)]^{3-}$

4.1 Synthesis

With careful control of stoichiometry and scale, the linear $[Fe_3S_4(SEt)_4]^{3-}$ complex can be generated from $[Fe(SEt)_4]^{2-}$ by reaction (10).[26]

$$3[Fe(SEt)_4]^{2-} + 4S \longrightarrow [Fe_3S_4(SEt)_4]^{3-} + 2.5\ EtSSEt + 3EtS^- \quad (10)$$

The other forms of the linear three-iron core shown in Table 6 can be generated by reaction (11) utilizing ligand substitution.[10,26]

$$[Fe_3S_4(SEt)_4]^{3-} + 4RSH \longrightarrow [Fe_3S_4(SR)_4]^{3-} + 4EtSH \quad (11)$$

The cuboidal form is closely related to the cubane structure, addressed in Section 5. To form the $[Fe_3S_4]$ cuboidal structure, Holm's group first used the semirigid trifunctional cavitand 1,3,5-*tris*((4,6-dimethyl-3-mercaptophenyl)thio)-2,4,6-*tris*(*p*-tolylthio)benzene (3-) (LS_3) to ligate a $[Fe_4S_4]$ cubane at three of the four iron corners, thereby forming a 3:1 site-differentiated cluster. The unique iron was then removed by reaction with *N*-methylimidodiacetate.[24,25] The $[Fe_3S_4(LS_3)]^{3-}$ structure, (**4**), is shown in Figure 5.

4.2 Structures

As shown in Tables 5 and 6, average Fe–S distances, Fe···Fe distances, and angles are in excellent agreement between synthetic models and protein clusters. The linear cluster consists of two rhombs of the $[Fe_2S_2]$ core, joined at one of the iron atoms, with bond lengths and angles quite similar to those found in that structure.

Structural data of the cuboidal model compound and of protein sites indicate that the cuboidal cluster is structurally closely related to the cubane cluster and shares many of the same structural properties.

4.3 Properties and Biochemical Activity

The $[Fe_3S_4]$ complex occurs naturally in a completely oxidized ($3Fe^{III}$) and mixed Fe^{III}/Fe^{II} oxidation states. Fully reduced forms of the three-iron clusters in either synthetic or natural systems have not been isolated. In mixed-valence clusters, electron delocalization and antiferromagnetic pairing

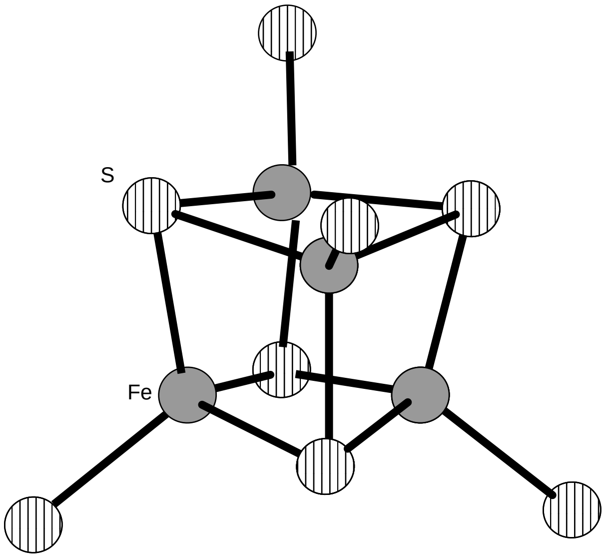
occur within a Fe^{III}–Fe^{II} pair, effectively rendering each as an $Fe^{2.5+}$ ion.

These compounds, both the model complexes and in nature, engage in electron transfer, reducing to successively more ferrous oxidation states. Reduction of the oxidized forms of the model complexes occur at negative potentials (~ -1.5 V).[10] The electrochemical properties and Mössbauer data of these clusters are shown in Table 7.

The linear and cuboidal clusters also demonstrate reactivity to produce four-iron $[Fe_4S_4]$ and heterometal $[MFe_3S_4]$ cubane clusters.[28–33] It has not been established whether the linear cluster remains intact in the reaction to form a cubane cluster.[33] The cuboidal cluster, however, readily bonds iron and many other metals at the voided site to form a cubane cluster with minimal structural change.[24,31,34] Biologically, this assembly of the $[Fe_4S_4]$ cluster by addition of iron to a cuboidal $[Fe_3S_4]$ core has been shown to be the regulatory step in the action of IRP-1 (*see* ***Metalloregulation***).



(**5**)

Figure 6 The cubane $[Fe_4S_4]$ cluster

5 $[Fe_4S_4]$ MODEL COMPLEXES

The $[Fe_4S_4]$ cluster, (**5**), appears in ferredoxins, in high-potential ferredoxin proteins (HP or HiPiP), and in a variety of enzymes. As shown in Table 8, the cluster itself is of mixed-valency (Fe^{III} and Fe^{II}) for all forms except the most reduced, $[Fe_4S_4]^0$.

5.1 Structures

All $[Fe_4S_4]$ cores have a 'cubane-type' structure consisting of six edge-shared nonplanar Fe_2S_2 rhombs, as seen in Figure 6. None have perfect T_d symmetry. A D_{2d}-compressed distortion is often encountered, producing four 'short' and eight 'long' Fe–S bonds, parallel and perpendicular, respectively, to an idealized fourfold axis. One-electron reduction of this form often produces a D_{2d}-elongated form, with the previously 'short' bonds lengthening significantly and the eight previous 'long' bonds shortening slightly.

As the oxidation state drops, Fe–SR bond lengths increase because of the increasing ferrous character of the core. Close agreement in bond lengths, angles, and core volume

is found both among the protein clusters themselves and with isoelectronic synthetic analogs. Structural parameters of a number of clusters are shown in Table 9.

Like the $[Fe_3S_4]$ cluster, the $[Fe_4S_4]$ exhibits electron delocalization across iron atoms in mixed-valence oxidation states. Within the $[Fe_4S_4]^{3+}$ state $[(Fe^{III})_3/Fe^{II}]$ and the $[Fe_4S_4]^{+}$ state $[Fe^{III}/(Fe^{II})_3]$, this pairing occurs within an Fe^{III}–Fe^{II} pair, while in the $[Fe_4S_4]^{2+}$ state $[(Fe^{III})_2/(Fe^{II})_2]$, electrons are delocalized across all four iron atoms, rendering all four electronically equivalent. Generally speaking, electron transfer energies and rates for these clusters reflect the interplay between electronic exchange, spin-dependent delocalization, and vibronic trapping of electrons on the Fe atoms.

The $[Fe_4S_4]$ cluster, like the $[Fe_2S_2]$ cluster, has been found to be very labile under reduced conditions. Catalytically, it has also been used to oxidize and/or reduce a number of alcohols, ketones, alkenes, and alkynes. Of particular interest, the $[Fe_4S_4(SCH_2Ph)_4]^{2-}$ cluster has been shown to catalyze the carboxylation of thioesters with CO_2, mimicking the fixation of CO_2 by coenzyme A in biological systems.

5.2 Synthesis and Properties

A summary of the CV and Mössbauer data of a variety of clusters is shown in Table 10.

5.2.1 $[Fe_4S_4]^{3+}$ Clusters

The $[Fe_4S_4]^{3+}$ state is isoelectronic with HP_{ox} cores. EPR and Mössbauer studies of the sole isolated synthetic cluster, $[Fe_4S_4(Stibt)_4]^{2-}$, indicate that it closely resembles HP_{ox} in electronic structure.[35,39] The redox couple exhibited by this and other model compounds, however, show significantly more negative potentials than the protein-bound cluster.

5.2.2 $[Fe_4S_4]^{2+}$ Clusters

The $[Fe_4S_4]^{2+}$ state is isoelectronic with HP_{red} and Fd_{ox} cores. A number of synthetic methods have been devised, including assembly reactions, (12) and (13), and ligand substitutions, (14) (X = halide) and (15) (n = 1 to 4).

$$4FeCl_2 + 10RS^- + 4S \longrightarrow [Fe_4S_4(SR)_4]^{2-} + 3RSSR + 8Cl^- \quad (12)$$

$$4FeCl_3 + 14RS^- + 4S \longrightarrow [Fe_4S_4(SR)_4]^{2-} + 5RSSR + 12Cl^- \quad (13)$$

$$[Fe_4S_4X_4]^{2-} + nRS^- \rightleftharpoons [Fe_4S_4X_{4-n}(SR)_n]^{2-} + nX^- \quad (14)$$

$$[Fe_4S_4(SR)_4]^{2-} + nR'S^- \rightleftharpoons [Fe_4S_4(SR)_{4-n}(SR')_n]^{2-} + nRSH \quad (15)$$

A very large set of clusters have been produced, only some of which are listed in Table 4; extensive study with a variety of methods have been performed on a number of these. Absorption spectra studies of alkylthiolate clusters have shown absorption bands very similar to those of HP_{red} and Fd_{ox}. As typical with other Fe–S cluster analogs, synthetic models have more negative reduction potentials than the native protein cluster: $E = -1.04$ to -1.42 V (in DMF) for the synthetic analogs, $E = -0.3$ to -0.8 V for most typical Fd_{ox}. Less negative values can be produced by suitable variation of ligand substituents. Additionally, the reduction potential of these clusters increases dramatically when in aqueous solution. Study of synthetic Cys-ligated $[Fe_4S_4]^{2+}$ clusters and of native Fd and HP proteins have shown similar shifts in redox potential due to variable N–H···S hydrogen bonding, solvent dielectric effects, pH, and ionic strength.[51]

5.2.3 $[Fe_4S_4]^{+}$ Clusters

The $[Fe_4S_4]^{+}$ state is isoelectronic with the Fd_{red} core. Compounds are typically prepared by reduction of $[Fe_4S_4(SR)_4]^{2-}$ with reducing agents of potential -1.5 V, as shown in reaction (16).

$$[Fe_4S_4(SR)_4]^{2-} + NaC_{12}H_8 \longrightarrow [Fe_4S_4(SR)_4]^{3-} + C_{12}H_8 + Na^+ \quad (16)$$

Spectra and spin states are generally similar between synthetic analogs and protein-bound clusters; however, both exhibit considerable variability from species to species.

5.2.4 $[Fe_4S_4]^0$ Clusters

The $[Fe_4S_4]^0$ state has been demonstrated in the fully reduced iron protein of *A. vinelandii* nitrogenase. The analog complex $[Fe_4S_4(SPh)_4]^{4-}$ has been detected electrochemically from the reversible reduction of $[Fe_4S_4(SPh)_4]^{3-}$ at −1.73 V, but neither this species nor any other has been isolated and fully characterized. Work continues in Holm's lab with $[Fe_4S_4(SPh)_4]^{3-/4-}$, $[Fe_4S_4(SCH_2CH_2CO_2)_4]^{7-/8-}$, phosphine-ligated clusters, and other pathways to construct and isolate this complex and to characterize it further.[52]

5.3 Peptide Clusters

To better simulate the behavior of Fe-S clusters in the protein environment, a logical step is to ligate the clusters to actual cysteinyl peptides. Peptide-ligated clusters can be prepared via ligand exchange reaction (17) or cluster reconstitution using $FeCl_3$, Na_2S, a reductant, and the peptide in aqueous buffer.

$$[Fe_4S_4(SR)_4]^{2-} + n(\mathrm{Cys})_x\mathrm{peptide} \longrightarrow [Fe_4S_4\{(\mathrm{Cys})_x\mathrm{peptide}\}_n]^{2-} + 4\mathrm{RSH} \quad (17)$$

These procedures have been used to create a number of peptide clusters with over 65 amino acid residues. A common motif for forming these clusters is the ferredoxin consensus sequence (**6**) (Figure 7) incorporated into a longer chain or even peptide sequences with additional secondary structure.

The clusters thus generated have been found to have properties closely matching those of native proteins.[51] Further studies have shown that N–H···S hydrogen bonding to sulfur atoms within the cluster creates a small positive shift in redox potentials. The sequence Cys-$(X)_3$-Cys-$(X)_2$-Cys-$(X)_2$-Cys, which includes sequence (**6**) and is often found in ferredoxins, has been shown to support efficient cluster reconstitution.[53]

The following conclusions can be drawn from the various peptide-ligated clusters studied. First, the ligation of the cluster by the Cys residue is more stabilizing than any other residue. Secondly, three Cys residues in the sequence Cys-$(X)_2$-Cys-$(X)_2$-Cys are critical for ligation; the fourth iron site may be occupied by an exogenous ligand. Finally, nonligating residues have important roles in stabilizing $[Fe_4S_4]$ clusters.

5.4 Site-differentiated $[Fe_4S_4]$ Clusters

Enzyme activity has been recognized in protein-bound 3:1 site-differentiated clusters, in which the cubane $[Fe_4S_4]$ is bound to a ligand other than a Cys residue at one of the iron sites. This differentiated iron atom is unique and becomes the site of substrate binding and catalysis. The first recognized example of this was in the enzyme aconitase. In this enzyme, the inactive form actually contains the cuboidal $[Fe_3S_4]$ cluster, which is activated by the reversible insertion of a fourth iron atom, with little change in structure.

Synthetically, similar clusters have been produced using deprotonated trithiols, which ligate three of the cubane iron sites at once. One example is the LS_3 ligand discussed earlier (Figure 5); steric factors force the ligand into a shape which is ready to capture the cluster in its cavity.[54] Additionally, an $[Fe_4S_4]$ cluster has been encapsulated in diphenylglycoluril and cyclotriveratrylene cavitands in a way that also created a 3:1 site-differentiation; this encapsulation modified the electrochemical properties of the cluster in ways analogous to the effects of encapsulation of the cluster by proteins.[55]

This unique iron site proves to be exceptionally labile, and supports a wide variety of ligand exchange and reactivity. Bridging to additional iron–sulfur clusters via a sulfide-containing bridge can also be supported at this site, allowing the construction of more complex clusters. Additionally, the unique iron atom can be removed altogether and replaced with other metals (as discussed in Section 4.3).

The $[Fe_4S_4(LS_3)(SR')]^{3-}$ cluster has been shown to engage in an electrophilic attack of the sulfonium ion, while causing reductive cleavage of the cofactor S-adenosylmethionine. This behavior is analogous to the enzymatic action of biotin synthase and other enzymes in the S-adenosylmethionine family (*see* ***Iron–Sulfur Proteins***).[43]

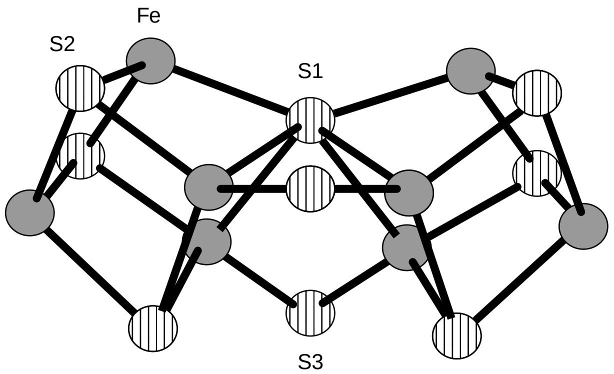
6 $[Fe_8S_7]$ NITROGENASE P-CLUSTER MODEL COMPLEXES

The $[Fe_8S_7]$ core of the P-cluster of nitrogenase (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase***

Cys-Ile-Ala-Cys-Gly-Ala-Cys

(**6**)

Figure 7 The ferredoxin consensus peptide sequence (**6**)



(**7**)

Figure 8 The P-cluster of nitrogenase

Catalysis & Assembly), (**7**) (Figure 8), consists of two [Fe_4S_3] cubane structures linked by a hexa-coordinated sulfur atom (μ_6-S) and two bridging sulfur atoms of Cys residues (μ_2-S_{Cys}). The cluster is attached at the terminus by four additional thiolates of Cys residues. Some have speculated that the core itself is unstable and cannot exist outside the protein environment in a sulfur-ligated state. To this date, there have been attempts by several laboratories to synthesize a model of this complex with varying degrees of incomplete success.

The first synthetic analog is the $[(Tp)_2M_2Fe_6S_9(SH)_2]^{n-}$ cluster (M = Mo, V; $n = 3, 4$). This cluster maintains the μ_2-S bridges (as S rather than S_{Cys}) and the hexa-coordinated sulfur, but replaces the outermost two iron atoms with Mo or V, two of the terminal cysteinyl ligands with the Tp ligand, and the other two terminal ligands with S–H. The most notable characteristic of this cluster is its near congruence structurally (bond lengths and angles) with the native P^N-cluster.[56]

Another cluster that has been prepared with the same topology as the native P-cluster is $[N(SiMe_3)_2(SC(NMe_2)_2)Fe_4S_3]_2$-($\mu_6$-S)($\mu_2$-$N(SiMe_3)_2$). The primary difference exists in bridging μ_2-$N(SiMe_3)_2$ groups rather than S_{cys}, and terminal ligation by two $N(SiMe_3)_2$ groups and two $SC(NMe_2)_2$ groups. The electronic properties of this cluster in some ways resemble those of the P^N-cluster, although the oxidation state of the model is that of the P^{2+} oxidized form.[57]

7 PERSPECTIVE

The research on iron–sulfur models has played a historical role in the elucidation of the topology and electronic structure of the active sites of iron–sulfur proteins. The development of iron–sulfur cluster chemistry paralleled the evolution of the field of bioinorganic chemistry. As protein crystallography and other structure determination techniques become more and more routine and accurate, it seems that building analogs of protein active sites would become less desirable. On the contrary, it turns out that the determination of a protein structure is often just a new starting point for the study of its function, mechanism, and biosynthesis. The existence and function of iron–sulfur proteins have inspired and propelled the development of synthetic iron–sulfur cluster chemistry, which now features the most structural types in any binary metal–nonmetal combination.[1] On one hand, most of these structural types have yet to be found in biological systems. On the other hand, building analog systems for the all-ferrous Fe_4S_4 center, P-cluster, and the FeMoco center of nitrogenase have posed a formidable challenge no less daunting than the total synthesis of natural products. Future breakthroughs in this endeavor will undoubtedly be beneficial to our further understanding of the biological systems.

1 INTRODUCTION

Iron–sulfur proteins are broadly defined as proteins containing Fe with at least partial S coordination. This definition, therefore, includes proteins containing mononuclear Fe centers coordinated by cysteinyl-S, in addition to the large group of proteins containing clusters of Fe bridged by inorganic S^{2-} and attached to the protein via amino acid side-chain coordination of Fe. Following the International Union of Biochemistry (IUB) recommendation,[1] they can be further classified into simple and complex Fe–S proteins. Simple Fe–S proteins have Fe–S centers as their sole prosthetic group, whereas complex Fe–S proteins have additional prosthetic groups, such as flavin, Mo/W cofactors, siroheme, or another type of metal center.

Since the discovery of ferredoxins in the early 1960s, the number and diversity of Fe–S proteins has greatly proliferated. There are now well in excess of 160 enzymes and proteins that contain Fe–S centers, and the list continues to grow rapidly. They are found ubiquitously in nature and are intimately involved in all membrane-bound electron transport systems in addition to the metabolism of carbon, oxygen, hydrogen, sulfur, and nitrogen. Not surprisingly, they have been the subject of recent books[2] and review articles.[3–8] The widespread occurrence of Fe–S proteins and the chemical versatility of iron and sulfur[4,5,9] are also of interest from an evolutionary standpoint. For example, they lend credence to the proposal for the exergonic formation of pyrite, FeS_2, from H_2S and Fe^{2+}, as the driving force for a chemoautotrophic theory for the origin of life under hyperthermophilic conditions. Further support for such a theory has come from the laboratory demonstration of C–C bond formation on Ni/Fe–S or Fe–S surfaces under primordial conditions.[10–12] Indeed it is conceivable that the first Fe–S proteins may have formed at a pyrite surface by replacement of SH-groups in inorganic Fe–S clusters by cysteinyl groups of surface-bonded peptides rather than polypetides folding around preformed Fe–S clusters in solution.

X-ray crystallography as well as other biophysical techniques, that is, X-ray absorption (XAS), electron paramagnetic resonance (EPR), electron-nuclear double resonance (ENDOR), electron-spin echo envelop modulation (ESEEM), Mössbauer, optical absorption, circular dichroism (CD), variable-temperature magnetic circular dichroism (VTMCD), resonance Raman, nuclear magnetic resonance (NMR), and saturation magnetization, have all been important in characterizing biological Fe–S centers. No one technique is a panacea. Rather they each provide unique and often complementary information that *taken together* provides a detailed picture of electronic, magnetic, structural, and functional properties. Parallel studies of structurally defined analog complexes have also played a crucial role in developing our current understanding of Fe–S biochemistry[13] (*see* ***Iron–Sulfur Models of Protein Active Sites***). In many instances, for example, [2Fe–2S] and linear [3Fe–4S] clusters, this approach has led to structural predictions for biological Fe–S centers prior to X-ray crystallographic studies.

With the improvements in diagnostic tools for identification and characterization, the structural and functional diversity of biological Fe–S centers is now becoming apparent. In the 1970s, the structural types were confined to mononuclear Fe centers, binuclear [2Fe–2S] clusters and cubane-type

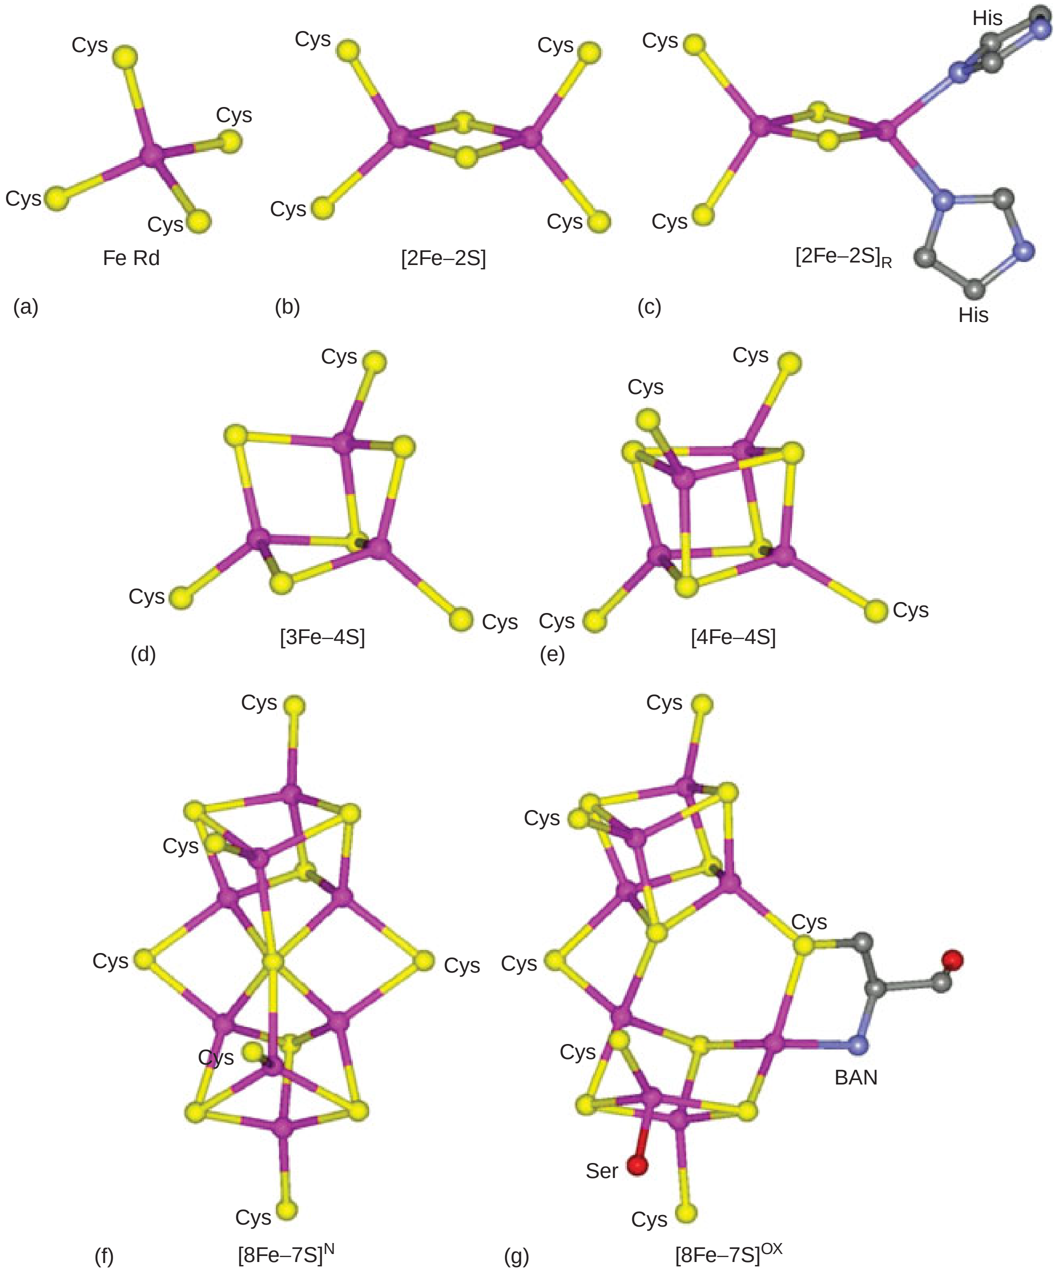

Figure 1 Crystallographically defined structures for Fe–S centers that function in biological electron transfer. Structures are taken from coordinates deposited in the Protein Data Bank: (a) Fe Rd, PDB ID# 8RXN, rubredoxin from *Desulfovibrio vulgaris*;[16] (b) [2Fe–2S], PDB ID# 1FRD, *Anabaena* pcc7120 Fd;[17] (c) $[2Fe–2S]_R$, PDB ID# 1JM1, *Sulfolobus acidocaldarius* Rieske protein;[18] (d) [3Fe–4S], PDB ID# 6FDR, *Azotobacter vinelandii* FdI;[19] (e) [4Fe–4S], PDB ID# 6FDR, *A. vinelandii* FdI;[19] (f) $[8Fe–7S]^N$, PDB ID# 1M1N, dithionite-reduced *A. vinelandii* MoFe protein;[20] (g) $[8Fe–7S]^{OX}$, PDB ID# 2 MIN, thionine-oxidized *A. vinelandii* MoFe protein.[15] Color code: purple, Fe; yellow, S; gray, C; red, O. Unlabeled S atoms correspond to bridging sulfides. BAN = backbone amide nitrogen

[4Fe–4S] clusters, all with cysteinyl-S completing tetrahedral Fe coordination (Figure 1) and the function was exclusively electron transport. New types of electron transfer Fe–S clusters involving cubane-type [3Fe–4S] clusters[14] and double-cubane-type [8Fe–7S] clusters[15] have subsequently been characterized (Figure 1). Moreover, the known functions of Fe–S centers have now expanded to include coupling electron and proton transfer, substrate binding and activation, storage of Fe, electrons or clusters, purely structural roles, regulation of gene expression and enzyme activity, disulfide reduction, and sulfur donation (see Table 1). The crystallographically defined structures of Fe–S centers involved with substrate binding and activation are shown in Figure 2.

Table 1 Functions of biological Fe–S centers

Function	Examples	Center or cluster type[a]
Electron transfer	Ferredoxins; soluble and membrane-bound redox enzymes[3,5,21]	Fe Rd; [2Fe–2S]; $[2Fe–2S]_R$; [3Fe–4S]; [4Fe–4S]
Coupled electron and proton transfer	Rieske protein[22,23]	$[2Fe–2S]_R$
	Nitrogenase[15,24]	[8Fe–7S]
Substrate binding and activation	Nitrile hydratase[25,26]	Fe NHase
	Fe–S cluster (de)hydratases[27,28]	[4Fe–4S]; [2Fe–2S]
	Superoxide reductase[29–31]	Fe SOR
	Radical-SAM enzymes[32–34]	[4Fe–4S]
	NiFe-hydrogenase[35,36]	Ni–Fe H_2ase
	Nitrogenase[20,37]	[Mo–7Fe–9S–X]
	Sulfite and nitrite reductase[38,39]	siroheme–[4Fe–4S]
	Fe-hydrogenase[40,41]	Fe–Fe–[4Fe–4S]
	CO dehydrogenase[42,43]	[Ni–4Fe–5S]
	Acetyl-CoA synthase[44–46]	Ni–Ni–[4Fe–4S], [Ni–4Fe–5S]
Fe/electron/cluster storage	Ferredoxins[47]	[4Fe–4S]
	Polyferredoxins[48,49]	[4Fe–4S]
Structural	Endonuclease III[50,51]	[4Fe–4S]
	MutY[52,53]	[4Fe–4S]
Regulation of gene expression	SoxR[54,55]	[2Fe–2S]
	FNR[56,57]	[4Fe–4S]/[2Fe–2S]
	IRP[27,58]	[4Fe–4S]
	IscR[59]	[2Fe–2S]
Regulation of enzyme activity	Glutamine PRPP amidotransferase[60,61]	[4Fe–4S]
	Ferrochelatase[62,63]	[2Fe–2S]
Disulfide reduction	Ferredoxin:thioredoxin reductase[64,65]	[4Fe–4S]
	Heterodisulfide reductase[65,66]	[4Fe–4S]
Sulfur donor	Biotin synthase[67,68]	[2Fe–2S]

[a]Structures shown in Figures 1 and 2.
PRPP = Phosphoribosylpyrophosphate.

The structures shown in Figures 1 and 2 illustrate several general structural themes that facilitate rationalization of functional diversity. Exclusive cysteinyl ligation is generally observed in centers that function purely in electron transfer roles. Histidine, aspartate, serine, or backbone amide N ligation at a unique Fe site are occasionally encountered in clusters that function in electron transport and serve to modify redox potential[22] and gate electron transport,[72] or facilitate coupling of proton and electron transport.[15,22–24] While $Fe(SCys)_4$, [2Fe–2S], [3Fe–4S] and [4Fe–4S] clusters all function as one-electron donors or acceptors, the more complex double-cubane [8Fe–7S] cluster that is found only in nitrogenases (*see* ***Nitrogenase Catalysis & Assembly***) has the potential to mediate two-electron transfer processes.[15,24] Three methods have been employed to functionalize Fe–S centers for substrate binding and activation. The first involves having an accessible Fe coordination site as in the mononuclear Fe centers of nitrile hydratase[25,26] and SOR,[31,73] and the [4Fe–4S] clusters at the active sites of hydratases/dehydratases[27,28] and radical-*S*-adenosylmethionine (SAM) enzymes.[33,74] Indeed the recent recognition of the importance of the superfamily of radical-SAM enzymes in initiating radical reactions, via cluster–mediated reductive cleavage of SAM to yield a transient 5′-deoxyadenosyl radical, has established Fe–S clusters as the dominant method of radical generation in biology.[32,34,75] The second involves incorporation of a heterometal site as in the case of the [M–7Fe–9S–X] cluster (M = Mo or V; X = N, O, or C) at the active site of nitrogenase[20,37] and the [Ni–4Fe–5S] active site of CO dehydrogenases[42,43] (*see* ***Nickel Enzymes & Cofactors***). The third involves attaching a substrate-binding metal site to an Fe site of a [4Fe–4S] cluster via a bridging cysteinyl residue as in the case of the Ni–Ni–[4Fe–4S] active site of acetyl-CoA synthase,[44–46] the Fe–Fe–[4Fe–4S] active site of Fe-hydrogenase,[40,41] and the siroheme–[4Fe–4S] active site of sulfite and nitrite reductases.[38]

The ability of designed and unstructured minimal synthetic peptides (maquettes) to correctly assemble Fe–S clusters,[76] coupled with examples of Fe–S cluster driven protein reorganization in response to medium effects[77] and cysteine substitutions,[78] demonstrate that Fe–S clusters control protein structure in the vicinity of the cluster. Hence, it not surprising that Fe–S clusters have important structural roles in DNA repair enzymes such as endonuclease III[50,51] and MutY,[52,79] as well as sensing and regulatory roles in controlling gene expression and enzyme activity[58] (*see* ***Metalloregulation***).

In fact, one of the most interesting discoveries of the past decade is that Fe–S clusters are used as sensors for a variety of different types of environmental stimuli and use a wide range of sensing mechanisms involving cluster assembly, transfer, conversion, or redox chemistry to perturb protein structure.

New roles have recently emerged for Fe–S clusters in disulfide reduction and sulfur donation. At least two classes of disulfide reductase, ferredoxin-thioredoxin reductase (FTR) in chloroplasts[64,65] and heterodisulfide reductase (HDR) in methanogenic archaea,[65,66] have been shown to use an active-site [4Fe–4S] cluster to cleave disulfides in two sequential one-electron steps, using novel site-specific cluster chemistry, involving an intermediate with two thiolate ligands at a unique Fe site. The radical-SAM enzyme biotin synthase contains a [2Fe–2S] cluster that degrades and provides the sulfur for the conversion of dethiobiotin to biotin during a single catalytic turnover.[67,68,80,81] This raises the possibility that Fe–S clusters can function as sulfur donors and that Fe–S cluster degradation and assembly can be part of a catalytic cycle. Understanding the structure/function relationships that have evolved for Fe–S clusters offers a fascinating challenge to inorganic biochemists and bioinorganic chemists and this review should be read as a progress report on this dynamic and rapidly advancing area of research.

The revitalization of interest in the diverse roles and properties of biological Fe–S centers and the realization that cluster degradation and assembly or repair may be important in regulatory and catalytic functions has occurred as major progress is being made in understanding the biogenesis of Fe–S clusters.[82,83] Although [2Fe–2S] and [4Fe–4S] clusters can be assembled in many simple Fe–S proteins by incubation of apo–protein with $Fe^{3+,2+}$ and S^{2-} ions under anaerobic conditions, the toxicity of free $Fe^{3+,2+}$ and S^{2-} ions indicates that this type of spontaneous self-assembly is unlikely to be a viable general mechanism for cluster biosynthesis. Rather Fe–S clusters or cluster fragments are delivered intact to apo Fe–S proteins by specific scaffold proteins that sequester Fe and S in non-toxic forms. Three distinct biological systems, termed the NIF, ISC, and SUF systems, have emerged for Fe–S biogenesis. However, the central theme of cysteine desulfurase-mediated assembly of transient Fe–S clusters on scaffold proteins appears to be remarkably conserved in almost all forms of life. The mechanism of assembly of Fe–S centers in proteins is a rapidly advancing area of research and is discussed in more detail elsewhere (*see* ***Metallocenter Biosynthesis & Assembly***).

2 STRUCTURES AND PROPERTIES OF IRON–SULFUR CENTERS

The accessible redox states and properties of the fundamental types of biological Fe–S centers involving $Fe(SCys)_4$, $Fe_2(\mu_2-S)_2(SCys)_4$, $Fe_3(\mu_2-S)_3(\mu_3-S)(SCys)_3$, and $Fe_4(\mu_3-S)_4(SCys)_4$ units are summarized in Figure 3. It is customary and convenient to refer to Fe–S clusters by the stoichiometry of Fe and inorganic-S in square brackets with the formal charge of the Fe inorganic-S core indicated as a superscript, that is, $[2Fe–2S]^{2+,+}$, $[3Fe–4S]^{+,0,2-}$, and $[4Fe–4S]^{3+,2+,+,0}$. The number of unpaired electrons in the electronic ground state, as determined by magnetic or spectroscopic studies at cryogenic temperatures, is indicated by the spin state, S. Figure 3 also indicates the extent of valence localization/delocalization as determined by Mössbauer spectroscopy for each type of cluster in each accessible redox state, with formal Fe^{3+} in red, Fe^{2+} in blue, and $Fe^{2.5+}$ in green. As discussed below for each type of cluster, the extent of valence delocalization is essential for understanding the redox and electronic properties. At this stage, it is sufficient to note that valence-delocalized $Fe_2(\mu_2-S)_2$ rhombs are an important building block of all higher nuclearity clusters. Such delocalization facilitates efficient electron transfer by minimizing reorganization energy[84,85] and hence is likely to be an important determinant of the use of Fe–S clusters in mediating biological electron transfer. In addition, Fe–S bonds are highly covalent as evidenced by sulfur K-edge XAS studies[86–88] and this approach coupled with density function theory (DFT) calculations have demonstrated that *both* Fe and S (inorganic and cysteinyl) are redox active.[89,90] Hence electron delocalization involves both Fe and S and the assignment of formal Fe oxidation states within a cluster should not be taken too literally.

Figure 2 Crystallographically defined active-site structures for Fe–S centers involved with substrate binding and activation. Structures are taken from coordinates deposited in the Protein Data Bank: (a) Fe NHase, PDB ID# 2AHJ, NO-bound form of *Rhodococcus erythropolis* nitrile hydratase;[25] (b) [4Fe–4S] + isocitrate, PDB ID# 7ACN, isocitrate-bound form of porcine heart aconitase;[69] (c) Fe SOR, PDB ID# 1DQK, reduced *Pyrococcus furiosus* SOR;[31] (d) [4Fe–4S] + SAM, PDB ID# 1OLT, SAM-bound *Escherichia coli* HemN;[33] (e) Ni–Fe H_2ase, PDB ID# 1H2R, reduced *D. vulgaris* NiFe-hydrogenase;[70] (f) Fe–Fe–[4Fe–4S], PDB ID# 1HFE, *Desulfovibrio desulfuricans* Fe-hydrogenase;[71] (g) siroheme–[4Fe–4S], PDB ID# 2GEP, sulfite–bound *E. coli* sulfite reductase;[39] (h) [Mo–7Fe–9S–X], PDB ID#1M1M, *A. vinelandii* MoFe protein;[20] (i) [Ni–4Fe–5S], PDB ID# 1SU8, reduced *Carboxydothermus hydrogenoformans* CO dehydrogenase II;[43] (j) Ni–Ni–[4Fe–4S], PDB ID# 1RU3, *C. hydrogenoformans* acetyl-CoA synthase.[46] Color code: purple, Fe; yellow, S; gray, C; red, O; green, Ni; gold, Mo; black, unknown low-Z atom (O/C/N). Unlabeled S atoms correspond to bridging sulfides and BAN indicates backbone amide N. BAN = backbone amide nitrogen

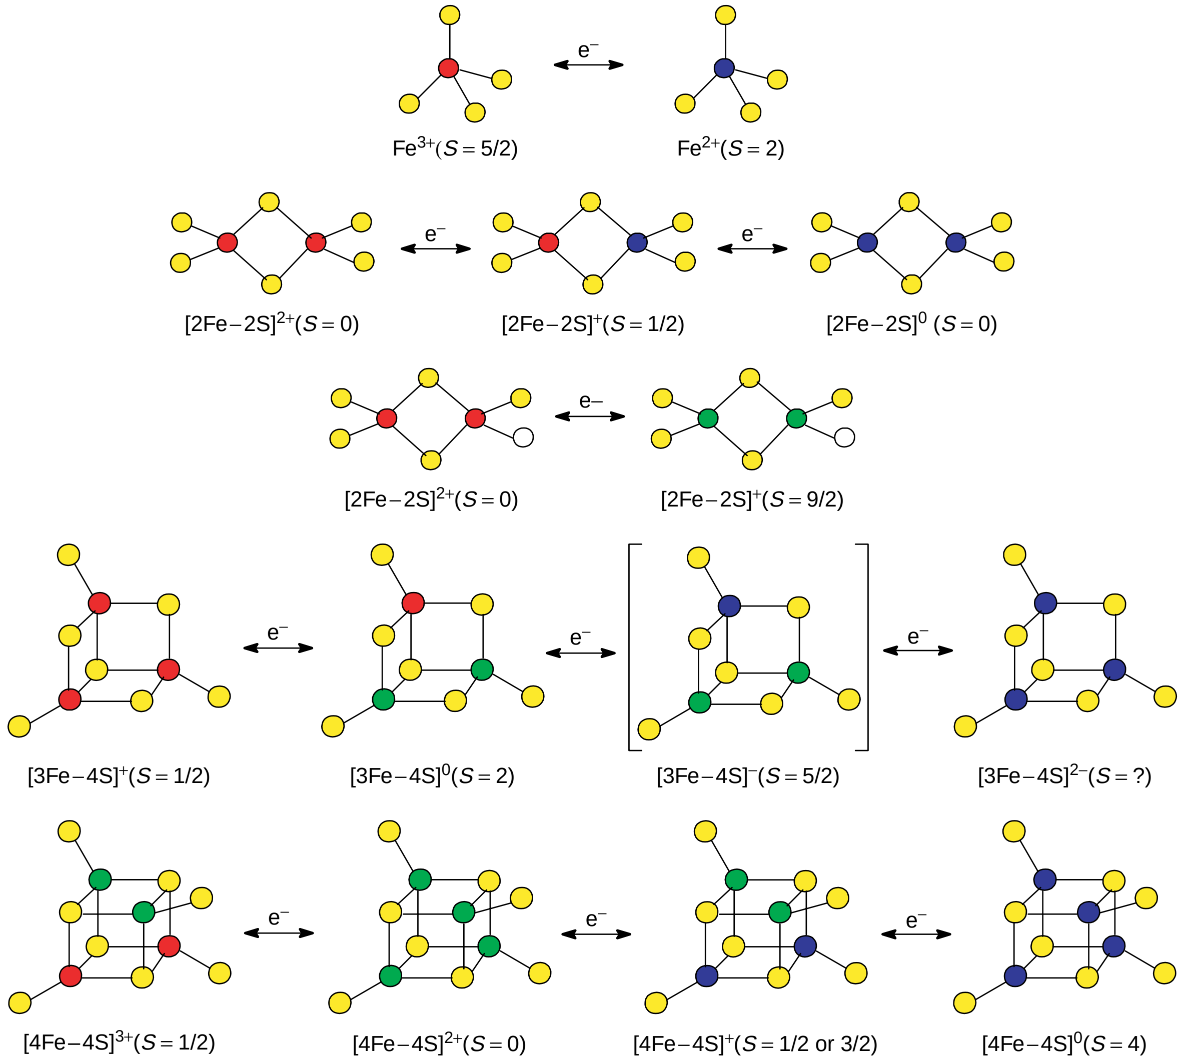

Figure 3 Ground-state spin (*S*) and valence-delocalization schemes for the fundamental types of Fe–S centers. Discrete $[3Fe–4S]^-$ clusters are shown in parenthesis since they have not been observed in any protein, but have been identified as fragments of heterometallic cubane clusters.[91] Reduction of the $[3Fe–4S]^+$ clusters by three electrons to yield the $[3Fe–4S]^{2-}$ cluster occurs with the concomitant addition of three protons.[92] Valence-delocalized $[2Fe–2S]^+$ clusters have only been observed in the C56S and C60S variants of *C. pasteurianum* 2Fe Fd.[93–95] Color code: Fe^{3+}, red; Fe^{2+}, blue; $Fe^{2.5+}$, green; S, yellow; O, white

The range of midpoint potentials that have been reported for redox cycling between the most common redox states of each of these fundamental types of Fe–S center in both complex and simple Fe–S proteins are summarized in Figure 4. Clearly the type of center, the specific redox couple, and the cluster ligands are all major determinants of the redox potential. For example, Rd-type centers, Rieske-type $[2Fe–2S]^{2+,+}$ clusters that have two histidyl ligands at the reducible Fe site, and $[4Fe–4S]^{3+,2+}$ clusters all can be viewed as high potential centers ($E_m > -100$ mV), whereas all-cysteinyl-ligated $[2Fe–2S]^{2+,+}$, $[3Fe–4S]^{+,0}$, and $[4Fe–4S]^{2+,+}$ clusters are low-potential centers ($E_m < +100$ mV). However, the potentials can span 350 to 800 mV even for a specific type of center, indicating that the protein environment plays a crucial role in determining the redox potential. Both theoretical and experimental approaches indicate that solvent exposure, the proximity and orientation of backbone and side-chain dipoles, the location of changed residues, and the extent of NH–S hydrogen-bonding interactions all need to be considered in rationalizing the observed potential of a specific center.[96,97]

2.1 Rubredoxin-type Centers

Mononuclear Fe centers in an approximately tetrahedral environment of cysteinyl-S (Rd-type centers) (see Figure 1) mediate electron transfer in a variety of different bacterial proteins and their structures and properties have recently

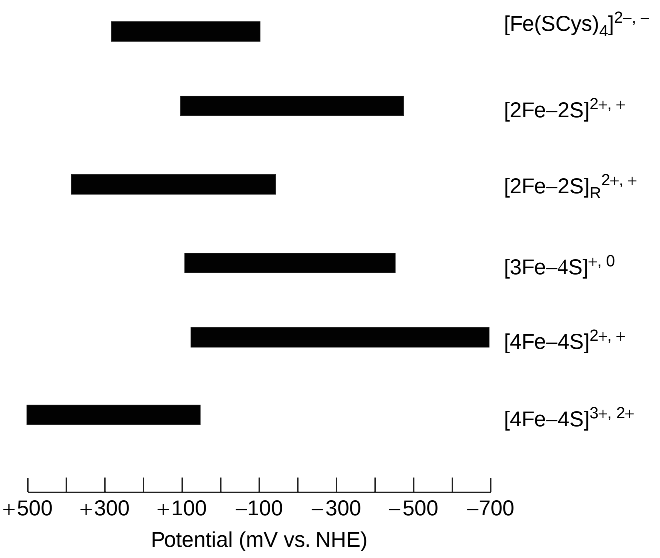

Figure 4 Ranges of midpoint potentials (mV vs. NHE) for biological Fe–S centers. $[2Fe\text{–}2S]_R^{2+,+}$, Rieske-type Fe–S center

been reviewed.[98] They constitute the sole prosthetic groups of rubredoxin (Rd) and desulforedoxin (Dx) and are found together with an oxo–bridged dinuclear Fe center in a class of nonheme peroxidases, formally known by the trivial names rubrerythrin and nigerythrin (*see* ***Iron Proteins with Dinuclear Active Sites***), and a novel mononuclear Fe active site in 2Fe SORs, formally known by the trivial name desulfoferredoxin (*see* ***Iron Proteins with Mononuclear Active Sites***).[99] Rd-type centers undergo redox cycling between high-spin Fe^{III} and high-spin Fe^{II} with reported midpoint potentials between +20 to −87 mV in the case of Rds, Dxs, and 2Fe SORs, and significantly higher potentials in the peroxidases, +281 mV for rubrerythrin and +213 mV for nigerythrin (Figure 4). X-ray crystallographic studies of Rds (0.95–1.8 Å resolution) indicate approximate D_{2d} symmetry for the FeS_4 unit (two opposite S–Fe–S angles in the range 102–104° with the remaining four S–Fe–S angles between 110° and 115°), with average Fe–S bond lengths of 2.28 Å for oxidized and 2.32 Å for the reduced. The structures are in accord with ground-state vibrational and electronic properties of oxidized Rds ($S = 5/2$ ground state, with $E/D \sim 0.25$, $D \sim -0.6\,\text{cm}^{-1}$)[100,101] and the intense thiolate-to-iron charge transfer transitions that dominate the UV-visible absorption spectra of oxidized Rds have been assigned under effective D_{2d} symmetry on the basis of single crystal polarization studies and VTMCD studies.[101]

The arrangement of coordinating cysteine residues is highly conserved in all Rds including the Rd-type centers in nonheme peroxidases, and involves Cys–X_2–Cys motifs near the C- and N-termini. Desulforedoxin and the Dx-type centers in 2Fe SORs provide an interesting variant with Cys–X_2–Cys and Cys–Cys motifs for the coordinating cysteine residues; the stereochemical constraint imposed by the adjacent cysteines results in a more distorted tetrahedral structure. The crystal structure of desulforedoxin (1.8 Å resolution) shows that the S–Fe–S angle involving the adjacent cysteines increases to between 120° and 126°, compared to the range of 102–110° for the other five angles, with the Fe–S bond lengths all very similar and in the range 2.25–2.38 Å.[29] This structural difference is also manifest in the ground-state vibrational and electronic properties of the oxidized Dx-type centers ($S = 5/2$ ground state with $E/D \sim 0.08$ and $D \sim +2.2\,\text{cm}^{-1}$),[102,103] and in the ground-state properties of the reduced centers as deduced by Mössbauer spectroscopy ($S = 2$, with $E/D \sim 0.28$ and $D \sim +7.5\,\text{cm}^{-1}$ for Rd, compared to $E/D \sim 0.19$ and $D \sim -6\,\text{cm}^{-1}$ for Dx).[103]

Site-directed mutagenesis studies of Rd in which the coordinating Cys residues were individually mutated to Ala/Gly or Ser residues have yielded interesting and in some cases surprising results. Rd-type centers are assembled in each of the Cys-to-Ser variants with reduction potentials for the $Fe^{III/II}$ couple decreased by 100–200 mV.[104] Moreover, the midpoint potentials are pH dependent, indicating protonation of the oxygenic ligand on reduction with pK_a values in the range 7–9. Crystallographic and/or spectroscopic evidence indicates serinate ligation at the Fe^{III} site in three of the Cys-to-Ser variants and hydroxide ligation in one of the two interior Cys-to-Ser variants.[104,105] Mutation of either of the two surface Cys residues to Ala or Gly resulted in unstable proteins which can assemble a mononuclear Fe^{III} site with three Cys and one hydroxide or noncysteinyl protein ligand.[106] However, in one case, spectroscopic studies of the as-purified recombinant protein have provided definitive evidence for a $[2Fe\text{–}2S]^{2+}$ cluster.[107] Although the location and ligation of the [2Fe–2S] cluster have yet to be fully defined, this is currently the first and only example of a polypeptide incorporating a binuclear cluster rather than a mononuclear Fe site as a result of a single point mutation.

2.2 [2Fe–2S] Clusters

[2Fe–2S] clusters generally have complete cysteinyl ligation and undergo redox cycling between the 2+ and 1+ core oxidation states (Figures 1 and 3). However, there is large group, termed Rieske-type centers $[2Fe\text{–}2S]_R$, with two histidyl ligands at one Fe site[22] (see Figure 1), and a few examples of [2Fe–2S] clusters with one noncysteinyl ligand, for example, aspartate in some succinate dehydrogenases[108] and a sulfide dehydrogenase,[109] and arginine in biotin synthase.[68] $[2Fe\text{–}2S]^{2+,+}$ centers mediate electron transfer in a wide range of Fds and complex metalloenzymes, as well as being intrinsic components in the photosynthetic and respiratory electron transport chains. Redox potentials for the $[2Fe\text{–}2S]^{2+,+}$ couple span a range from +380 to −460 mV, with Rieske-type centers generally having higher potentials (+380 to −150 mV) than all-cysteinyl-ligated centers (+100 to −460 mV) owing to the presence of the more electropositive histidine ligands at the reducible Fe site

(Figure 4). While their role is predominantly electron transfer, there is one example of a [2Fe–2S]-containing dehydratase, several examples of [2Fe–2S] clusters that have regulatory roles and one example of a [2Fe–2S] cluster acting as a sulfur donor (see Table 1).

Structures are available for [2Fe–2S] centers in several Fds[21,110–114] and Rieske-type proteins,[22,23] as well as in more complex enzyme systems such as mammalian ferrochelatase,[62] succinate dehydrogenase and fumarate reductase,[108,115] members of the xanthine oxidase family of molybdoenzymes,[116,117] Fe-hydrogenase,[40] and biotin synthase.[68] In all cases, coordination at each Fe is approximately tetrahedral, and the $Fe_2(\mu_2{-}S)_2$ core is approximately planar with Fe–Fe distances in the range 2.7–2.8 Å, and Fe–S distances generally between 2.2–2.3 Å. In addition, high-resolution structures of the oxidized and reduced forms of a plant-type [2Fe–2S] Fd (1.3 and 1.17 Å resolution, respectively) show that reduction occurs with no major structural reorganization and slight lengthening of the Fe–S bonds (maximally 0.01 to 0.02 Å).[118] Several different types of protein folds are apparent in [2Fe–2S]-cluster proteins or domains. The Fd-fold is common to plant-type, hydroxylase- or mammalian-type, and Isc-type [2Fe–2S] Fds, in addition to several complex [2Fe–2S]-containing Fe–S enzymes, and contains a Cys–$X_{4/5}$–Cys–X_2–Cys–X_{29-37}–Cys motif of coordinating cysteines.[110] A thioredoxin-fold is utilized by a distinct class of [2Fe–2S] Fds and uses a Cys–$X_{10/12}$–Cys–X_{29-34}–Cys–X_3–Cys arrangement of coordinating cysteines.[114] Homologous subunits or domains in complex Fe–S enzymes such as NADH dehydrogenase and hydrogenases also appear to contain thioredoxin-type [2Fe–2S] centers, albeit with a different cysteine motif, Cys–X_4–Cys–X_{30-35}–Cys–X_3–Cys.[114] The Rieske-fold is common to all Rieske-type centers and coordinates the [2Fe–2S] cluster via the Cys and His residues in a Cys–X–His–X_{15-47}–Cys–X_2–His motif.[22] Unique folds are also associated with [2Fe–2S] centers in biotin synthase[68] and members of the xanthine oxidase family of molybdoenzymes.[116]

The electronic, magnetic, and vibrational properties of $[2Fe–2S]^{2+,+}$ clusters have been extensively characterized using the combination of absorption, CD, VTMCD, EPR, ENDOR, Mössbauer, NMR and resonance Raman spectroscopies, and the ground-state electronic properties are summarized in Figure 3. In the oxidized state, the two $S = 5/2$ Fe^{III} ions in the $[2Fe–2S]^{2+}$ cluster are antiferromagnetically coupled ($J \approx 360\,cm^{-1}$ for plant-type Fds and $>550\,cm^{-1}$ for hydroxylase-type Fds) to give a diamagnetic $S = 0$ ground state (Figure 3). In the reduced $[2Fe–2S]^+$ form, Mössbauer has shown that the valences are localized and the $S = 2$ Fe^{II} and $S = 5/2$ Fe^{III} sites are antiferromagnetically coupled ($J \approx 200$, 330, and $130\,cm^{-1}$ for plant-type Fds, hydroxylase-type Fds, and Rieske proteins, respectively) to give an $S = 1/2$ ground state with a rhombic or axial g-tensor (Figure 3). NMR has been used to assess the cysteine residues that coordinate the reducible Fe site in simple Fds.[119] Such information, coupled with the available structural data, suggests that the nature of the coordinating residues, solvent exposure, and the asymmetry in hydrogen-bonding interactions involving coordinated cysteinyl-S and backbone amide NH are primarily responsible for determining the site of reduction. The g-value anisotropy and average g-values of the $S = 1/2$ EPR signal of $[2Fe–2S]^+$ centers have been successfully rationalized in terms of distortion at the Fe^{II} site using a ligand field model[120] and more recently in terms of the Fe–Fe–S–C dihedral angles at the Fe^{II} site using DFT calculations.[121] However, antisymmetric exchange interactions are required to explain the anomalous EPR properties of the $[2Fe–2S]^+$ centers in Rieske-type centers at pH 14 and in members of the xanthine oxidase family of enzymes.[122] Rieske-type centers have also recently been shown to have an accessible all-ferrous $[2Fe–2S]^0$ redox state that is stabilized by protonation on one of the μ_2–sulfides.[123] The $[2Fe–2S]^0$ cluster was found to have an $S = 0$ ground state as a result of antiferromagnetic interaction between the two $S = 2$ Fe^{II} sites ($J = 60\,cm^{-1}$) (see Figure 3). However, since the $[2Fe–2S]^{+,0}$ couple is ~1.0 V lower than the $[2Fe–2S]^{2+,+}$ couple,[123] it seems unlikely that the all-ferrous redox state is physiologically relevant.

Site-directed mutagenesis studies involving coordinating cysteines and histidines have shown that individual cysteinates can be replaced as cluster ligands by serinate or aspartate in all-cysteine-ligated [2Fe–2S] clusters[124,125] and that an individual histidine can be replaced by a cysteinate ligand in a Rieske–type center.[126] All three types of substitutions decrease the redox potential, provided the substituted residue ligates the reducible Fe site, indicating that the $[2Fe–2S]^{2+,+}$ redox potentials decrease with increasing ligand nucleophilicity, that is, histidine > cysteinate > serinate ~ aspartate. Mutagenesis studies also led to the discovery of the only known examples of valence-delocalized $[2Fe–2S]^+$ clusters. EPR and Mössbauer studies of the C56S and C60S variants of *Clostridium pasteurianum* [2Fe–2S] Fd revealed the presence of valance-delocalized $[2Fe–2S]^+$ clusters with $S = 9/2$ ground states[93–95,127] (Figure 3). Ferromagnetic coupling facilitates valence delocalization since the electron with antiparallel spin can visit both Fe sites without undergoing a spin flip. These high-spin states are stabilized via spin-dependent resonance delocalization (double exchange) and theoretical studies indicate that the ground and excited properties of $[2Fe–2S]^+$ centers are critically dependent on the interplay of Heisenberg exchange, double exchange, and vibronic interactions.[85] As indicated in Figure 3, valence-delocalized $[2Fe–2S]^+$ units are integral components of all higher nuclearity clusters and the ability to investigate such clusters in isolation has facilitated characterization of the ground and excited state electronic properties as well as the vibrational properties using the combination of EPR, Mössbauer, VTMCD, and resonance Raman spectroscopies.[95,127]

2.3 [3Fe–4S] Clusters

Both cubane-type and linear [3Fe–4S] clusters have been reported in biological systems, but only the cubane-type appears to be physiologically relevant. Cubane-type clusters have a $Fe_3(\mu_3{-}S)(\mu_2{-}S)_3$ core that is best visualized as a cubane $Fe_4(\mu_3{-}S)_4$ core minus one Fe, with cysteinyl-S invariably completing the tetrahedral coordination at each Fe site (Figure 1). Indeed, the early discovery that cubane-type [3Fe–4S] clusters can be formed via oxidative loss of one Fe from [4Fe–4S] clusters led to speculation that all clusters of this type may be artifacts of aerobic protein isolation procedures.[128] While this is clearly the case in (de)hydratase enzymes such as aconitase and several Fds, particularly those containing [4Fe–4S] clusters with noncysteinyl ligation at a unique Fe site, there is now overwhelming evidence, based on X-ray structures, primary sequences, and *in vivo* detection, that cubane-type [3Fe–4S] clusters are also intrinsic components of numerous redox enzymes and proteins.[14] Electron transfer is the only known biological function and they have been established as intrinsic redox-active centers in numerous 3Fe and 7Fe Fds, succinate dehydrogenase, fumarate reductase, nitrate reductase, NiFe-hydrogenase, arsenite oxidase, and Fd- and NAD(P)H-dependent glutamate synthases.[14,129] In contrast, linear [3Fe–4S] clusters have only been rigorously identified in the 1+ oxidation state in alkaline (pH > 9.5) or denatured forms of [3Fe–4S] aconitase,[130,131] by virtue its unique electronic and magnetic properties, via comparative spectroscopic studies (absorption, Mössbauer, EPR, and VTMCD) of crystallographically defined synthetic analog complexes such as $[Fe_3S_4(SEt)_4]^{3-}$ (*see* ***Iron–Sulfur Models of Protein Active Sites***). Although no direct structural information is available for protein-bound linear $[3Fe–4S]^+$ clusters, the close correspondence in spectroscopic properties to those of synthetic $[3Fe–4S]^+$ complexes provides compelling evidence for a linear $Fe_3(\mu_2{-}S)_4$ core with cysteinyl-S completing tetrahedral coordination at the two terminal Fe sites. Thus far there is no evidence for the presence of a linear $[3Fe–4S]^+$ cluster as a functional component of any Fe–S protein.

Electrochemical studies indicate that biological cubane-type [3Fe–4S] clusters have accessible 1+, 0, and 2− redox states.[14] However, only the $[3Fe–4S]^{+,0}$ couple appears to be used to mediate biological electron transport and redox potentials for this couple span a range from +90 to −460 mV[14] (Figure 4). The midpoint potential for the two-electron $[3Fe–4S]^{0,2-}$ couple is ∼ −700 mV at pH 7, and is strongly pH dependent with reduction to the $[3Fe–4S]^{2-}$ state involving the net uptake of three protons.[132] Protonation of the $[3Fe–4S]^0$ clusters in some 7Fe Fds has also been observed with a $pK_a \sim 7.5$.[14] Although the protonation sites of reduced clusters have yet to be definitively established, the three $\mu_2{-}S$ atoms are the most likely candidates.[133]

X-ray crystal structures are available for cubane-type [3Fe–4S] centers in 3Fe and 7Fe Fds, aconitase, NiFe-hydrogenases, succinate dehydrogenase, fumarate reductase, arsenite oxidase, and nitrate reductase, and formate dehydrogenase.[14,21,108,115,129,134,135] In all cases, coordination at each Fe is approximately tetrahedral and the $Fe_3(\mu_3{-}S)(\mu_2{-}S)_3$ core has approximate C_{3v} symmetry. High-resolution structures are available for both the $[3Fe–4S]^+$ and $[3Fe–4S]^0$ centers in *Azotobacter vinelandii* FdI (1.4 Å resolution).[19,136] The core structures in both oxidation states are the same within experimental error and both exhibit a splayed configuration with respect to the three μ_2S atoms in the absence of the fourth Fe. However, the structure of the $[3Fe–4S]^0$ center displays significant distortions compared to a well-characterized analog complex,[137] suggesting that the protein−bound structure may represent an entatic state in order to facilitate electron transfer.[19] The average Fe–μ_2S bonds lengths (2.24 Å for $[3Fe–4S]^+$ and 2.26 Å for $[3Fe–4S]^0$) are generally shorter than the average Fe–μ_3S bond lengths (2.29 Å for $[3Fe–4S]^+$ and 2.28 Å for $[3Fe–4S]^0$) and the average Fe–S(Cys) bond lengths (2.28 Å for $[3Fe–4S]^+$ and 2.29 Å for $[3Fe–4S]^0$), and the Fe–Fe distances are significantly distributed with two short (2.64−2.67 Å) and one long (2.70−2.73 Å). A variety of arrangements of cysteine residues can coordinate cubane-type [3Fe–4S] clusters. However, in structurally characterized centers, the arrangement involves two closely spaced cysteines, Cys–X_2–Cys (aconitase), Cys–X_5–Cys (e.g. some 3Fe and 7Fe Fds, succinate dehydrogenase, fumarate reductase, nitrate reductase), or Cys–X_7–Cys (some 3Fe and 7Fe Fds), and one other remote cysteine.[21] Facile interconversion between [3Fe–4S] and [4Fe–4S] clusters is possible in aconitase and many ferredoxins (see Section 2.5). With this in mind, it is important to note that the consensus sequence for coordination of a [4Fe–4S] cluster in bacterial Fds is Cys–X_2–Cys(or Asp)−X_2–Cys with a more remote cysteine supplying the fourth ligand. Indeed, in ferredoxins where it is possible to effect facile [3Fe–4S] ⟷ [4Fe–4S] interconversions, a coordinating residue, either cysteine or aspartic acid, is located between two closely spaced cysteines that coordinate the [3Fe–4S] clusters in a Cys–X_2–Cys/Asp–X_2–Cys arrangement.

The electronic, magnetic, and vibrational properties of [3Fe–4S] centers in each accessible redox state have been characterized in detail using the combination of absorption, VTMCD, EPR, ENDOR, Mössbauer, saturation magnetization, NMR, and resonance Raman. The results have recently been reviewed[14] and the ground-state properties and valence-delocalization schemes for cubane-type [3Fe–4S] centers are summarized in Figure 3. In cubane-type $[3Fe–4S]^+$ clusters, the three $S = 5/2$ Fe^{III} ions are antiferromagnetically coupled to give an $S = 1/2$ ground state. This gives rise to an isotropic or axial EPR signal centered with g_{av} between 2.02 and 1.96 with a well-defined low-field g-value close to 2.02. Saturation magnetization studies and NMR measurements have been interpreted in terms of three nearly equivalent exchange interactions with $J_{12} \sim J_{13} \sim J_{23} \sim 300\ cm^{-1}$, and recent studies have demonstrated that antisymmetric exchange

coupling with slightly distributed J values are required to explain the broad high-field EPR spectra that are observed for many $[3Fe–4S]^+$ clusters.[138] In contrast, linear $[3Fe–4S]^+$ clusters exhibit a rhombic $S = 5/2$ ground state ($E/D \sim 0.31$) that results from highly asymmetric coupling among the three Fe atoms, $J_{12} \sim J_{23} > 2J_{13}$, reflecting the linear rather than triangular arrangement of Fe atoms.[130] One-electron reduction of cubane-type $[3Fe–4S]^+$ centers results in a $[3Fe–4S]^0$ cluster with a $S = 2$ ground state ($D \sim -2.5\,cm^{-1}$ and $E/D = 0.20–0.25$) that arises from antiferromagnetic interaction between a valence-delocalized Fe^{II}/Fe^{III} pair ($S = 9/2$) and a valence trapped Fe^{III} site ($S = 5/2$). Although there is no spectroscopic or electrochemical evidence for discrete $[3Fe–4S]^-$ clusters in biological samples, the properties of center have been deduced from studies of protein-bound heterometallic cubanes $[M–3Fe–4S]^+$ (see Section 2.5), in which M is a redox-inert diamagnetic d^{10} transition metal ion such as Zn^{2+} or Cd^{2+}. The $[3Fe–4S]^-$ cluster fragment has an $S = 5/2$ ground state ($D \sim -2.5\,cm^{-1}$ and E/D in the range 0.18–0.33) that arises from antiferromagnetic interaction between a valence-delocalized Fe^{II}/Fe^{III} pair ($S = 9/2$) and a valence trapped Fe^{II} site ($S = 2$). The electronic properties of the all-ferrous cubane-type $[3Fe–4S]^{2-}$ center have yet to be established.

2.4 [4Fe–4S] Clusters

Cubane-type clusters involving a $Fe_4(\mu_3\text{–}S)_4$ core are one of the most pervasive electron transfer centers in biology (Figure 1). Almost all have complete cysteinyl-S ligation. However, there are a few well-characterized examples of electron transfer [4Fe–4S] clusters with noncysteinyl ligation at one Fe site: aspartate in some ferredoxins[139] and histidine in both NiFe- and Fe-hydrogenases[35,40] and nitrate reductase.[134] Mutagenesis studies have also demonstrated that [4Fe–4S] clusters can be assembled with one cysteinate ligand replaced by serinate,[140,141] aspartate[142] or histidine.[143] In addition to their ubiquitous role in mediating biological electron transport, [4Fe–4S] clusters also have catalytic roles in substrate binding and disulfide reduction, as well as regulatory, structural, and storage roles (Table 1). In both (de)hydratases[27,28] and radical-SAM enzymes,[34,144] the absence of an amino acid residue ligand at a unique Fe site of a [4Fe–4S] cluster creates a site for binding and activating the substrate (Figure 2).

Biological [4Fe–4S] clusters have been characterized in the 3+, 2+, 1+, and 0 core oxidations states. However, with the notable exception of the nitrogenase Fe-protein, all electron transfer [4Fe–4S] clusters only undergo one-electron redox cycling between either the $[4Fe–4S]^{3+,2+}$ or $[4Fe–4S]^{2+,+}$ couples under physiological conditions. Fd-type centers cycle between the $[4Fe–4S]^{2+,+}$ states with midpoint potentials between +80 and −715 mV, whereas high potential iron–sulfur protein, HiPIP-type centers cycle between the $[4Fe–4S]^{3+,2+}$ states at higher potentials, +50 to +500 mV (Figure 4). Despite the existence of several ultrahigh–resolution (≤1.0 Å) crystal structures for HiPIP-type and Fd-type $[4Fe–4S]^{2+}$ centers,[145–148] the factors that determine the choice of redox couple are not yet clearly defined. One important factor is the number of amide NH–S hydrogen bonds to the [4Fe–4S] center (~5 in HiPIPs compared to 8–10 in Fds). However, other factors such as hydrophobic interactions, solvent exposure, and the electrostatic interaction of the charged cluster with its protein environment also play an important role in determining both the redox couple and the redox potential within a particular class.[149] The nitrogenase Fe-protein is unique in containing a subunit-bridging [4Fe–4S] cluster that can be stabilized in three core oxidation states, 2+, 1+, and 0, and hence has the capability to act as a two-electron donor. Following the pioneering work of Watt and coworkers,[150] the all-ferrous $[4Fe–4S]^0$ center was prepared by reduction with Ti(III) citrate and characterized spectroscopically and structurally.[151,152] Structural data and calculations suggest that increased solvent exposure and NH–S H-bonding interactions (~14 in Fe-protein) are responsible for stabilizing the $[4Fe–4S]^0$ center in the Fe-protein.[149] However, the most recent estimates for the redox potential of the $[4Fe–4S]^{+,0}$ couple, ~−790 mV, indicate that it is substantially more negative than the $[4Fe–4S]^{2+,+}$ couple, ~−350 mV, and consequently raise doubts concerning the physiological relevance of the all-ferrous form of the nitrogenase Fe-protein.[153]

X-ray crystal structures are available for [4Fe–4S] centers in a large number of simple and complex Fe–S proteins (see Table 1 for examples), and atomic resolution structures are available for $[4Fe–4S]^{2+}$ centers in HiPIP,[145,146] 4Fe Fd,[148] 7Fe Fd,[136] and 8Fe Fd.[147] In accord with the structures of analog complexes[13] and resonance Raman studies of protein-bound $[4Fe–4S]^{2+}$ centers,[154] a tetragonal compression resulting in approximate D_{2d} symmetry is generally observed within the [4Fe–4S] core, resulting in four parallel short bonds (average Fe–S distances between 2.24 and 2.28 Å) and eight long bonds (average Fe–S distances between 2.29 and 2.31 Å), with the average Fe–S(Cys) and Fe–Fe distances in the range 2.26–2.28 Å and 2.71–2.75 Å, respectively. The tetragonal compression appears to be more pronounced in HiPIP- than Fd-type $[4Fe–4S]^{2+}$ clusters, with average long Fe–S minus average short Fe–S distances in the range 0.06–0.07 Å for HiPIPs and 0.02–0.05 Å for Fds. Although no high-resolution X-ray crystal structures are currently available for protein-bound $[4Fe–4S]^{3+}$ and $[4Fe–4S]^+$ clusters, crystallographic studies of analog complexes[13] suggest that oxidation will primarily involve contraction of the eight long Fe–S bonds and that reduction will primarily involve elongation of the four short Fe–S bonds, yielding clusters with decreased tetragonal compressions. An alternative and useful method of analyzing distortions in [4Fe–4S] centers has recently been proposed based on the radii and circumcenters of the circumspheres defined by the Fe, inorganic-S, and cysteinyl-S atoms.[155] The circumcenters are generally non-coincident by 0.01–0.06 Å and the Fe radius (1.66–1.69 Å) appears

to be relatively insensitive to the core oxidation state, whereas the inorganic-S and cysteinyl-S radii (2.18–2.24 Å and 3.87–3.94 Å, respectively) both increase by ∼3% on reduction from the 3+ to 1+ core oxidation states. The X-ray crystal structure of the $[4Fe–4S]^0$ in the nitrogenase Fe-protein has been reported at 2.25 Å resolution.[152] However, this resolution may not be adequate for defining cluster distortion and it is significant that the metrical parameters are not in accord with those derived from extended x-ray absorption fine structure (EXAFS) analysis.[156] For example, the best fit to the EXAFS data gives a 4:2 short-to-long pattern of Fe–Fe distances with average Fe–Fe distances of 2.52 and 2.77 Å, whereas the X-ray structure gives a 2:4 short-to-long pattern with Fe–Fe distances in the ranges 2.54–2.57 Å and 2.66–2.79 Å. Nevertheless, comparison with other Fe-protein X-ray crystal structures clearly demonstrates that reduction to the all-ferrous state occurs without major conformational changes in the protein environment and that the [4Fe–4S] core stays intact.[152]

The magnetic and electronic properties of [4Fe–4S] centers are less well understood than for [2Fe–2S] and [3Fe–4S] centers. Phenomenologically, the Mössbauer and EPR data have been rationalized in terms of antiferromagnetic exchange interaction between valence-delocalized, ferromagnetically coupled [2Fe–2S] units (Figure 3): $[4Fe–4S]^{3+}$ ($S = 1/2$) results from Fe^{III}/Fe^{III} ($S = 5$) coupled to Fe^{II}/Fe^{III} ($S = 9/2$); $[4Fe–4S]^{2+}$ ($S = 0$) results from Fe^{II}/Fe^{III} ($S = 9/2$) coupled to Fe^{II}/Fe^{III} ($S = 9/2$); $[4Fe–4S]^{+}$ ($S = 1/2$) results from Fe^{II}/Fe^{II} ($S = 4$) coupled to Fe^{II}/Fe^{III} ($S = 9/2$). However, this is likely to be an oversimplification, since analyses of hyperfine coupling constants and/or NMR studies of $S = 1/2$ $[4Fe–4S]^{3+}$ and $[4Fe–4S]^{+}$ clusters suggests that $S = 7/2$ or $S = 7/2$, 9/2 mixed spin are likely to be more appropriate formal spin states for the valence-delocalized $[2Fe–2S]^{+}$ fragments in these clusters.[157,158] Moreover, NMR studies of protein-bound $[4Fe–4S]^{3+}$ centers indicate that the location of the valence-delocalized pair is dynamic on the NMR timescale, such that the cluster exists in rapid equilibrium between different forms. Both $[4Fe–4S]^{3+}$ and $[4Fe–4S]^{+}$ centers have $S = 1/2$ ground states, but they are readily distinguished by EPR. $[4Fe–4S]^{3+}$ centers give rise to axial EPR signals (typically $g_{\parallel} = 2.12$ and $g_{\perp} = 2.04$) with $g_{av} > 2$, whereas $[4Fe–4S]^{+}$ centers give rise to rhombic EPR signals (typically $g = 2.06, 1.92, 1.88$) with $g_{av} < 2$. The EPR signals from $S = 1/2$ $[4Fe–4S]^{+}$ centers are similar to those exhibited by $[2Fe–2S]^{+}$ centers in plant-type Fds, but can usually be distinguished, since they are faster relaxing and not generally observable above 30 K. Although the majority of biological $[4Fe–4S]^{+}$ centers exhibit $S = 1/2$ ground states, there are many that exist as a mixture of species with $S = 1/2$ and 3/2 ground states,[3] as well as a few examples of pure $S = 3/2$ ground states[159,160] and quantum mechanically admixed $S = 1/2$, 3/2 ground states.[161] The implication is that $S = 1/2$ and 3/2 states of $[4Fe–4S]^{+}$ centers are close in energy and the structural, electronic, or environmental factors that determine which is lower in energy are subtle and have yet to be fully elucidated.[162] EPR and Mössbauer studies have determined an $S = 4$ ground state for the $[4Fe–4S]^0$ center in the nitrogenase Fe-protein.[151] Moreover, the coupling scheme appears to be quite distinct from that characterized in the three higher oxidation states, with four high-spin Fe(II) sites coupled in a 3:1 alignment of up:down spin vectors.[163] This would predict a 3:3 pattern of short-to-long bonds reflecting the three ferromagnetic and three antiferromagnetic Fe–Fe interactions, rather that the 2:4 or 4:2 short-to-long patterns that have been reported based on EXAFS and crystallographic data, respectively.[152,156] A higher resolution crystal structure will clearly be required in order to provide a structural framework for the observed coupling scheme.

Numerous different arrangements of cysteine residues and protein folds are able to accommodate [4Fe–4S] clusters. By far the most common among electron transfer [4Fe–4S] centers are the Fd-type fold which involves ligation by three closely spaced Cys residues, typically Cys–X_2–Cys–X_2–Cys plus a more remote Cys, and the HiPIP-type fold which involves ligation by four Cys residues in a Cys–X_2–Cys–X_{8-16}–Cys–X_{11-15}–Cys arrangement.[21] In addition, electron transfer [4Fe–4S] clusters can also bridge subunits in homodimeric proteins using two cysteines from each monomer. The best-characterized examples are nitrogenase Fe-protein,[164] the F_X cluster in photosystem I (*see* ***Photosynthesis***),[165,166] and cluster D in CO dehydrogenase and acetyl-CoA synthase.[42,44] The protein folds and arrangements of coordinating cysteine residues in [4Fe–4S] clusters whose function is not solely electron transfer (Table 1) are described in Section 3.

2.5 Cluster Conversions

Biological Fe–S clusters can frequently be degraded or converted into other structural types in response to exposure to O_2 or NO, chemical oxidation or reduction, changes in pH, denaturants, or site-directed mutagenesis of specific residues. Moreover, since Fe–S clusters control a local region of protein structure, cluster transformations, or degradation can provide a sensory mechanism for regulating gene expression or enzyme activity in response to external stimuli.[58] Figure 5 provides a summary of the well-characterized types of cluster transformation that have been observed in Fe–S proteins.

Aconitase has been a particularly fertile protein for investigating and establishing cluster transformations.[27] Aerobic isolation of aconitase or air-exposure of the active $[4Fe–4S]^{2+,+}$ form results in an inactive enzyme containing a $[3Fe–4S]^{+}$ cluster. However, under reducing conditions the $[3Fe–4S]^0$ cluster avidly takes up Fe to reform the catalytically active $[4Fe–4S]^{2+,+}$ cluster. The [4Fe–4S] clusters in (de)hydratases such as aconitase and ferredoxins which have noncysteinyl ligation at a specific Fe atom are particularly susceptible to this type of reversible cluster

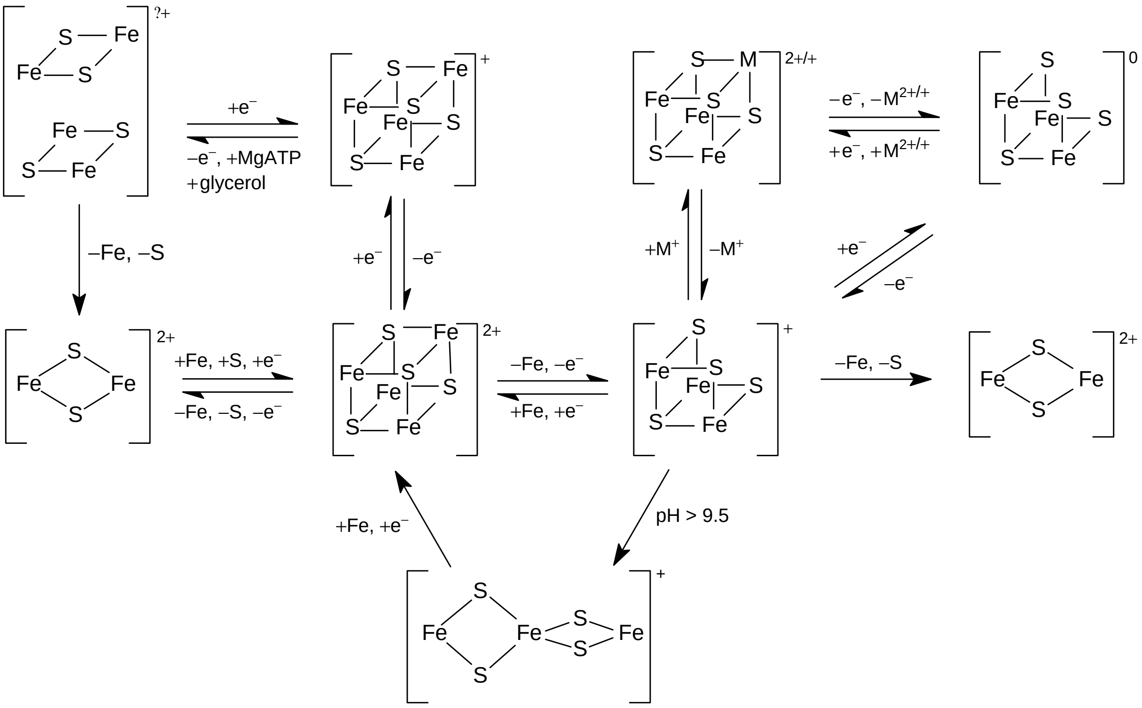

Figure 5 Summary of the types of cluster transformations that have been observed in Fe–S proteins. $M^+ = Cu^+$ and Tl^+; $M^{2+} = Cr^{2+}$, Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}

transformation. Indeed this has been used to great effect for the assembly and characterization of mixed-metal cubane clusters of the type $[M–3Fe–4S]^{2+,+}$ (M = Zn, Co, Ni, Cr, Mn, Cu, Cd, Ga, Tl) in bacterial ferredoxins.[14] Many [4Fe–4S] clusters with complete cysteinyl ligation are also susceptible to partial oxidative degradation to $[3Fe–4S]^+$ clusters, although the conditions required are usually more extreme, that is, prolonged exposure to air and/or large excesses of ferricyanide. [3Fe–4S] ↔ [4Fe–4S] and [4Fe–4S] ↔ [3Fe–4S] cluster conversions have also been accomplished by site-directed mutagenesis for clusters containing Fd-like arrangements of cysteine residues. In enzymes such as fumarate reductase[167] and NiFe-hydrogenase[168] containing an endogenous [3Fe–4S] cluster ligated by a Fd-type Cys–X_2–Y–X_2–Cys grouping of cysteines, conversion to a [4Fe–4S] cluster is effected upon replacement of the Y residue by Cys. Conversely, mutagenesis of the middle Cys in the Fd-type Cys–X_2–Cys–X_2–Cys grouping of cysteines in dimethylsulfoxide (DMSO) reductase[169] and NiFe-hydrogenase[170] result in [4Fe–4S] to [3Fe–4S] cluster conversions.

Aconitase is currently the only well-characterized example of a cubane-type $[3Fe–4S]^+$ to linear $[3Fe–4S]^+$ cluster conversion.[130,131] This remarkable transformation occurs at pH > 9.5 or under conditions of partial denaturation, despite requiring a major protein rearrangement. Only two of the cysteine ligands to the cubane-type $[3Fe–4S]^+$ cluster are retained and two more remote cysteines are recruited as cluster ligands.[77] On the basis of absorption data alone, linear $[3Fe–4S]^+$ clusters have also been reported under alkaline conditions or during denaturation of 7Fe and [2Fe–2S] Fds.[171–173] However, definitive evidence for linear $[3Fe–4S]^+$ clusters in these proteins requires the application of more discriminating spectroscopic techniques, as soluble polymeric iron-sulfides exhibit similar absorption characteristics. Reduction of the linear $[3Fe–4S]^+$ center in aconitase in the presence of Fe leads to the formation of $[4Fe–4S]^{2+,+}$ clusters. Similar cluster transformations have been observed with synthetic clusters and have been utilized to synthesize a variety of mixed-metal cubane clusters of the type $[M–3Fe–4S]^{2+,+}$.[13]

There are also several examples of $[4Fe–4S]^{2+}$ and cubane-type $[3Fe–4S]^+$ clusters that undergo degradation to $[2Fe–2S]^{2+}$ clusters under oxidative or denaturing conditions. For example, some $[2Fe–2S]^{2+}$ clusters are formed, in addition to linear $[3Fe–4S]^+$ clusters, during denaturation of aconitase.[130] The SAM-binding $[4Fe–4S]^{2+}$ clusters in radical-SAM enzymes also undergo facile aerial oxidative conversion to yield a semistable $[2Fe–2S]^{2+}$ cluster,[174] and in some cases this conversion appears to proceed via a $[3Fe–4S]^+$ cluster intermediate. Oxygen-induced $[4Fe–4S]^{2+}$ to $[2Fe–2S]^{2+}$ cluster conversion in the FNR (fumarate–nitrate reduction) regulatory protein constitutes the O_2-sensing mechanism that triggers the switch from

anaerobic to aerobic growth of *E. coli*,[57,58] and recent spectroscopic studies indicate that this conversion involves a $[3Fe–4S]^+$ intermediate.[175] Another intriguing example of $[4Fe–4S]^{2+}$ to $[2Fe–2S]^{2+}$ cluster conversion is provided by nitrogenase Fe-protein.[176] MgATP binding to the oxidized protein in the presence of iron chelators such as α, α'-dipyridyl results in conversion of the endogenous $[4Fe–4S]^{2+}$ cluster to a $[2Fe–2S]^{2+}$ cluster. Moreover, recent crystallographic and spectroscopic studies of a mimic of the nucleotide-bound form of the nitrogenase Fe-protein have revealed a novel transformation in which the reduced [4Fe–4S] cluster is reversibly cleaved into two [2Fe–2S] fragments separated by ~5Å under oxidizing conditions in the presence of glycerol.[177] Each [2Fe–2S] fragment has one cysteinyl ligand at each Fe site and glycerol appears to be bound as a bidentate bridging ligand. This is likely to correspond to stabilized intermediate in the oxidative $[4Fe–4S]^{2+}$ to $[2Fe–2S]^{2+}$ conversion and provides a model system for investigating reductive coupling of $[2Fe–2S]^{2+}$ clusters at a subunit interface to yield $[4Fe–4S]^{2+}$, a process that may be of fundamental importance in the biosynthesis of $[4Fe–4S]^{2+}$ clusters.[83,178] All of these oxidatively induced $[4Fe–4S]^{2+}$ to $[2Fe–2S]^{2+}$ cluster conversions are reversible under reducing conditions in the presence of ferrous ions and sulfide.

Iron–sulfur clusters are frequently sensitive targets for NO cytotoxicity and are generally degraded to yield dinitrosyl-iron-dithiol species, as judged by the appearance of the characteristic EPR signal ($g_\perp = 2.03$, $g_\parallel = 2.01$).[179] Recent studies of the nitrosylated form of a 2Fe Fd have shown that the dinitrosyl-iron-dithiol species can be converted back to a [2Fe–2S] cluster by cysteine desulfurases.[180] Although it remains to be established if this constitutes a general method of repair of nitrosylated Fe–S centers, it does provide a plausible mechanism for NO sensing by Fe–S centers.

3 FUNCTIONS OF BIOLOGICAL IRON–SULFUR CENTERS

3.1 Electron Transport

Biological electron transfer chains containing one or more Fe–S centers are present in numerous membrane-bound and soluble oxidoreductases and play important roles in both respiratory and photosynthetic energy conversion. In addition, Fds, Rds, and HiPIPs constitute one of the largest groups of mobile electron carriers that serve as electron donors or acceptors. The recent proliferation of oxidoreductase structures has revealed that Fe–S centers are generally arranged in chains connecting the sites of catalysis and interprotein electron transfer. Moreover, their proximity (edge-to-edge distances between 4 to 14 Å) is sufficient to allow for tunneling of electrons at rates far faster than the substrate redox reactions, thereby obviating the need for specific through-bond electron transfer pathways.[181] In accord with this hypothesis, the redox potentials of Fe–S centers in many chains are frequently not ordered in increasing sequence, and up-and-down variations spanning up to 300 mV still allow thermal electron tunneling through the chains much faster than typical msec–sec catalytic turnovers. Other oxidoreductases modulate Fe–S cluster redox potential and/or conformation with external affecters, for example, MgATP in nitrogenase[182] and benzoyl-CoA reductase,[183] in order to change intracluster distances and bring thermally activated tunneling into the range of measured catalytic rates. Fe–S clusters are also implicated in coupled electron/proton transfer reactions in NADH-quinone oxidoreductase, quinol-cytochrome *c* oxidoreductases and nitrogenases, and many Fe–S enzymes contain active sites at which proton-coupled redox reactions occur. The combination of spectroscopic and crystallographic studies has also revealed three examples of metalloenzyme active sites with [4Fe–4S] clusters that are directly attached to the substrate-binding site via a bridging cysteinate in order the facilitate rapid electron transfer to or from the substrate: the siroheme–[4Fe–4S] active site of sulfite and nitrite reductases[38,39] (Figure 2(g)); the Fe–Fe–[4Fe–4S] active site of Fe-hydrogenases[40,41] (Figure 2(f)); the Ni–Ni–[4Fe–4S] active site of acetyl-CoA synthases[44–46] (Figure 2(j)).

3.1.1 *Mobile Electron Transport Proteins*

As indicated above, much of our current understanding of biological Fe–S centers comes from studies of low-molecular weight (6–12 kDa) simple Fe–S proteins containing $[Fe(Cys)_4]^{2-,-}$, $[2Fe–2S]^{2+,+}$, $[3Fe–4S]^{+,0}$, $[4Fe–4S]^{3+,2+,+}$ centers, that is, Rds, Dxs, 2Fe-, 3Fe-, 4Fe-, 7Fe-, and 8Fe-Fds, and HiPIPs. The 7Fe- and 8Fe-Fds contain one $[3Fe–4S]^{+,0}$ and $[4Fe–4S]^{2+,+}$ center and two $[4Fe–4S]^{2+,+}$ centers, respectively, with the clusters separated by approximately 12 Å. Ferredoxins function as electron donors/acceptors for a wide variety of prokaryotic and eukaryotic oxidoreductases, for example, hydrogenase, nitrogenase, cytochrome P-450, nitrite reductase, nitrate reductase, sulfite reductase, formate dehydrogenase, aldehyde oxidoreductase, glutamate synthase, and dioxygenases. However, in many cases, their lack of specificity prevents assignment of a specific electron transport function, and many appear to function as electron donors/acceptors for several different enzymes. For example, the chloroplast 2Fe Fds which accept electrons from photosystem I can act as the electron donor to nitrite reductase, sulfite reductase, glutamate synthase, thioredoxin reductase, or $NADP^+$ reductase.[21] Homologs of the hydroxylase–type of 2Fe Fds that function as electron donors to cytochrome P-450s, also have a role as an electron acceptors or donors in Fe–S cluster biosynthesis.[83] HiPIPs are found in purple phototrophic bacteria and halophilic denitrifying

bacteria, and suggested roles include electron transport in photosynthesis, anaerobic metabolism, thiosulfate oxidation, and iron oxidation. Rubredoxins have been shown or proposed to function as electron donors to nitrate reductase, hydrogenase, alkane hydroxylase, and bacterioferritin, and an electron acceptor for pyruvate-ferredoxin oxidoreductase.[98] In addition, Rds appear to play an important role as the electron donors to 1Fe and 2Fe SORs, the nonheme Fe peroxidase rubrerythrin, and rubredoxin:oxygen oxidoreductase, three key enzymes involved in oxidative stress protection in anaerobic organisms.[184]

3.1.2 *Membrane-bound Electron Transport Chain Enzymes and Proteins*

The [2Fe–2S], [3Fe–4S], and [4Fe–4S] clusters that are found in simple Fe–S proteins are also constituents of respiratory and photosynthetic electron transport chains. Multicluster Fe–S enzymes such as hydrogenase, formate dehydrogenase, NADH dehydrogenase, and succinate dehydrogenase feed electrons into respiratory chains, while others such as nitrate reductase, fumarate reductase, DMSO reductase, and HDR catalyze the terminal step in anaerobic electron transport chains that utilize nitrate, fumarate, DMSO, and the CoB–S–S–CoM heterodisulfide as the respiratory oxidant. All comprise membrane anchor polypeptide(s) and soluble subunits on the membrane surface that mediate electron transfer to or from Mo cofactor (Moco), NiFe, Fe–S cluster or flavin active sites. Multiple Fe–S clusters define electron transport pathways between the active site and the electron donor or acceptors associated with the membrane anchor subunits. For example, *E. coli* nitrate reductase (NarGHI) and formate dehydrogenase (FdnGHI) each contain linear electron transport chains comprising four $[4Fe–4S]^{2+,+}$ and one $[3Fe–4S]^{+,0}$ cluster (NarGHI) or five $[4Fe–4S]^{2+,+}$ clusters (FdnGHI) in the soluble GH subunits, and two *b*-type cytochromes in the membrane anchor I subunits, that mediate transfer of electrons from menaquinol to the Moco active site (NarGHI) or from the Moco active site to menaquinone (FdnGHI).[134,185] Positioning the soluble subunits on the periplasmic (FdnGHI) and cytoplasmic (NarGHI) side of the membrane facilitates proton motive force generation via a redox loop involving menaquinol/menaquinone redox cycling in the membrane associated quinone pool.[134,185] This mechanism for proton motive force generation is common to a wide range of bacterial respiratory enzymes.

The mitochondrial respiratory chain, which contains at least 13 Fe–S clusters (Figure 6), perhaps best illustrates the importance of Fe–S clusters in membrane-bound electron transport. Electrons enter via three principal pathways, from the oxidation of NADH to NAD^+ (NADH-ubiquinone oxidoreductase or Complex I) and succinate to fumarate (succinate:ubiquinone oxidoreductase or Complex II), and from the β-oxidation of fatty acids via the electron transferring flavoprotein (ETF-ubiquinone oxidoreductase). All three pathways involve a complex Fe–S flavoprotein dehydrogenase, that is, NADH dehydrogenase, succinate dehydrogenase, and ETF dehydrogenase, and in each case the Fe–S clusters mediate electron transfer from the flavin active site to the ubiquinone pool via protein-associated ubiquinone.

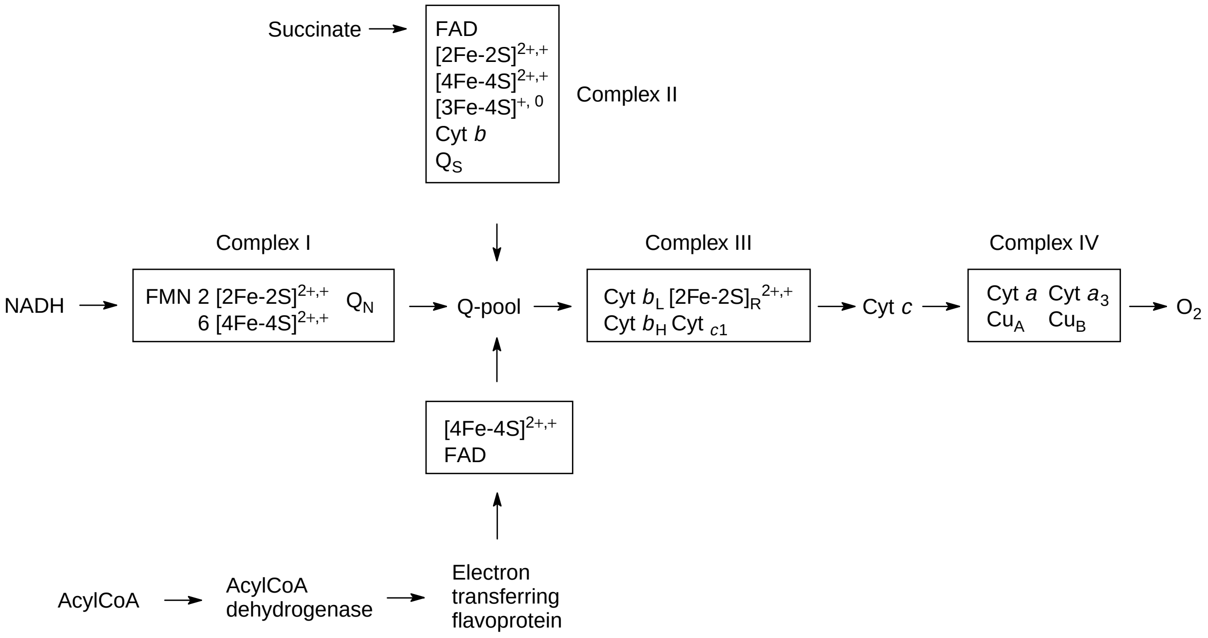

Figure 6 Mitochondrial respiratory chain. Q_S and Q_N are protein-associated pools of ubiquinone that can be distinguished from the bulk ubiquinone pool

Ubihydroquinone is then used to reduced cytochrome *c* via ubihydroquinone-cytochrome *c* reductase (Complex III) which contains two *b*-type and one c_1-type cytochrome in addition to a Rieske-type [2Fe–2S] center (*see* ***Iron: Heme Proteins & Electron Transport***). Cytochrome *c* is the electron donor for cytochrome *c* oxidase where the terminal electron acceptor O_2 is reduced to H_2O (*see* ***Cytochrome Oxidase***). Electron transfer along the respiratory chain is coupled to ATP synthesis via the generation of a proton electrochemical gradient across the inner mitochondrial membrane, in the process known as oxidative phosphorylation. The coupling sites are in Complexes I, III, and IV. Understanding the detailed molecular mechanisms of redox-linked proton translocation remains one of the major goals of bioenergetics research and the recent crystal structures of Complex II, III, and IV, represent important landmarks in this endeavor.

Complex I catalyzes electron transfer from NADH to quinone (Q) coupled with the translocation of four protons (see equation 1)

$$\mathrm{NADH} + \mathrm{Q} + 5\mathrm{H}_\mathrm{N}^+ \longrightarrow \mathrm{NAD}^+ + \mathrm{QH}_2 + 4\mathrm{H}_\mathrm{P}^+ \qquad (1)$$

where H_N^+ and H_P^+ indicate proteins on the negative inner side and the positive outer side of the membrane, respectively. It is the most elaborate of all Fe–S proteins and has yet to be structurally defined by crystallography. Mitochondrial complex I comprises at least 46 subunits (~1 MDa). However, characterization of Complex I from bacteria has revealed a conserved catalytic core comprising 14 subunits (~535 kDa) that appears to correspond to the minimal functional unit for a proton-pumping NADH:ubiquinone oxidoreductase.[186,187] The extra eukaryotic subunits are all encoded by nuclear genes and may be necessary for regulating assembly or insulating Complex I to prevent the escape of high-energy electrons. Of the 14 core subunits, seven are peripheral proteins on a hydrophilic arm that protrudes out from the membrane and contains all known redox cofactors, and seven are intrinsic membrane-spanning proteins, with the overall structure approximately L-shaped. On the basis of sequence analysis, Complex I is proposed to have evolved from three major modules for electron transport and proton translocation.[187] The soluble NADH dehydrogenase module is for electron input and is found in many nonenergy converting NAD(P)H-dependent hydrogenases and dehydrogenases. The hydrogenase module is involved with redox-coupled proton translocation, comprises hydrophilic and hydrophobic subunits, and is also found in membrane-bound NiFe-hydrogenases. The membrane transporter module is composed entirely of hydrophobic subunits, some which are homologous with H^+/Na^+ or H^+/K^+ antiporter subunits, suggesting a role in conformationally driven ion translocation. Extensive spectroscopic studies of purified Complex I samples have provided evidence for two $[2Fe–2S]^{2+,+}$ clusters and approximately six $[4Fe–4S]^{2+,+}$ clusters, although there is still an ongoing debate concerning the number and subunit location of some of the $[4Fe–4S]^{2+,+}$.[186–188] The NADH dehydrogenase module contains the NADH and flavin mononucleotide (FMN) binding sites in addition to two $[2Fe–2S]^{2+,+}$ and three or four $[4Fe–4S]^{2+,+}$ clusters, and the hydrogenase module contains the ubiquinone binding site and two or three $[4Fe–4S]^{2+,+}$ clusters, one of which has a pH-dependent midpoint potential and is likely to be directly involved with redox-linked proton coupling.[186,187,189,190] Crystallographic refinement of Complex I is anticipated in the near future and is awaited with great interest by both the bioenergetics and bioinorganic communities.

A clearer picture has emerged for Complex II and crystal structures are available for the *E. coli* succinate–quinone oxidoreductase (SQR) and closely related bacterial quinol–fumarate oxidoreductases (QFR) that catalyze the reverse reaction in order to use fumarate as a terminal electron donor in anaerobic respiration.[108,115] The structure of the SQR monomer showing the location of the redox cofactors is shown in Figure 7.[108] The $[2Fe–2S]^{2+,+}$ ($E_m = +10$ mV), $[4Fe–4S]^{2+,+}$ ($E_m = -175$ mV) and $[3Fe–4S]^{+,0}$ ($E_m = +65$ mV) clusters in the SdhB subunit provide a linear electron transport chain for transferring electrons from the flavin adenine dinucleotide (FAD) active site ($E_m = -79$ mV) in the SdhA subunit to ubiquinone ($E_m = +113$ mV) in the SdhC membrane anchor subunit. The edge-to-edge distances

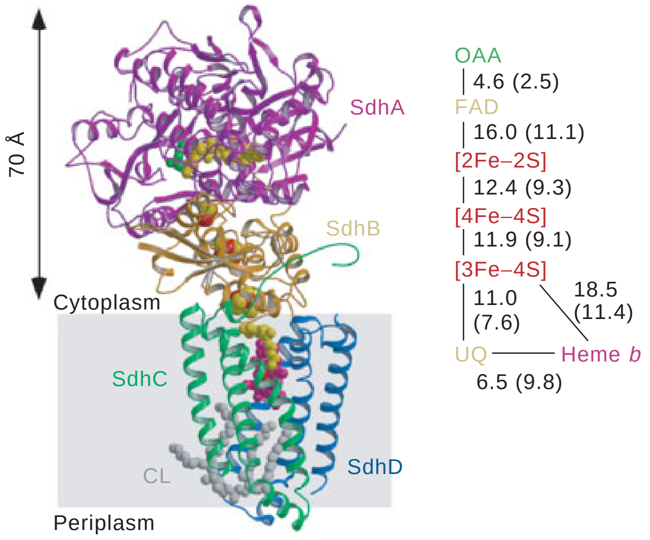

Figure 7 Structure of *E. coli* succinate-ubiquinone oxioreductase monomer. SdhA, SdhB, SdhC, and SdhD subunits are shown in purple, orange, green, and blue, respectively. FAD is shown gold, oxaloacetate (OAA) in green, heme *b* in magenta, ubiquinone (UQ) in yellow, Fe in red, inorganic-S in yellow, and cardiolipin (CL) in gray. Gray shading indicates the position of the membrane. The center-to-center distances (Å) between the cofactors are shown to the right, with edge-to-edge distances in parenthesis. (Reprinted with permission from V. Yankovskaya, R. Horsefield, S. Törnroth, C. Luna-Chavez, H. Miyoshi, C. Léger, B. Byrne, G. Cecchini, and S. Iwata, *Science*, 2003, **299**, 700. © 2003 AAAS)

are in the range established for efficient tunneling (4–14 Å),[181] which means that the low potential of the central $[4Fe–4S]^{2+,+}$ cluster is not a thermodynamic barrier to efficient electron transfer. Very similar arrangements of redox cofactors in the A and B subunits are found in the structurally characterized QFRs from *E. coli*[191] and *Wolinella succinogenes*.[192] The only major differences are that the [2Fe–2S] cluster in the SQR has a monodentate aspartate in place of a cysteine ligand (the majority of SQRs and QFRs have complete cysteinyl ligation for all Fe–S clusters) and that the [4Fe–4S] cluster in the SQR has an additional H-bond involving the thiol group of a fifth cysteine residue and the S of a coordinated cysteine. These differences are likely to relate to the differences in the redox potentials, for example, the $[4Fe–4S]^{2+,+}$ couple is 100–150 mV higher in SQRs than QFRs in accord with increased H-bonding in SQRs. The major differences in the structurally characterized SQR and QFRs reside in the membrane anchor subunits. *E. coli* SQR has a ubiquinone binding site and a bis-histidine ligated cytochrome $b(E_m = +35\,mV)$ that bridges the SdhC and SdhD subunits.[108] In contrast, *E. coli* QFR has no cyt *b* and two menaquinone binding sites that are both different from the SQR quinone binding sites[191] and *W. succinogenes* QFR has a single membrane anchor subunit with two *b*-type cytochromes and lacks a SQR quinone binding site.[192] The implication is that cyt *b* is not an essential component of the electron transfer chain, and the closer proximity of the [3Fe–4S] cluster to ubiquinone compared to cyt *b* in SQR supports this conclusion (Figure 7). An alternative role for the cyt *b* is as an electron sink to prevent electron leakage and build–up of reactive oxygen species has been proposed.[108]

ETF-ubiquinone reductase is one of the simplest quinone oxidoreductases comprising a single subunit (64 kDa) Fe–S flavoprotein with one $[4Fe–4S]^{2+,+}$ cluster ($E_m = +47\,mV$) and one FAD ($E_m = +28$ and $-6\,mV$) separated by ∼12 Å.[193,194] It accepts electrons from ETF, which oxidizes 11 primary flavoprotein dehydrogenases in the mitochondrial matrix, thereby providing a link for electrons derived from a variety of oxidative processes into the respiratory chain. While it was generally assumed that electrons from ETF enter ETF-ubiquinone oxidoreductase through FAD and are transferred to ubiquinone via the $[4Fe–4S]^{2+,+}$ cluster, the spatial proximity of FAD and ubiquinone (minimum separation 8.5 Å, compared to 19 Å between the [4Fe–4S] cluster and ubiquinone), suggests that ubiquinone accepts electrons directly from FAD.[193] Both the role of the cluster and the origin of the anomalously high redox potential for a $[4Fe–4S]^{2+,+}$ center in a Fd-like domain remain to be elucidated.

Complex III (cytochrome bc_1 complex or quinol-cytochrome *c* oxidoreductase) has been structurally characterized[195–197] and is one of the best understood of the Fe–S containing mitochondrial respiratory complexes.[198,199] The mammalian complex consists of 11 subunits, three of which contain redox centers: a hydrophobic cytochrome *b*, which contains the high and low-potential *b*-type hemes (cyt b_L, $E_m = -50\,mV$; cyt b_H, $E_m = +50\,mV$); cytochrome c_1, which contains covalently bound heme c_1 ($E_m = +250\,mV$); and Rieske protein, which contains a high potential Rieske-type $[2Fe–2S]^{2+,+}$ center ($E_m = +280\,mV$ at pH 7) (*see* ***Iron: Heme Proteins & Electron Transport***). Analogous centers with similar redox potentials are also present in the homologous bc_1 complex of respiratory and photosynthetic bacteria. In all cases, the electron transfer from quinol to cyt *c* is coupled to proton translocation by the Q-cycle mechanism first proposed by Mitchell.[200] The essential reaction of the Q-cycle mechanism is the bifurcation of the pathway for the electron transport pathway upon oxidation of quinol. One electron is transferred to the Rieske center and then to cyt c_1 and cyt *c*, while the other is transferred to cyt b_L and from there across the membrane to cyt b_H, where it is used to reduce quinone. Thus half of the electrons from the oxidation of quinol are cycled back to quinone, thereby doubling the protonmotive efficiency of the bc_1 complex.[198,199] The crystallographic data indicate that the bifurcation of the electron pathways is facilitated by mobility of the catalytic domain of the Rieske protein, such that the Rieske center shuttles between positions close to the quinol binding site and the propionate group of cytochrome c_1, which are some 22 Å apart.[195,196] Moreover, both spectroscopic and crystallographic evidence point to a direct H-bonding interaction between the quinol OH and the Nε of one of the Rieske center histidine ligands.[195,198] Taken together with the electrochemical and structural evidence for redox-linked protonation of the Rieske center histidine ligands,[23,201] the implication is that the Rieske center couples proton and electron transfer from quinol, by using a histidine ligand to shuttle a proton out of the quinol binding site.

Spectroscopic and crystallographic studies have identified four Fe–S clusters in the membrane-bound photosynthetic electron transport chain of plant and cyanobacterial chloroplasts. One is the Rieske-type $[2Fe–2S]^{2+,+}$ center in the cyt b_6f complex, which catalyzes electron transfer from plastoquinol to plastocyanin with concomitant proton translocation, and is functionally analogous to the cyt bc_1 complex, with cyt f in place of cyt c_1.[202] The remainder are low-potential $[4Fe–4S]^{2+,+}$ centers in Photosystem I which constitute the terminal part of the electron transfer chain that is initiated by the primary donor chlorophyll.[165,166] One is a very low-potential $[4Fe–4S]^{2+,+}$ center, F_X ($E_m = -705\,mV$), that bridges two similar subunits (PsaA and PsaB) and is coordinated by two cysteines from each subunit in a $C–X_8–C$ arrangement. This cluster transfers electrons to the 2Fe-Fd acceptor via an electron transfer chain composed of F_A, a $[4Fe–4S]^{2+,+}$ cluster with $E_m = -530\,mV$, and F_B, a $[4Fe–4S]^{2+,+}$ clusters with $E_m = -580\,mV$. F_A and F_B are in a low-molecular weight subunit (PsaC, 9 kDa) that shows strong sequence and structural homology with bacterial 8Fe-Fds. The center-to-center distance between F_X and F_A and between F_A and F_B are 14.9 Å and 12.3 Å, respectively, well

within the limits for efficient electron tunneling, and a putative 2Fe Fd docking site has been identified.

3.1.3 Soluble Redox Enzymes

A wide range of soluble redox enzymes contain one or more intrinsic $[2Fe–2S]^{2+,+}$, $[3Fe–4S]^{+,0}$, or $[4Fe–4S]^{2+,+}$ clusters that function in electron transport chains to transfer electrons to or from nonheme Fe, Moco/Wco, corrinoid, flavin, thiamine pyrophosphate (TPP), Fe–S cluster containing, or NiFe active sites. Many have been structurally and spectroscopically characterized and only a few of the most recent examples of each type are summarized here. Dioxygenases that function in the dihydroxylation of aromatics such as benzene, toluene, benzoate, naphthalene, and phthalate contain a Rieske-type $[2Fe–2S]^{2+,+}$ cluster that serves as the immediate electron donor to the monomeric nonheme Fe active site (*see* ***Iron Proteins with Mononuclear Active Sites***).[203] The xanthine oxidase family of molybdoenzymes (*see* ***Molybdenum: MPT-containing Enzymes***) contain two $[2Fe–2S]^{2+,+}$ clusters that mediate electron transfer between the Moco active site and the FAD.[116,117,204] Other soluble molybdoenzymes and tungstoenzymes (*see* ***Tungsten Proteins***) have electron transfer chains involving a single $[4Fe–4S]^{2+,+}$ cluster (e.g. dissimilatory nitrate reductase,[205] W-containing aldehyde oxidoreductases,[206,207] and W- and Mo-containing formate dehydrogenases[208,209]), three $[4Fe–4S]^{2+,+}$ clusters (e.g. pyrogallol-phloroglucinol transhydroxylase[210]), and one $[3Fe–4S]^{+,0}$ and one Rieske-type $[2Fe–2S]^{2+,+}$ cluster (e.g. arsenite oxidase[129]). Currently there is only one example of a corrinoid-containing Fe–S protein, the corrinoid iron–sulfur protein that functions as a methyl transferase in acetyl-CoA synthase (*see* ***Cobalt: B$_{12}$ Enzymes & Coenzymes***).[211] The protein contains a $[4Fe–4S]^{2+,+}$ cluster that does not participate directly in the methyl transfer step, but appears to provide a conduit for electron flow to the Co center from physiological reductants to effect reductive activation.[211] Soluble iron–sulfur enzymes with flavin active sites include Fd-dependent glutamate synthase (FMN and one $[3Fe–4S]^{+,0}$ cluster[212]) and NADPH-dependent glutamate synthase (FMN, FAD, one $[3Fe–4S]^{+,0}$ and two $[4Fe–4S]^{2+,+}$ clusters[212]), trimethylamine dehydrogenase (FMN and one $[4Fe–4S]^{2+,+}$ cluster[213]), 2,4-dienyl-CoA reductase (FMN, FAD, and one $[4Fe–4S]^{2+,+}$ cluster[214]), adenylylsulfate reductase (FAD and two $[4Fe–4S]^{2+,+}$ clusters[215]), and dihydroorotate dehydrogenase (FMN, FAD and one $[2Fe–2S]^{2+,+}$ cluster[216]). Oxoacid-ferredoxin oxidoreductases such as pyruvate-ferredoxin oxidoreductase and 2-oxoglutarate-ferredoxin oxidoreductase are radical enzymes with a TPP active site and an electron transfer chain involving one or three $[4Fe–4S]^{2+,+}$ clusters.[217,218]

All structurally characterized NiFe- and Fe-hydrogenases contain redox chains involving 2–4 Fe–S clusters that deliver electrons to or take electrons from the NiFe (Figure 2(e)) or Fe–Fe–[4Fe–4S] (Figure 2(f)) active sites. Soluble NiFe-hydrogenases generally catalyze H_2 uptake and comprise a large subunit that houses the NiFe active site and a small subunit containing three linearly arranged and evenly spaced Fe–S clusters: two low-potential $[4Fe–4S]^{2+,+}$ clusters that are proximal and distal with respect to the active site and a middle cluster that can be either a high potential $[3Fe–4S]^{+,0}$ cluster or a low-potential $[4Fe–4S]^{2+,+}$ cluster.[35] Mutagenesis-induced conversion of the $[3Fe–4S]^{+,0}$ cluster to a $[4Fe–4S]^{2+,+}$ cluster in *Desulfovibrio fructosovorans* NiFe-hydrogenase results in a ∼300-mV decrease in the potential of the middle cluster, making it approximately isopotential with the proximal and distal clusters.[168] However, in accord with the electron tunneling theory for electron transport, this did not result in a significant change in catalytic activity using natural and artificial electron acceptors. In contrast, the reverse cluster transformation in the F_{420}-reducing NiFe–hydrogenase from *Methanococcus voltae* raises the potential of the middle cluster to ∼400 mV higher than that of the proximal and distal clusters and results in a 10-fold decrease in activity using the physiological electron acceptor F_{420}.[170] The implication is that the increase in potential is too large to permit efficient tunneling, such that electron transfer has become the rate-limiting step in the mutant protein. Fe-hydrogenases catalyze H_2 uptake or H_2 evolution, and both contain an 8Fe–Fd-like domain containing two low-potential $[4Fe–4S]^{2+,+}$ clusters that mediates electron transfer to or from the Fe–Fe–[4Fe–4S] active site.[41,219] Some H_2-evolving enzymes, such as hydrogenase I from *Clostridium pasteurianum*, have extended electron transfer chains involving additional domains containing one $[4Fe–4S]^{2+,+}$ and one $[2Fe–2S]^{2+,+}$ cluster.[40]

Ni-containing CO dehydrogenases catalyze the oxidation of CO to CO_2 and are homodimeric proteins containing two buried [Ni–4Fe–5S] active sites (C-cluster, see Figure 2(i)), two $[4Fe–4S]^{2+,+}$ centers (B-cluster), and a solvent-exposed subunit-bridging $[4Fe–4S]^{2+,+}$ cluster (D-cluster).[42,43] In each monomer, the electron transfer pathway is from C → B → D and the edge-to-edge distances are 11 Å and 10 Å, respectively, well within the range for efficient tunneling. Acetyl-CoA synthases build on this core by adding two identical subunits containing the Ni–Ni–[4Fe–4S] active site (A-cluster, see Figure 2(j)) that is responsible for the synthesis of acetyl-CoA using CO that is derived from CO_2 reduction at the C-cluster.[44–46] The different active sites of this bifunctional enzyme complex are connected via a channel, 138 Å long, which provides a conduit for transfer of CO generated at the C-cluster to the A-cluster.

Nitrogenase catalyzes the ATP-driven eight-electron and eight-proton reduction of N_2 to $2\,NH_3$ and H_2 and offers the most complex and fascinating example of Fe–S cluster mediated electron transfer. The electron transport chain involves transfer of electrons from the subunit-bridging [4Fe–4S] center on the homodimeric Fe-protein,[182] to the subunit-bridging double-cubane [8Fe–7S] P-cluster (see

Figure 1(f) and 1(g)) and then to the [Mo–7Fe–9S–X] FeMoco active site (see Figure 2(h)), both of which are located in the MoFe protein.[20,220] Electron transfer is facilitated by MgATP hydrolysis[221] and the Fe-protein has two nucleotide binding sites, one in each subunit. Moreover structures of the Fe-protein in its native, MgATP- and MgADP-bound conformations and of the Fe-protein-MoFe protein complex in an MgATP-bound conformation indicate that the Fe-protein undergoes major conformational changes on complex formation and nucleotide binding.[164,177,182] This conformational change appears to facilitate electron transfer by decreasing the distance between the [4Fe–4S] and [8Fe–7S] clusters.[182]

Numerous questions remain concerning the MgATP control of complex formation and the redox properties of the [4Fe–4S] cluster, whether the electrons are transferred in eight one–electron or four two-electron steps, and the mechanism of coupling of proton and electron transfer. Both the all-ferrous $[4Fe–4S]^0$ and $[4Fe–4S]^+$ forms of the Fe-protein bind MgATP, undergo a MgATP-induced conformational change, form a productive complex with the MoFe protein, and transfer electrons to the MoFe protein, leaving the cluster in the $[4Fe–4S]^{2+}$ redox state, indicating that it has the potential to act as a one- or two-electron donor.[222] Indeed, the concept of a two-electron donor is particularly appealing for nitrogenase as the intermediate electron carrier, the [8Fe–7S] P-cluster, is a two-electron acceptor, all known substrates are reduced by multiples of two electrons, and it would cut the ATP requirement in half. Nevertheless, potential physiological electron donors are not able to reduce Fe-protein to the $[4Fe–4S]^0$ state and the midpoint potential for the $[4Fe–4S]^{+,0}$ couple is highly negative, ~ -790 mV, implying that this redox state is unlikely to be attainable in vivo.[153] The double-cubane [8Fe–7S] P-cluster is stable in the all-ferrous $[8Fe–7S]^{2+}$ redox state (P^N) and the two-electron oxidized $[8Fe–7S]^{4+}$ redox state (P^{OX}) and a transient one-electron oxidized $[8Fe–7S]^{3+}$ state has been observed during redox titrations.[223] Moreover, a dramatic structural change accompanies two-electron oxidation from the P^N to the P^{OX} states (cf. see Figures 1(f) and 1(g)) involving the cleavage of two Fe–μ_6S bonds and coordination by serine and a backbone amide nitrogen (BAN) to maintain tetracoordinated Fe sites.[15] Hence oxidation by two electrons has the potential to occur with the release of two protons, since both recruited ligands will be protonated in their free state and may be deprotonated in their bound states. In accord with the proposal that the [8Fe–7S] P-cluster couples proton and electron transfer, the P-cluster has been shown to have a pH-dependent redox potential.[24] Although the $[8Fe–7S]^{+,0}$ couple ($E_m = -310$ mV) is independent of pH over the range 6.0–8.5, the $[8Fe–7S]^{2+,+}$ couple decreases from $E_m = -224$ to -338 mV over the same range, indicating that oxidation occurs with release of one proton. The BAN is currently the best candidate for the protonation/deprotonation site as the pH-dependent redox potential is retained on mutation of the coordinating serine residue.[24]

3.2 Substrate Binding and Activation

Several redox and nonredox enzymes have Fe–S centers that constitute the active site, in whole or in part. As illustrated by the active-site structures shown in Figure 2, the clusters are functionalized for binding and activating substrates by having unique ligation at a specific Fe site, incorporating a heterometal into the cluster, or attachment of a metal site at a unique Fe site.

3.2.1 Nonredox Enzymes

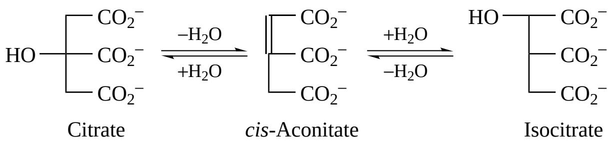
Nitrile Hydratase (see ***Iron Proteins with Mononuclear Active Sites****).* Nitrile hydratase catalyzes the hydrolysis of organic nitriles to the corresponding amide (see equation 2) and plays an important role in the assimilation of nitriles by microorganisms.

$$R–C{\equiv}N + H_2O \longrightarrow R–CONH_2 \qquad (2)$$

The structure of the NO-inhibited form of Fe nitrile hydratase revealed a remarkable active site comprising a monomeric octahedral Fe^{III} site with two BANs and the sulfur atoms of postranslationally modified cysteine sulfinic and sulfenic groups providing the equatorial ligands and a cysteinate trans to a bound NO providing the axial ligands (Figure 2(a)).[25] In the functional form of the enzyme, NO is replaced by hydroxide. However, the mechanism of catalysis, that is, Lewis acid activation of the bound hydroxyl or a bound nitrile, and the role of the novel set of sulfur ligands remains largely unresolved.[224]

Fe–S Cluster Containing (de)hydratases. The pioneering spectroscopic and crystallographic studies of aconitase by Beinert and coworkers[27] led to the characterization of a large class of Fe–S cluster containing hydratases and dehydratases that includes phosphogluconate dehydratase, maleate hydratase, lactyl-coenzyme A dehydratase, 2-hydroxyglutaryl-coenzyme A dehydratase, tartarate dehydratase, serine dehydratase, isopropylmalate isomerase, fumarase, and bacterial dihydroxy acid dehydratase.[28] With the exception of the putative $[2Fe–2S]^{2+}$-containing plant dihydroxy acid dehydratase that has yet to be structurally or mechanistically characterized,[225] all contain a $[4Fe–4S]^{2+}$ cluster with a unique, non-cysteine-ligated Fe site that acts a Lewis acid to facilitate reversible abstraction of the hydroxyl and a proton from adjacent carbon atoms on the substrate. By far the best-characterized example is the citric acid cycle enzyme aconitase, which catalyzes both the dehydration and rehydration steps in the stereospecific isomerization of citrate

to isocitrate via a *cis*-aconitate intermediate (see equation 3).



(3)

The ligation at the unique Fe site in the absence and presence of the hydrated substrates was initially deduced from a series of elegant Mössbauer, EPR, and ENDOR studies and subsequently confirmed by crystallography for the isocitrate-bound form (Figure 2(b)). In the absence of substrate, the unique Fe site is four-coordinate with the fourth ligand a solvent hydroxyl. Substrate binding occurs with protonation of the bound hydroxyl, and involves coordination via the hydroxyl and the β-carboxyl (for citrate) or the α-carboxyl (for isocitrate) resulting in a six-coordinate unique Fe site (Figure 2(b)). The dehydrated intermediate, *cis*-aconitate, can be bound by either the α- or β-carboxyl groups via a bridging and exchangeable hydroxyl at the α or β carbon and must rotate by 180° between these modes during catalysis.

3.2.2 Redox Enzymes

Superoxide Reductase (see ***Iron Proteins with Mononuclear Active Sites****).* Detoxification of reactive oxygen species in anaerobic microorganisms has recently been shown to center around SOR, a novel mononuclear iron enzyme that reduces superoxide to hydrogen peroxide (see equation 4),[30] rather than dismuting superoxide to oxygen and hydrogen peroxide as is the case for the superoxide dismutases found in aerobic organisms.

$$O_2^- + 2H^+ + e^- \longrightarrow H_2O_2 \qquad (4)$$

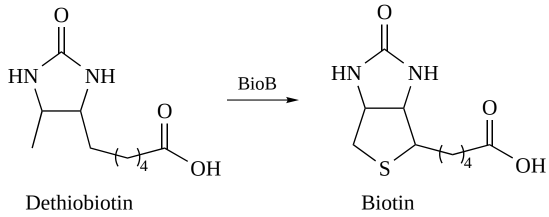
Spectroscopic and crystallographic studies indicate that the active site is six-coordinate in the Fe^{III} state, with four equatorial histidine ligands and axial cysteinate and monodentate glutamate ligands, and five-coordinate with a vacant coordination site as a result of loss of the glutamate ligand on reduction to the Fe^{II} state (Figure 2(c)).[31,73] Optically monitored pulse radiolysis have revealed one or two transient catalytic intermediates that are proposed to correspond to a ferric-peroxo and ferric-hydroperoxo species[226,227] and a transient ferric-peroxo species with a side-on peroxo has been spectroscopically characterized in samples frozen rapidly in the presence of H_2O_2.[228,229] The proposed mechanistic scheme therefore involves superoxide binding at the vacant coordination site of reduced SOR, coupled with electron transfer from Fe to superoxide, to yield a side-on ferric-peroxo intermediate. Protonation yields a transient end-on ferric-hydroperoxo that rapidly dissociates yielding hydrogen peroxide. Since electronic studies indicate strong (Cys)S(p_π)–Fe(d_π) bonding in both the oxidized and reduced states,[73] the presence of a cysteine ligand trans to the binding site has been proposed as the major determinant of SOR rather than superoxide dismutase activity.[230] This would facilitate reduction of O_2^- on binding at the ferrous site and promote dissociation of the hydroperoxide product from the ferric site.

Radical-SAM Enzymes. The initial characterization of a diverse group of SAM-dependent Fe–S enzymes catalyzing radical reactions,[75,231] led to the discovery of a radical-SAM superfamily that may contain over 600 distinct enzymes based on bioinformatics analysis.[32] These enzymes catalyze diverse reactions involving radical mechanisms, including unusual methylations, isomerization, sulfur insertion, ring formation, anaerobic oxidation, and protein radical formation and they function in DNA precursor, vitamin, cofactor, antibiotic and herbicide biosynthesis, and in biodegradation pathways. For example, radical-SAM enzymes are now known to catalyze previously unresolved steps in the biosynthesis of biotin (vitamin H), lipoic acid, thiamine, heme, bacteriochlorophyll, molybdopterin, nitrogenase FeMo-cofactor, and the diiron active site of Fe–hydrogenases. Radical-SAM enzymes have attracted intense recent interest from both the bioinorganic and bioorganic communities and constitute arguably the most rapidly expanding area of Fe–S protein research, as evidenced by a proliferation of recent publications and reviews.[8,34,232,233]

Radical-SAM enzymes share a common C–X_3–C–X_2–C motif that coordinates an oxidatively labile $[4Fe–4S]^{2+,+}$ cluster in an incomplete triosephosphate isomerase barrel domain.[33,68,144] The role of the cluster is to initiate the radical reaction by binding SAM at the unique Fe site in order to facilitate reductive cleavage to yield a 5′-deoxyadenosyl radical. This highly reactive radical then generates a substrate radical in enzymes such as lysine 2,3-aminomutase, lipoyl synthase (LipA), biotin synthase (BioB), spore photoproduct lyase, an oxygen-independent coproporphyrinogen III oxidase (HemN), and a tRNA–methylthiotransferase (MiaB), or a catalytic glycyl radical in enzymes such as in anaerobic ribonucleotide reductase, pyruvate formate-lyase (PFL), benzylsuccinate synthase, and glycerol dehydratase, that utilize a radical-SAM activating enzyme (AE).[34,232,233] The mode of attachment of SAM at the [4Fe–4S] cluster was originally determined by an elegant series of ENDOR studies on PFL-AE[74] and subsequently confirmed in the crystal structures of HemN,[33] BioB,[68] and MoaA, the enzyme that catalyzes the first step in molybdopterin biosynthesis involving the formation of precursor Z from 5′-guanosine triphosphate (5′-GTP).[144] SAM is anchored to the cluster via coordination of the amino nitrogen (Fe–N distance ~2.6 Å) and carboxyl oxygen (Fe–O distance 1.9–2.3 Å) of the methionine, with the sulfonium sulfur 3.3–3.5 Å from the same Fe and 3.6–3.7 Å from a μ_3–S (Figure 2(d)). The detailed mechanism of the reductive cleavage of SAM has still to be elucidated, but the available evidence points to a concerted reaction

involving transfer of an electron from the cluster to the sulfonium sulfur coupled with homolytic cleavage of the S–C bond.[34,232]

The recent discovery that several radical-SAM enzymes contain an Fe–S cluster in addition to the [4Fe–4S] cluster that is responsible for binding and cleaving SAM has led to proposals for new roles for Fe–S clusters. Spectroscopic and crystallographic studies of BioB have revealed the presence of an additional $[2Fe–2S]^{2+}$ cluster[68,174] that has been shown to act as the immediate sulfur donor for biotin formation from dethiobiotin in a single turnover reaction[80] (equation 5).



(5)

Since the $[2Fe–2S]^{2+}$ cluster is degraded during a single turnover,[67,81] this suggests that BioB is either a suicide enzyme or that cluster reassembly occurs after each turnover. An alternative possibility is that the $[2Fe–2S]^{2+}$ cluster is an artifact of overexpression of recombinant BioB and that degradation leads to formation of a cysteine persulfide which acts as the immediate sulfur donor.[67] LipA catalyzes a similar sulfur insertion reaction involving the incorporation of two sulfur atoms and spectroscopic and analytical studies have recently demonstrated the presence of an additional $[4Fe–4S]^{2+,+}$ cluster that is coordinated by cysteine residues in a $C–X_4–C–X_5–C$ motif.[234] However, the role of the additional [4Fe–4S] cluster in LipA has still to be determined. MoaA and its human counterpart, MOCS1A, do not catalyze a sulfur insertion reaction, but spectroscopic and crystallographic studies have demonstrated the presence of a second $[4Fe–4S]^{2+,+}$ cluster that is coordinated by only three cysteines in a $C–X_2–C–X_{13}–C$ motif and located 17 Å from the SAM-binding [4Fe–4S] cluster.[144,235] On the basis of the crystal structure, the second [4Fe–4S] cluster is proposed to bind the 5′-GTP substrate at a unique Fe site, in order to position and/or activate the substrate for radical attack by the 5′-deoxyadenosyl radical.

NiFe- and Fe-hydrogenases. Hydrogenases catalyze the simplest of all reactions in microorganisms, the reversible two-electron reduction of two protons to yield hydrogen gas, and have been the subject of several recent reviews.[236–238] Hydrogen cleavage is invariably heterolytic, requiring the active sites to contain proton and hydride acceptor sites as well as a H_2 binding site. The two main classes of hydrogenases are termed NiFe and Fe (also known as Fe–Fe or Fe-only) based on the metal composition of the active-site cluster or subcluster, both of which contain the diatomic π-acceptor ligands, CO and CN^-, in order to stabilize low metal oxidation states. Consequently active-site structures have largely been determined using the novel combination of crystallography and Fourier-transform infrared (FTIR) spectroscopy, with EPR playing a crucial role in defining paramagnetic species in the catalytic cycles.

NiFe-hydrogenases generally catalyze H_2 uptake under physiological conditions. The functional active site comprises a binuclear NiFe center bridged by two cysteinyl-S ligands, with two terminal cysteinyl-S ligands (in NiFeSe hydrogenases one is substituted by selenocysteine) completing distorted tetrahedral coordination at the Ni center, and two CN^- and one CO completing approximate square pyramidal coordination at the Fe center (Figure 2(e)).[239] Oxidized inactive forms (termed Ni-A and Ni-B) have an additional oxo or hydroxo bridging ligand, and there is growing consensus that this is replaced by a bridging hydride in one of the reduced active forms (Ni-C).[238,239] There is also a general consensus from both spectroscopic studies and DFT calculations that the Ni center cycles between formal Ni^{II} and Ni^{III} oxidation states during catalysis, while the Fe site remains low spin Fe^{II}.[238,239] However, the H_2 and H^+ binding sites have still to be determined, with the Fe site and the terminal cysteinyl ligands, respectively, as the most likely candidates. A more detailed discussion of the catalytic cycle of NiFe-hydrogenases is presented elsewhere.

Fe-hydrogenases catalyze either H_2 uptake or evolution under physiological conditions and are unrelated to NiFe-hydrogenase in terms of protein sequence and structure.[41] Hence the striking similarities in the active sites (cf Figures 2(e) and 2(f)) appear to reflect convergent evolution.[41,219] The Fe-hydrogenase active site (also known as the H-cluster) comprises a [4Fe–4S] cluster that is directly attached via a bridging cysteinyl-S to a 2Fe subcluster, which is the site for H_2 activation (Figure 2(f)). The Fe atoms in the 2Fe subcluster (termed distal and proximal with respect to the [4Fe–4S] cluster) each have a terminal CO and CN^- ligand and are bridged by a nonprotein ligand that was first modeled as a 1,3-propane dithiolate[71] (Figure 2(f)). However, a di-(thiomethyl)-amine in which the central nitrogen could serve a catalytic base is a viable and attractive alternative.[41] A bridging CO (not shown in the structure depicted in Figure 2(f)) that becomes terminal on the distal Fe on reduction, and a weakly bound solvent molecule on the distal Fe (not shown in Figure 2(f)) that is lost during reductive activation, completes the ligation. Indeed, the variability in the published crystal structures concerning the bridging CO ligand[40,71] is likely to reflect the redox–induced conformational flexibility of the center. The current consensus is that the three oxidation states of the 2Fe subcluster formally correspond to $Fe^{II}Fe^{II}$ (oxidized, inactive, and EPR silent), $Fe^{II}Fe^{I}$ (oxidized, active, and EPR active, $S = 1/2$), and $Fe^{I}Fe^{I}$ (reduced, active, and EPR silent), with each having the [4Fe–4S] cluster in the 2+ redox state.[238] However, defining a detailed structure-based catalytic mechanism has been complicated by the FTIR and theoretical evidence for facile

conversion between forms containing terminal and bridging CO ligands in the $Fe^{II}Fe^{I}$ redox state and the H_2, H^+ and H^- binding sites have yet to be definitively determined.[238] By analogy with NiFe-hydrogenases, it is tempting to speculate on the existence of a bridging hydride intermediate, but there is as yet no direct experimental evidence for this mode of ligation. The mechanism of this fascinating 'organometallic' active site is a subject of intense current interest and has been greatly enhanced by the study of organometallic analog complexes[237,240] and DFT calculations.[241,242]

Sulfite and Nitrite Reductase. Sulfite and nitrite reductases are found in plants and bacteria and catalyze similar reactions involving the six-electron reduction of SO_3^{2-} and NO_2^- to yield S^{2-} and NH_4^+, respectively (equations 6 and 7).[243,244]

$$SO_3^{2-} + 6H^+ + 6e^- \longrightarrow S^{2-} + 3H_2O \qquad (6)$$

$$NO_2^- + 8H^+ + 6e^- \longrightarrow NH_4^+ + 2H_2O \qquad (7)$$

Both contain active sites comprising a $[4Fe–4S]^{2+,+}$ cluster attached to siroheme (iron isobacteriochlorin) via a bridging cysteinyl-S. These active sites are exquisitely designed to catalyze multielectron reduction of SO_3^{2-} or NO_2^- bound at the vacant coordination site of the siroheme (Figure 2(g)). A series of elegant crystallographic studies of the hemoprotein subunit of *E.* coli sulfite reductase in different redox states and complexed with substrates, inhibitors, intermediates, and products have provided a detailed picture of the catalytic mechanism.[38,39,245] Sequential two-electron transfers from the coupled [4Fe–4S]–siroheme prosthetic groups to the bound anions result in successive cleavage of S-O and N-O bonds, leaving the oxygen atom as part of a water molecule. Hydrogen bonds supplied by basic residues in the substrate-binding pocket facilitate the charge transfer and reductive cleavage.

Nitrogenase (see ***Nitrogenase Catalysis & Assembly****).* Nitrogenase catalyzes the MgATP-dependent reduction of nitrogen gas to ammonia according the reaction shown in equation (8).[246]

$$N_2 + 8e^- + 16MgATP + 8H^+ \longrightarrow 2NH_3 + H_2 + 16MgADP + 16P_i \qquad (8)$$

The MgATP requirement would be cut in half if the Fe-protein functions as a two-electron donor (see discussion in Section 3.1.3). In addition to N_2, nitrogenase will also catalyze the reduction of a variety of triple-bonded substrates including alkynes and cyanide.[246] The substrate-binding site is a unique heterometallic Mo–Fe–S cluster, [Mo–7Fe–9S–X] (termed the FeMo-cofactor), that is attached to the protein by a single cysteinyl–S–Fe and histidyl–N–Mo linkage with homocitrate, coordinated by its 2-hydroxy and 2-carboxy groups, completing octahedral coordination at the Mo center (Figure 2(h)). The discovery of a low-Z central atom (μ_6N/O/C) resulted from a recent high-resolution (1.16 Å) crystal structure[20] and dramatically changes the predicted reactivity and properties,[247] since the cluster no longer has a central cavity surrounded by six three-coordinate Fe atoms, as indicated in the original crystal structure.[248] The nature of the central atom has yet to be determined, although it is generally assumed to be N. However, the available evidence indicates a purely structural role for the central atom, since ENDOR and ESEEM studies indicate that none of the N atoms associated with the cluster exchange with $^{15}N_2$ or $^{14}N_2$ during catalytic turnover.[249] The available evidence strongly suggests a similar structure for the FeV-cofactor in V nitrogenases, with Mo replaced by V,[250] although this has yet to be confirmed by crystallography (*see* ***Vanadium in Biology***).

One of the major unresolved questions in nitrogenase research concerns where and how substrates bind to the FeMo-cofactor during catalysis. Indeed, the question of whether substrates bind to Mo or Fe has been the subject of a recent comprehensive review that does not arrive at any definitive conclusion.[251] This issue has been difficult to address experimentally as the FeMo-cofactor only binds substrates when it is further reduced from the well characterized and EPR-detectable resting state ($S = 3/2$ ground state). Such reduction requires turnover conditions and generally leads to transient EPR-silent species. However, EPR signals from more reduced states have been observed in samples frozen during turnover with C_2H_2 and CS_2 as substrates and in the presence of the inhibitor CO, and in all cases ENDOR studies implicate binding through C to one or more Fe atoms.[251] In addition, evidence has recently been obtained for the binding of acetylene, the physiological substrate dinitrogen, and its semireduced form hydrazine, to a specific FeS face of the FeMo-cofactor.[252] The activity with each of these three substrates was dramatically modulated by mutating the valine residue that controls access to this face, to a smaller (alanine) or larger (isoleucine) residue. Furthermore, the binding of a non–physiological substrate (propargyl alcohol, $HC{=}C–CH_2OH$) to the Val-to-Ala variant enzyme has been localized to a specific Fe site via EPR and ENDOR studies of a freeze-trapped intermediate.[253] Intriguingly, it is proposed that the intermediate involves an organometallic iron-cyclopropane ring.[253] These very recent studies provide compelling mutagenesis and spectroscopic evidence for substrate binding to Fe rather than Mo. Moreover, they are consistent with the existence of Fe-only nitrogenases that appear to have a similar active site with Mo or V replaced by Fe.[254] Hence the role of the heterometal in the Mo and V nitrogenase active sites remains an enigma.

CO dehydrogenase/Acetyl-CoA Synthase. Both CO dehydrogenases and acetyl-CoA synthases contain novel Ni–Fe–S actives sites and a more detailed discussion of their active-site structures and catalytic mechanism is presented elsewhere. CO dehydrogenases catalyze the reversible oxidation of CO

to CO_2 (see equation 9).

$$CO + H_2O \rightleftharpoons CO_2 + 2H^+ + 2e^- \qquad (9)$$

The structure of the functional form of the [Ni–4Fe–5S] active site[42,43] (Figure 2(i)) is best considered in terms of a [3Fe–4S] fragment that is covalently attached via bridging S atoms to a μ_2–S–bridged NiFe fragment. The NiFe center comprises a Ni(μ_2–S)(μ_3–S)$_2$(SCys) site with approximate square-planar geometry for the NiS_4 unit and a Fe(μ_2–S)(μ_3–S)(SCys)(NHis) site with distorted tetrahedral geometry for the FeS_3N unit. Crystallographically defined active-site structures corresponding to a [Ni–4Fe–4S] cluster that lacks the μ_2–S, have also been reported at lower resolution.[44,45,255] However, this form has recently been shown to correspond to an inactive decomposition product.[43] Oxidation of CO is proposed to occur by CO binding at the square-planar Ni center because of the direct accessibility of this site via a substrate channel. The Fe site of μ_2-S-bridged NiFe fragment is presumed to be the hydroxyl donor ligand for CO_2 formation.[256] However, the mechanistic details have yet to be fully worked out.

The acetyl-CoA synthase active site catalyzes formation of acetyl-CoA from CO, CoA, and a methyl group supplied by the corrinoid-containing iron–sulfur protein (equation 10).

$$CO + CH_3\text{–}Co^{III}FeSP + CoASH \rightleftharpoons CH_3\text{–}C(O)\text{–}SCoA + Co^{I}FeSP + H^+ \qquad (10)$$

The structure of the functional Ni–Ni–[4Fe–4S] active site (Figure 2(j)) consists of a novel dinickel center bridged by two cysteinyl-S ligands, that is attached to a [4Fe–4S] cluster via another bridging cysteinyl-S. The distal Ni has approximate square-planar geometry with two BANs as the terminal ligands and the proximal Ni is ligated by the three bridging cysteinyl-S ligands with another small molecular ligand that has been modeled as acetate and water in different structures.[45,46] Controversy has arisen over the identity of the proximal metal center. Although this site can also accommodate Cu or Zn,[44,45] it is now clear that only the Ni form is catalytically active. However, it is currently unclear if acetyl formation occurs via a mononuclear mechanism involving binding of CO and CH_3 to only the proximal Ni center or via a dinuclear mechanism with CO and CH_3 binding to different Ni sites. In addition, the role of the [4Fe–4S] cluster in the catalytic mechanism is still unresolved. Rapid progress in elucidating the details of the catalytic mechanism is anticipated now that the active-site structures are known and the ambiguities concerning the metal content have been resolved. An excellent series of commentaries that discuss these issues has recently appeared in the *Journal of Biological Inorganic Chemistry*.[257–262]

3.3 Structural

Two classes of DNA repair enzymes contain $[4Fe\text{–}4S]^{2+}$ clusters that are not involved in catalysis and appear to have purely structural roles. Several members of the superfamily of helix-hairpin-helix DNA repair enzymes contain a redox-inert $[4Fe\text{–}4S]^{2+}$ cluster coordinated by a C–X_6–C–X_2–C–X_5–C cysteine motif, for example, endonuclease III,[50,51,263] MutY,[52,79,264,265] and thymine-DNA glycosylase.[266] These enzymes target specific base lesions and function in DNA repair either as pure glycosylases or combined glycosylases/apurinic-apyrimidinic lyases. The structurally distinct family 4 uracil-DNA glycosylase is specific for the excision of uracil bases from DNA and contain a $[4Fe\text{–}4S]^{3+,2+}$ cluster coordinated by N-terminal C–X_2–S and central C–X_{14-17}–C arrangements of cysteine residues.[267,268] The crystallographic, spectroscopic, and mutagenesis studies of members of both classes (cited above) clearly demonstrate that the [4Fe–4S] clusters are not directly involved in substrate binding or catalysis. Rather the $[4Fe\text{–}4S]^{2+}$ clusters function as structural cross-links, analogous to disulfide bonds or zinc fingers (*see* ***Zinc: DNA-binding Proteins***), and thereby contribute to enzyme stability and reactivity by maintaining conformation in regions associated with DNA interactions.

3.4 Regulation

The ability of an Fe–S center to control a local region of protein structure by cluster assembly/disassembly, cluster transformation, or changes in cluster redox state, means that Fe–S centers can function as sensors for a variety of different types of environmental stimuli.[58] Indeed there are now four well-documented examples of Fe–S proteins that are involved in regulating gene expression and several examples in which Fe–S centers have been proposed to regulate enzymatic activity (*see* ***Metalloregulation***).

3.4.1 Gene Expression

SoxR. SoxR is a dimeric protein containing one all-cysteine-ligated $[2Fe\text{–}2S]^{2+,+}$ cluster ($E_m = -285$ mV) in each subunit, that functions as a redox-responsive genetic switch for monitoring cellular oxidative stress in bacteria.[55] When oxidative stress increases in *E. coli*, SoxR mediates transcriptional regulation of the *soxRS* regulon that leads to the activation of ∼45 genes whose products (e.g. superoxide dismutase) facilitate removal of superoxide and the repair of oxidative damage.[55] The SoxR protein remains tightly bound to its target SoxS promoter in the absence or presence of oxidative stress,[269] and both in vitro and in vivo EPR studies indicate that SoxR is activated by oxidation or nitrosylation of the $[2Fe\text{–}2S]^{2+,+}$ cluster in order to stimulate transcription of the *soxS* gene.[270,271] However, it is currently unclear if the cluster is oxidized by superoxide directly or if superoxide acts on the recently identified reductase system that maintains

SoxR in the reduced state in the cell.[272] Detailed understanding of molecular mechanism of transcription activation by SoxR awaits structural refinement.

FNR. The *E. coli* FNR regulatory protein is an oxygen-sensing protein that controls the switch between aerobic and anaerobic respiration by controlling the expression of >100 genes.[56] In contrast to SoxR, the FNR protein belongs to the family of helix-turn-helix transcription factors whose activity is dictated by site-specific binding to DNA. The active, DNA-binding form of FNR is a homodimer containing one $[4Fe–4S]^{2+}$ cluster per subunit.[273] Mössbauer studies of the purified protein and in whole cells have shown that O_2 exposure results in rapid conversion to a monomeric form containing one $[2Fe–2S]^{2+}$ cluster per subunit.[57] Hence the O_2-sensing mechanism involves oxidative $[4Fe–4S]^{2+}$ to $[2Fe–2S]^{2+}$ cluster conversion which destabilizes the active dimeric form. Recent spectroscopic studies indicate that this cluster conversion involves a $[3Fe–4S]^{+}$ intermediate (Figure 5) and is accompanied by the production of H_2O_2.[175] The proposed O_2 sensing mechanism predicts that the $[2Fe–2S]^{2+}$-containing from of FNR would be present under aerobic conditions. However, FNR isolated from aerobically grown cells is predominantly in the apo form.[56] This dilemma appears to have been resolved by recent spectroscopic studies which demonstrate that the $[2Fe–2S]^{2+}$ cluster in FNR is labile to superoxide both *in vitro* and *in vivo*.[274] The mechanism of assembly of the $[4Fe–4S]^{2+}$ cluster in apo FNR under anaerobic conditions and the molecular details of the O_2 sensing mechanism remain to be established. NO has also been shown to be effective for inactivating FNR via the formation of monomeric and dimeric dinitrosyl-iron-dithiol species.[275] However, the physiological relevance of NO-induced inactivation remains to be established and it has yet to be determined if the nitrosylated form of FNR can be repaired *in vivo*.

IscR/SufR. IscR is a transcriptional regulator of the iron–sulfur cluster biosynthesis operon (*iscRSUAhscBAfdx*) and contains a DNA-binding region as well as an Fe–S cluster-binding region comprising three conserved cysteine residues.[59] Spectroscopic studies have shown that IscR can accommodate a $[2Fe–2S]^{2+,+}$ cluster and the cluster-bound form has been shown to act as a transcriptional repressor of the *isc* operon by binding to a promoter upstream of *iscR*.[59] In the current model of IscR-directed regulation, apo Fe–S proteins compete with apo IscR for $[2Fe–2S]^{2+}$ clusters assembled on the IscU or IscA scaffold proteins. Hence IscR appears to be an Fe–S cluster sensor that provides feedback regulation to control the supply of clusters generated by the ISC cluster assembly machinery when supply exceeds demand. A similar mechanism has recently been suggested for the SufR protein in cyanobacteria.[276] SufR is proposed to act as a transcriptional repressor of the *sufBCDS* operon, which encodes for SUF iron–sulfur cluster assembly proteins. However, the arrangement of the four conserved cysteines in the Fe–S binding domain of SufR is completely different to IscR and preliminary EPR studies indicate that SufR binds a $[4Fe–4S]^{2+,+}$ cluster rather than a $[2Fe–2S]^{2+,+}$ cluster.[276] Much has still to be learned concerning the role and mechanism of both IscR and SufR. For example, it has yet to established if they are specific for regulating the *isc* and *suf* operons, the processes by which the Fe–S clusters are acquired and removed have still to be addressed, and the molecular mechanisms by which cluster binding induces DNA binding are currently unknown.

IRP. Iron-regulatory proteins (IRPs) corresponding to apo and holo forms of aconitase are responsible for translational regulation in response to iron availability and/or oxidative stress in both eukaryotic and prokaryotic cells.[27,58] Under conditions of iron starvation in eukaryotic cells, apo IRP stabilizes the transferrin receptor and inhibits the translation of ferritin mRNAs by binding to iron-responsive elements (IREs) within their untranslated regions. Under Fe-replete conditions, IRP assembles a [4Fe–4S] cluster with three cysteine ligands and this prevents IRE binding. Hence the ability to assemble an Fe–S cluster is used as the sensor of iron availability. However, it is becoming increasing apparent that the [4Fe–4S] clusters in the holo forms of both eukaryotic and prokaryotic IRPs respond in diverse ways to other stimuli associated with reactive oxygen and nitrogen species, such as H_2O_2, NO, superoxide, and peroxynitrite. This suggests a complex interplay of the iron sensing and oxidative stress responses and the involvement of IRPs in the latter are still being characterized.[58,277]

3.4.2 *Enzyme Activity*

There are several examples of enzymes containing Fe–S clusters that are essential for activity, but are not required for substrate activation or electron transfer, implying a structural or regulatory role. However, direct evidence for a regulatory role is often difficult to obtain. The best-documented example of an enzyme containing a regulatory Fe–S cluster is the *Bacillus subtilis* glutamine phosphoribosylpyrophosphate amidotransferase that catalyzes the first step in purine nucleotide biosynthesis. The combination of biochemical and crystallographic evidence strongly suggest that the [4Fe–4S] cluster is selectively destroyed by O_2 with concomitant proteolysis.[60,61] The cluster therefore appears to act as an O_2 sensor in order to regulate purine biosynthesis. Another proposed example is mammalian ferrochelatase, the enzyme responsible for the iron-insertion step in heme biosynthesis. In contrast to almost all bacterial ferrochelatases, mammalian ferrochelatases contain a [2Fe–2S] cluster that is essential for activity and is very sensitive to NO-induced degradation.[62,63] Since bacterial infections can be viewed as a ‘fight over iron’ and some pathogenic microorganisms can directly use heme made by host, local inactivation of ferrochelatase in the region

of infection, in response to NO produced by macrophages, may be desirable. Hence the notion of the [2Fe–2S] cluster in mammalian ferrochelatases acting as a NO sensor is an attractive, albeit unproven, possibility.

3.5 Disulfide Reduction

Biological disulfide reduction is generally catalyzed by a large family of pyridine nucleotide-disulfide oxidoreductase flavoenzymes that use NADPH as a two-electron donor to effect FAD-mediated two-electron reduction of an active-site disulfide. The reduced active-site dithiol then reduces substrate disulfides via dithiol-disulfide exchange. However, the FTRs found in chloroplasts and the HDRs found in methanogenic archaea have emerged as unique types of disulfide reductase that catalyze disulfide reduction using one-electron donors and an active site comprising a [4Fe–4S] cluster. The combination of spectroscopic and crystallographic approaches has recently yielded major insights concerning the role of [4Fe–4S] clusters in cleaving disulfides in two sequential one-electron steps.[65]

3.5.1 Ferredoxin–Thioredoxin Reductase

FTR plays the central role in light regulation of the activity of enzymes involved in oxygenic photosynthesis. The light signal is converted into reducing equivalents in the form of reduced 2Fe Fd by photosystem I and FTR catalyzes the reduction of disulfides in thioredoxin (Trx) *f* and *m* using the reduced 2Fe Fd as the one-electron donor (see equation 11).

$$2Fd_{red} + Trx_{ox} + 2H^{+} \longrightarrow 2Fd_{ox} + Trx_{red} \qquad (11)$$

The reduced thioredoxins activate or inactive numerous target enzymes involved with oxygenic photosynthesis by reduction of regulatory disulfides. FTR is a disc-shaped $\alpha\beta$-heterodimer, 40–50 Å in diameter and ~10Å thick, comprising a highly conserved catalytic β-subunit that contains a [4Fe–4S] cluster with nearby asymmetrically disposed cysteine disulfide (Figure 8) and a variable α-subunit with low sequence homology between species.[64] Detailed spectroscopic characterization of FTR and a modified form in which one of the cysteines of the active site has been alkylated, indicate that the one-electron reduced catalytic intermediate involves two-electron disulfide reduction coupled with one-electron cluster oxidation of a $[4Fe–4S]^{2+}$ cluster to yield a unique type of $S = 1/2$ $[4Fe–4S]^{3+}$ cluster with two cysteine residues ligated at a specific Fe site.[278,279] The results provide the basis for a novel mechanism for disulfide cleavage in two one-electron steps involving site-specific [4Fe–4S] cluster chemistry and distinct roles for each of the cysteines of the active-site disulfide[65] (Figure 8).

3.5.2 Heterodisulfide Reductase

In the final step of methanogenesis, methyl coenzyme M reductase catalyzes the reaction of methyl coenzyme M (CH_3–S–CoM) with coenzyme B (CoB–SH) to form methane and the CoM–S–S–CoB heterodisulfide.[280] The heterodisulfide functions as the terminal electron acceptor of

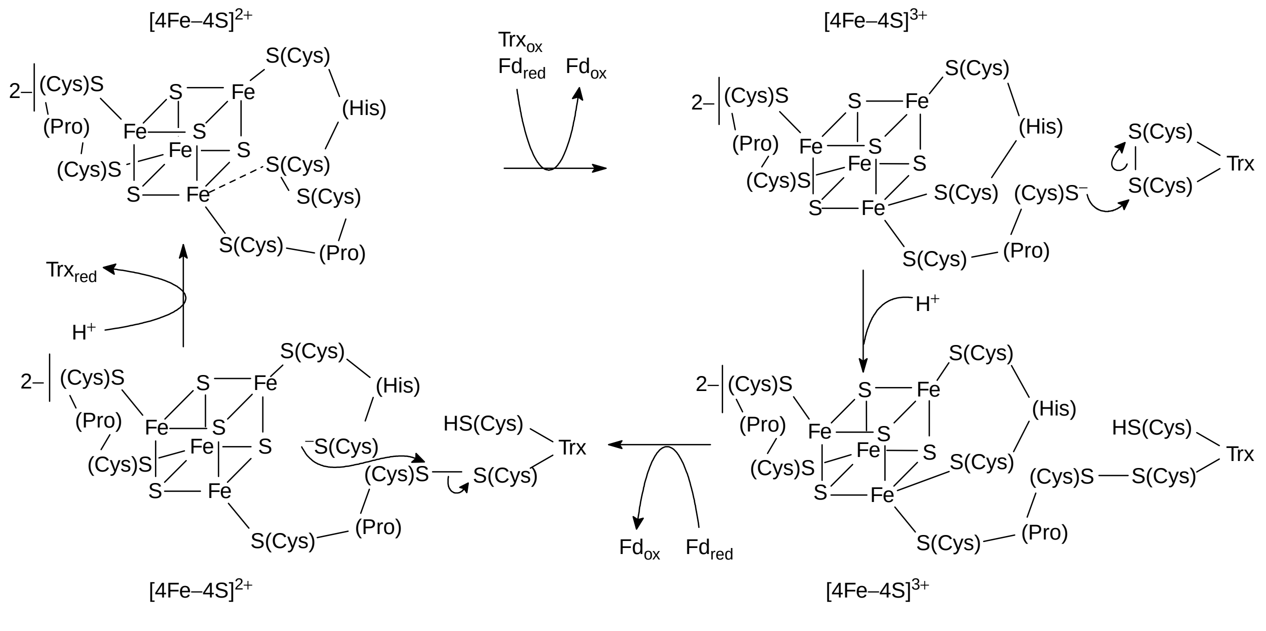


Figure 8 Proposed catalytic mechanism for ferredoxin–thioredoxin reductase

an energy-conserving electron transport chain, in a process called disulfide respiration.[281] HDR is the terminal enzyme in the disulfide respiratory chain and catalyzes the reversible reduction of the CoM–S–S–CoB heterodisulfide to yield coenzyme M (CoM–SH) and CoB–SH (equation 12).

$$\text{CoM–S–S–CoB} + 2\text{H}^+ + 2\text{e}^- \longrightarrow \text{CoM–SH} + \text{CoB–SH} \quad (12)$$

Spectroscopic studies indicate a [4Fe–4S] cluster active site that interacts directly with the substrate disulfide, rather than via an active–site disulfide as in FTR.[66] Moreover, they have provided compelling evidence for a one-electron reduced intermediate, similar to that characterized in FTR, involving a $[4Fe–4S]^{3+}$ cluster with both cysteinate and the CoM thiolate bound at a unique Fe site.[66,282] Hence a similar mechanism to that shown in Figure 8 for FTR is also proposed for the direct [4Fe–4S]-mediated cleavage of the CoM–S–S–CoB heterodisulfide in methanogenic archaea by HDR.[65]

3.6 Iron, Electron, or Cluster Storage

A convincing case has been made for an iron storage role for 8Fe Fds containing two $[4Fe–4S]^{2+,+}$ clusters in *Clostridia*[47] and similar arguments can be made for many anaerobic bacteria and archaea. This is further supported by the presence of polyferredoxins containing up to 14 [4Fe–4S] clusters in seven repeated 8Fe Fd-like domains in methanogenic archaea.[48,49,283] Genes encoding polyferredoxins are found in operons encoding enzymes such as hydrogenase and formylmethanofuran dehydrogenase, which contain multiple [4Fe–4S] clusters. Hence it has been proposed that polyferredoxins and 8Fe Fds function in iron and/or electron storage.[48] However, an attractive alternative proposal that arises from the realization that Fe–S clusters are assembled on scaffold proteins prior to insertion into apoproteins,[82,83] is that 8Fe Fds and polyferredoxins provide storage sites for [4Fe–4S] clusters that are used in the maturation of Fe–S proteins.

1 INTRODUCTION

For all plants and animals, and for virtually all microbes, with the exception of some *Lactobacilli* and a *Borrelia* species,[1] life without iron is impossible. A multitude of essential enzymes bind iron in their active centers. Therefore, up to 10^5 Fe-ions are typically required in key metabolic processes of a single bacterial cell. Why iron has gained such an eminent role in the course of biological evolution remains open to speculation.[2] Though iron is the fourth most abundant element in the Earth's crust, it is present under aerobic conditions at nearly neutral pH in the form of extremely insoluble minerals like hematite, goethite, and pyrite, or as polymeric oxidehydrates, carbonates, and silicates, which severely restricts the bioavailability of this metal. In response to this, microorganisms secrete high-affinity iron-binding compounds called siderophores (from the Greek, 'iron carrier').[3–10] In any natural environment of microbial activity, siderophores are present. Significant amounts of siderophores can be extracted from soil and from fresh or salt water. Even some foods contain siderophores.[8] Biosynthesis of siderophores is executed on a cellular level by a set of enzymes specific for the respective siderophore. The corresponding genes are located on the chromosome or on a plasmid.[11] Expression of these genes is controlled by the amount of cellularly available iron (Section 5).[11–14] Therefore, microbial metabolic products (mainly secondary metabolites) can be classified as siderophores, if (1) they exhibit iron chelating capability, (2) they participate in active transport across the cell membrane(s), and (3) their biosynthesis is regulated by the intracellular iron level.

During the last decade we witnessed exceptional progress in the field of iron-transport research (*see also* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***).[3–6] Almost 500 naturally occurring siderophores have been isolated and characterized (Section 2),[3,4] and the discovery of new siderophores is continuing at a good rate. The physical properties of siderophores yield important information on biological mechanisms involving siderophore-iron complexes. Fundamental data on solution thermodynamics (Section 4.1), electrochemistry (Section 4.3), and kinetic studies (Section 4.2) have been used in the search for likely intracellular iron-release mechanisms (Section 5). Moreover, sufficient thermodynamic and kinetic data facilitate an estimation of the advantages of certain siderophores over others in their competition for iron. Siderophore uptake in microorganisms is, in general, a receptor-dependent process (Section 5.1). A diversity of high-affinity receptors has evolved either to recover iron-loaded endogenous siderophores that have been excreted to scavenge iron from the environment, or to utilize xenosiderophores or iron-sequestering agents of a host. Crystal structures have been solved of a variety of siderophore receptors and of other components of the high-affinity, energy-dependent siderophore-transport systems as well (Section 5.1). Nevertheless, siderophores may exhibit both optical and geometrical isomers (Section 3). Synthesis of Cr^{3+} or Rh^{3+} siderophores enables isolation and characterization of these isomers (Section 3.3). Stereochemically well-characterized isomers are an indispensible prerequisite for studying the specificity of siderophore-mediated iron uptake in microorganisms (Section 5.2). A variety of cellular iron-release mechanisms from siderophores have been characterized, the majority of which involve reduction of ferric iron either on the membrane level or in the cytoplasm (Section 5.4). The molecular nature of the overall transport process is complex (Section 5.3) and strictly regulated (Section 5.5).

In vivo Mössbauer spectroscopic investigations on the time course of iron assimilation revealed that siderophores

function as iron-storage compounds in various fungi (Section 6.1). Siderophores are also employed clinically for removal of iron and aluminum from the body (Section 6.2). Siderophores may serve as magnetic resonance imaging (MRI) agents and as templates for novel classes of antibiotics. Invading microorganisms exposed to circulating blood produce siderophores to compete for iron with the human transport protein transferrin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***, ***Metalloregulation***), thus constituting one aspect of virulence and pathogenicity (Section 6.3).

2 STRUCTURES OF SIDEROPHORES

As with secondary metabolites, various and complex chemical structures are typical within the siderophores, preventing their unequivocal and universal classification. Since the biosyntheses and structural features of siderophores are diverse, a classification scheme will be to some extent arbitrary. Criteria may include the producing organisms (bacteria, fungi, plants), the nature of the backbone (peptidic or nonpeptidic, cyclic or open chain), or the nature of the chelating group. Despite the considerable structural variation found in the siderophores, their common feature is to form six-coordinate complexes with iron (III) of great thermodynamic stability. The ligating groups contain the oxygen atoms of hydroxamate, catecholate, α-hydroxy-carboxylic acids, and α-keto-carboxylic acids. In addition, siderophores with diverse Fe^{III} ion binding groups were isolated, like salicylic acid, oxazoline and thiazoline nitrogen, and even negatively charged nitrogen (in the case of maduraferrin). Comprehensive reviews on the structural variety of siderophores are available.[3,7–9,15] Therefore we shall focus on salient structural features of siderophores. NMR studies of most siderophores have been part of the general chemical and structural characterization. The metal is generally removed from the complex prior to NMR spectroscopy, because Fe^{III} causes severe line broadening of the NMR signals. To obtain spectra of the siderophore in the metal-chelated form, usually the diamagnetic Ga^{3+} or Al^{3+} siderophore analogs are employed.[15–18] ^{1}H and ^{13}C NMR data of a variety of hydroxamate-type siderophores have been tabulated.[19]

Investigations on the biosynthesis of siderophores represent a major activity in the field.[11] Considerable effort has been devoted to the chemical synthesis of natural siderophores, enantiomeric siderophores, and completely synthetic siderophore analogs. This topic will not be covered here and the reader is referred to the corresponding literature.[8,10,20–23]

2.1 Hydroxamate-type Siderophores

Hydroxamate group-bearing siderophores are mainly synthesized by fungi and Gram-positive filament-forming bacteria (streptomycetes). In fungal systems the hydroxamic acid chelating group is commonly derived from acylated N^{δ}-acyl-N^{δ}-hydroxy-L-ornithine.

The ferrichromes comprise one large family of hydroxamate siderophores (Figure 1(a)) and were isolated from low-iron cultures of many fungi.[24] With few exceptions, ferrichromes possess cyclic hexapeptide backbones in which one tripeptide is linked to a second tripeptide of N^{δ}-acyl-N^{δ}-hydroxy-L-ornithine. Linear derivatives of the latter tripeptide form backbones of various antibiotics, termed albomycines.

Crystal structures have been determined of several ferrichromes. Most of this work was performed by van der Helm and coworkers.[25,26] The crystal structures of the members of this siderophore family can be superposed and a root-mean-square deviation of the 49 atoms, which are common to all members, is obtained of approximately 0.30 Å. A comparison of the conformational angles around the cyclic hexapeptide ring shows differences of not more than 25°. This indicates that the structures and conformations are not the same but that they are similar with some conformational freedom. In all structures, the iron coordination site is on one side of the molecule, the coordination of the metal is Λ-*cis*, and the conformation of the amino acids is L. A β (II) bend and a β (I) bend of the cyclic peptide skeleton is found. In addition, extensive conformational analyses of siderophores in solution were performed by Llinas and coworkers employing ^{1}H and ^{13}C NMR.[9]

Building blocks composed of N^{δ}-hydroxyornithine acylated with *cis*-5-hydroxy-3-methyl-2-pentoic acid are found in fusarinens (fusigens) isolated from *Aspergillus, Penicillium*, and *Fusarium* species. These building blocks are esterified head-to-tail to build the various linear and cyclic fusarinines (Figure 1(b)). The crystal structure of N',N'',N'''-triacetylfusarinine C shows a disk-like shape with the metal being located in the center of the molecule.[27,28]

Ferrioxamines, typical constituents of culture broths of *Actinomycetes*, occur as both linear and cyclic compounds containing 1-amino-5-hydroxyaminopentane (N-hydroxycadaverine) and succinic acid as building blocks (Figure 1(c)). A cyclic trimer of succinyl-(N-hydroxycadaverine), is named ferrioxamine E. In some cases the pentane moiety is replaced by a butane carbon skeleton (putrescine). The most prominent representative of this siderophore family, desferrioxamine B (Figure 1), has become the drug of choice for the treatment of transfusional iron overload (Section 6.2).[29] The crystal structure of ferric ferrioxamine B has been published recently.[30] Certain derivatives of the ferrioxamines display antibiotic activity and therefore have been designated as ferrimycins.[31]

Coprogen is a linear trihydroxamate composed of three units of N^{δ}-acyl-N^{δ}-hydroxy-L-ornithine, the acyl groups of which are represented by anhydromevalonic acid

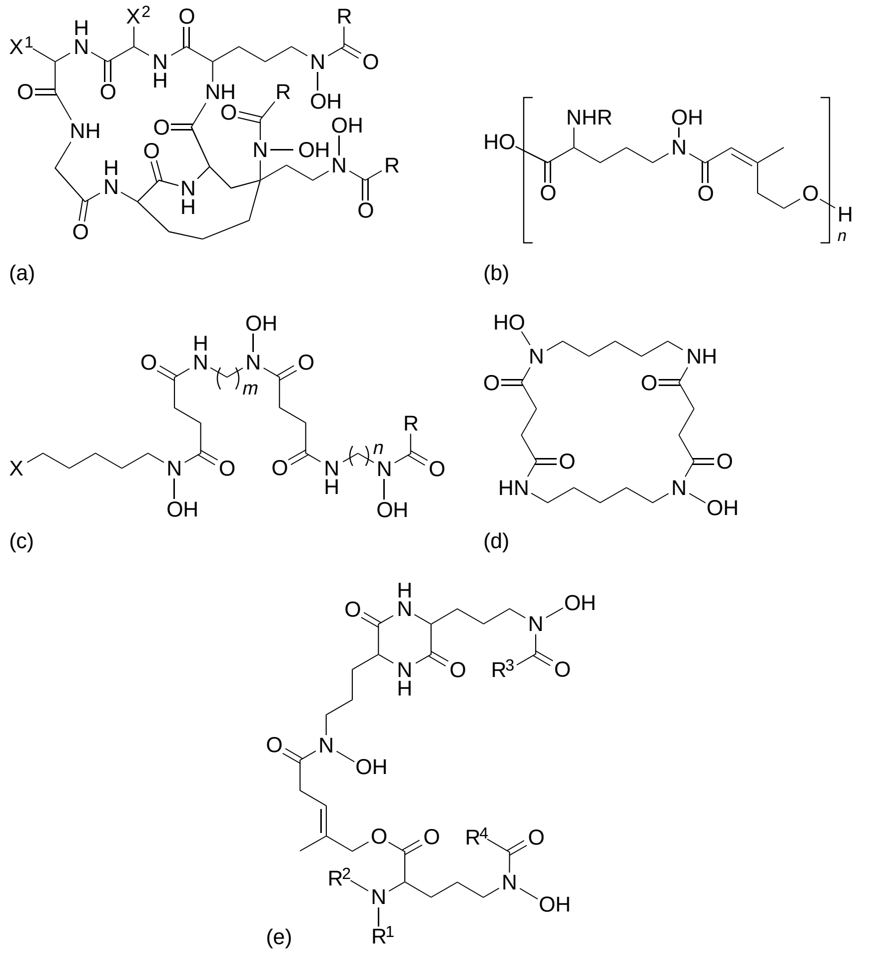

Figure 1 Structures of representative hydroxamate siderophores: (a) ferrichromes (R = Me, $X^1 = X^2 = H$, ferrichrome; R = Me, $X^1 = CH_2OH$, $X^2 = H$, ferricrocin); (b) fusarinines ($n = 1$, fusarinine; $n = 3$, R = acetyl, cyclic, triacetylfusarinine); (c) ferrioxamines (X = NH_2, $m = n = 5$, R = Me, ferrioxamine B; X = NH (cyclic), $m = n = 5$, R = $(CH_2)_2CO$-[X], ferrioxamine E); (d) bisucaberin; (e) coprogens (R^1 = H, R^2 = COMe, $R^3 = R^4$ = isopentenol, coprogen; R^1 = H, R^2 = COMe, $R^3 = R^4$ = Me, neocoprogen II)

(Figure 1(e)).[19] Two of these building blocks are cyclized to form a diketopiperazine ring. This unit, named dimerum acid, is typical of all coprogens. Coprogens are produced by *Penicillium* species, *Neurospora crassa*, *Curvularia subulata*, *Alternaria longipes*, *Epicoccum purpurascens*, and *Fusarium dimerum*.[19] The crystal structure of one member of this family has been determined, namely of neocoprogen I.[32] Like in ferrichromes, the metal coordination site is not located in the center of the molecule and not sheltered by the carbon skeleton. The metal appears to be rather accessible. Typical tetradentate representatives of the hydroxamate-siderophore family include rhodotorulic acid,[32] dimerum acid,[19] bisucaberin,[33] alcaligin[34] and putrebactin.[35] Bisucaberin (Figure 1(d)), a cyclic dimer of succinyl-(*N*-hydroxycadaverine), which sensitizes tumor cells to macrophage-mediated cytolysis, was isolated from the supernatant of cultures of the marine bacterium *Alteromonas haloplanktis*.[33] Putrebactin is a cyclic dimer of succinyl-(N-hydroxyputrescine) whereas rhodotorulic acid is a linear tetradentate chelator assembled of two N^{δ}-(res)-N^{δ}-hydroxyornithine units which are cyclized to form a diketopiperazine ring.[32] The crystal structure of the Fe-alcaligin complex disclosed a monobridged topology and a Fe_2L_3 stoichiometry at near neutral pH.[36]

2.2 Siderophores with Catecholate Ligands

Under conditions of iron deficiency, many bacteria excrete siderophores exhibiting phenolate or 2,3-dihydroxybenzoate (DHB) iron-binding groups. In 1970, enterobactin (also known as enterochelin), the first tricatechol siderophore, was isolated from culture fluids of *Escherichia coli*, *Aerobacter aerogenes*, and *Salmonella typhimurium* (Figure 2(a)).[37] Enterobactin is the cyclic triester of DHBS (2,3-dihydroxybenzoylserine) exhibiting extraordinary features: (1) an extremely high complex formation constant; (2) a redox potential too low

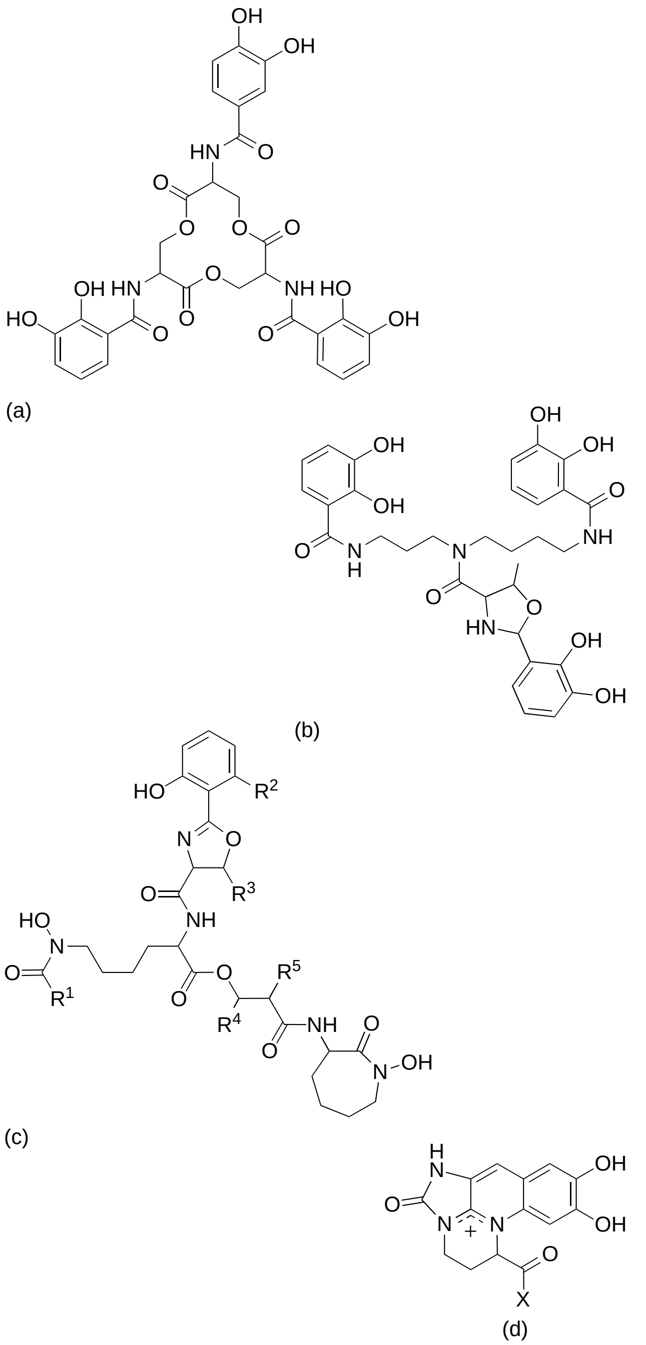

Figure 2 Structures of representative catecholate and mixed-ligand siderophores: (a) enterobactin; (b) parabactin; (c) mycobacins (R^1 = various alkyl chains, $R^2 = R^3 = R^5$ = Me or H, R^4 = alkyl chains or H;[3]) (d) fluorescent chromophore of pseudobactins and pyoverdins

for physiological reductants; (3) a strong pH-dependence of (1) and (2); and (4) a trilactone backbone, the cleavage of which lowers the redox potential. Due to these exceptional properties relevant to its physiological reactions, enterobactin is one of the most intensively analyzed siderophores. Recently, enterobactin was also isolated from Gram-positive bacteria[38] as well as the enterobactin homolog corynebactin from *Corynebacterium glutamicum* and *Bacillus subtilis*[39,40] Corynebactin incorporates threonine trilactone and glycine spacers, which elongate the three chelating arms as compared with enterobactin. All other known tris-catecholate siderophores exhibit a linear backbone based on spermidine or norspermidine. Parabactin, N^4-(2,3-dihydroxybenzene-3-methyloxazoline-2-carboxamidyl)-N^1, N^8-bis(2,3-dihydroxybenzoyl) spermidine, is produced by *Paracoccus denitrificans* (Figure 2(b)). Exposure to acid destroys the oxazoline ring, producing a threonyl moiety.[41] Other members of the linear tris-bidentate catecholate-type siderophores include Vibriobactin,[7] Vulnibactin,[7] Fluvibactin,[7] Protochelin,[7] and Salmochelin-2.[42] Salmochelin is unique, because the backbone of the DHBS-chelating units is made up by glucose. Azotochelin, Myxochelin, Serratiochelin, and Amonabactin belong to the bis-bidentate catecholates, whereas aminochelin, chrysobactin, and DHBS form the mono-bidentate group of catecholate siderophores.[3,7]

2.3 Carboxylate-type Siderophores

A great variety of siderophores exhibit carboxylate and hydroxy donor groups. Many of these siderophores belong to the mixed-ligand group (see next section). In the nineties of the last century, however, a completely novel class of siderophores was detected whose members neither possess hydroxamate nor phenolate ligands. Rather, Fe^{III} binding is achieved exclusively by α-hydroxycarboxylates and carboxylates. The late discovery of these compounds is mainly based on the fact that they are colorless, therefore requiring novel methods for screening and isolation (chromazurole test and iron nutrition bioassays).[43] These siderophores are found in the kingdom of bacteria as well as in the realm of fungi. A very hydrophilic complex, termed staphyloferrin A, was isolated from *Staphylococcus hyicus* (Figure 3(b)).[44] The molecule is composed of two moles of citrate linked by ornithine. Besides Staphyloferrin A,[44] also staphyloferrin B,[45] vibrioferrin,[46] and rhizoferrin[47] contain citric acid building blocks. Rhizoferrin has been isolated from culture filtrates of *Rhizopus* and other members of the class of Zygomycetes (Figure 3(c)).[47] In this compound, two citric acid residues are linked to diaminobutane, resulting in N^1, N^4-bis(1-oxo-3-hydroxy-3,4-dicarboxybutyl)diaminobutane. Although citrate is an intracellular primary metabolite, it may be regarded – from an evolutionary view – as the simplest siderophore from which the above-mentioned siderophores, as well as the mixed-ligand compounds schizokinen, arthrobactin, and aerobactin (Section 2.4), have evolved. Under acidic conditions, rhizoferrin undergoes dehydration and cyclization to imidorhizoferrin and bisimidorhizoferrin. Moreover, this type of siderophore might be photolabile, given that light-mediated decarboxylation reactions of α-hydroxy carboxylic acids complexed to transition metals are well known. In fact,

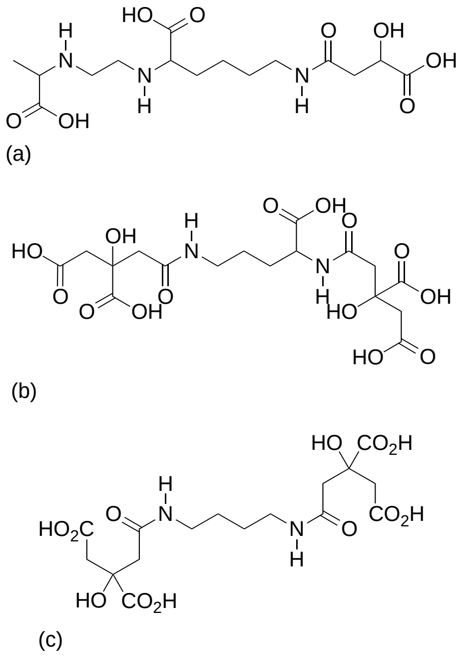

Figure 3 Structures of carboxylate siderophores: (a) rhizobactin; (b) staphyloferrin; (c) rhizoferrin

photolability was demonstrated in a novel siderophore, named petrobactin from *Marinobacter hydrocarbonoclasticus*. The ferric complex of petrobactin undergoes a ligand-to-metal charge-transfer reaction resulting in decarboxylation and oxidation of the citryl moiety forming 3-ketoglutarate.[48]

Rhizobium meliloti, capable of fixing atmospheric nitrogen when symbiotically associated with certain legumes, excretes and utilizes rhizobactin DM4 (Figure 3(a)), N^2-[2-{(1-carboxymethyl)amino}ethyl]-N^6-(3-carboxy-3-hydroxy-1-oxopropyl)lysine. Iron binding is achieved via ethylenediaminedicarboxyl- and α-hydroxycarboxyl-ligands.[49] Phytosiderophores, detected in root washings of gramineous plants, represent a separate subclass of the carboxylate-type of siderophores. For example, the phytosiderophores nicotianamin, mugineic, avenic and distichonic acid are produced and utilized by cereals, like barley, wheat, rye, oat, and so on.[3]

2.4 Siderophores with mixed ligands and heterocyclic chelating groups

Fifty-six years ago the very first siderophore, mycobactin, was isolated by the crystallization of the aluminum complex.[50] Mycobactins from Gram-positive *Mycobacteria* and the closely related nocobactins from *Nocardia* embody a series of lipid-soluble siderophores located in the lipid-rich boundary layers of these bacteria (Figure 2(c)).[51] The X-ray structure revealed that iron binding in mycobactins is accomplished by two hydroxamates, a phenolate group, and oxazoline nitrogen. It is generally assumed that in oxazoline- and thiazoline-containing donor-deficient siderophores, the imine-N will participate in ferric ion complexation. These heterocycles result physiologically from an enzymatic cyclization of cysteinyl, seryl, or threonyl side chains. The imine-type of Fe-coordination is a common feature of the siderophores pyochelin, yersiniabactin, anguibactin, and acinetobactin (Figure 4).[3,7] In the case of anguibactin (ab), the crystal structure of the Ga-complex, $[Ga(ab)_2(CH_3O)_2]$, established the imine nitrogens as part of the iron coordination.[52] Another heterocyclic binding group, β-hydroxyhistidine, participates in Fe^{3+} complex formation of exochelin MN from *Mycobacterium neoaurum*.[53]

A variety of fluorescent chromopeptide siderophores, termed pseudobactins and pyoverdins, are synthesized by *Pseudomonas* species.[54] The chromophores, derived from 2,3-diamino-6,7-dihydroxyquinoline (Figure 2(d)), are linked to a peptide chain exhibiting either two hydroxamate groups or one hydroxamate and one α-hydroxycarboxylate group.

Another major group within the mixed-ligand siderophores combines carboxylate and hydroxamate ligands. Representatives are, for example, the ornibactins.[55] In one subgroup, citric acid constitutes the central building block. Members of this group include schizokinen, rhizobactin 1021, acinetoferrin, arthrobactin, aerobactin and nannochelins.[7]

Recently, a suite of amphiphilic peptide siderophores, named amphibactins, containing a unique peptidic headgroup that coordinates Fe^{3+} and one of a series of fatty acid appendices, was discovered.[56] The compounds were isolated from *Halomonas aquamarina* (aquachelins), and *Marinobacter* sp. (marinobactins) and characterized.[57] Iron

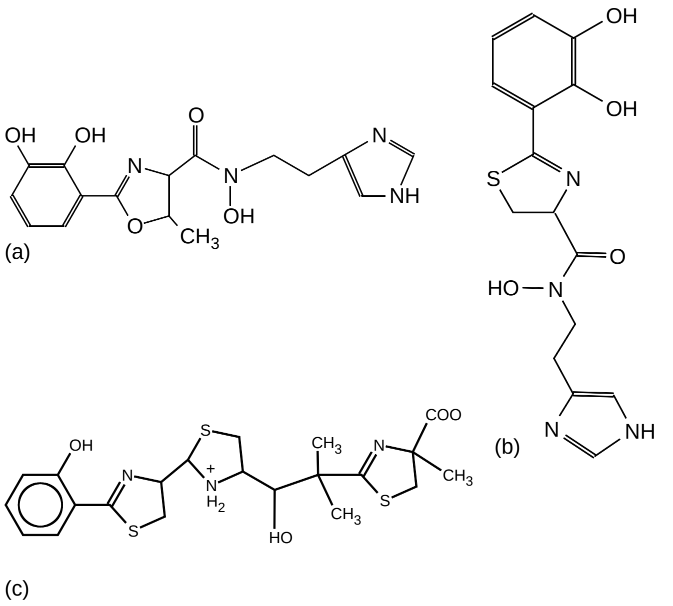

Figure 4 Structures of siderophores with heterocyclic ligands: (a) acinetobactin, (b) anguibactin, and (c) yersiniabactin

binding occurs via hydroxamates and β-hydroxy-aspartate residues.[57] Finally, in another group, ferric ion is encapsulated employing hydroxamate and catecholate/phenolate ligands, observed in a recently characterized antibiotic from *Nocardia asteroides*, named asterobactin, and in the heterobactins from *Rhodococcus erythropolis*.[58,59]

3 COORDINATION GEOMETRY OF SIDEROPHORES

The stereochemistry of siderophores is a very important aspect of their role in mediated iron uptake, since it has been shown that very subtle discrimination by microbial iron transport systems takes place between siderophore isomers. In fact, uptake of siderophores by microorganisms shows – at least in part – stereospecific preferences (Section 5.2).

3.1 Geometrical and Optical Isomers

Upon metal chelation, a tris complex with a bidentate ligand forms a more or less distorted coordination octahedron via three five-membered chelate rings. According to IUPAC rules,[60] the planes of these five-membered rings may form a right-handed (Δ) propellor or a left-handed (Λ) propellor (Figure 5). If the ligand is not optically active, one will find a racemic mixture of Δ and Λ optical isomers. If the ligand is chiral (e.g. D), two complexes are again possible, DΛ and DΔ. However, they are not formed in equal amounts because they have different standard free energies of formation. Exclusively, one optical isomer may be formed if there is a large thermodynamic advantage for this isomer (as, for instance, in the case of ferrichromes where LΛ is exclusively observed).

Many siderophores are hexadentate ligands with three asymmetrical bidentate functional units attached to an asymmetrical backbone. These complexes reveal a rather complicated stereochemistry. The bidentates are not equivalent and there will be $2^3 = 8$ cis and trans isomers. Each can have a Λ and Δ metal environment and when the siderophore is made from chiral residues there are 16 diastereomers, none of which is enantiomeric to one another. A selection of such diastereomers is shown in Figure 5. Nomenclature for the geometrical isomers of hydroxamate tris-bidentates was outlined by Leong and Raymond.[10,61] No general rule can be applied for an absolute assignment of the chelate ring sequence. However, if the structure exhibits a unique functional group, this group can be utilized to define the chelate ring sequence. In the case of ferrioxamine B or D1, the unique functional group is the N-terminus. (1) In the case of the coprogens, this group is a diketopiperazine ring placed between rings 1 and 2. (2) Looking down the $C3$ axis the sequence of the chelate rings 1, 2, and 3 corresponds to the rotation direction, that is,

Not shown is the set of eight Λ diastereomers. R, X correspond to unique functional groups, for example, amino terminus of ferrioxamine B (R) or diketopiperazine ring of coprogen (X)[25]

clockwise for Λ-isomers and counterclockwise for Δ-isomers. (3) If the ring 1 has the carbon atom of the hydroxamate group below the nitrogen, it is denoted 'C'; if the reverse is true, it is called 'N'. (4) For rings 2 and 3, each is called *cis* or *trans* depending upon whether it has the same or opposite relative orientation with respect to the coordination axis as does ring 1.

The X-ray crystallographic analysis of all ferrichrome siderophores yielded Λ-C-*cis,cis* configurations of the

coordination octahedron.[62] Neocoprogen I adopts a Δ-C-*trans,trans* configuration in the crystal structure.[61] N,N',N''-Triacetylfusarinine crystallizes as either the Δ or Λ isomer, depending on the solvent system used.[63] Achiral siderophores such as ferrioxamine E and ferrioxamine D_1 crystallize as racemic mixtures of Δ and Λ isomers.[64,65] Similarly, the crystal structure of Ferrioxamine B displays a racemic mixture of Λ-N-*cis, cis* and Δ-N-*cis,cis*,[30] although various geometrical isomers of the inert Cr-complex are present in solution (see Section 3.3).

A multitude of siderophores achieve iron chelation via catecholates. Unlike hydroxamate, catecholate is a symmetric, bidentate ligand. Thus, there are no geometrical isomers of simple tris(catecholate) metal complexes. The chirality at the metal center of (bis(catecholato)-siderophores) was determined in amonobactins, where a slight Δ preference in Fe_2L_3 stoichiometry was observed whereas the corresponding $FeL(H_2O)_2$−complexes in the low-pH region are achiral.[66] Enterobactin displays a Δ-*cis* configuration, dictated by the asymmetric centers (L) of the trilactone ring.[67] Synthetic enterobactin analogs composed of tris(2-aminomethyl)amine (TREN) as anchors and amino acids linking the anchor to catechol units also form Fe^{3+} complexes of preferential Δ-*cis* configuration when L-amino acids are used. These complexes are stabilized by intramolecular H-bonds from the catechoylamides CONH to the catecholate oxygens, as in enterobactin. When the possibility of this type of H-bond is eliminated by replacing the amide proton CONH by an amide *N*-methyl (CONMe), the chiral preference of the complex is inverted from the Δ-*cis* to the Λ-*cis* configuration.[68] Surprisingly, the recently detected trilactone siderophore corynebactin forms a Λ-ferric complex. The addition of a glycine spacer and the methylation of the trilactone ring as compared with enterobactin are sufficient to favor the opposite chirality.[69,70]

3.2 UV/vis and CD Spectra of Ferric Siderophores

The d^5 electronic configuration of Fe^{3+} rules out any crystal field stabilization energy (CFSE) and makes the complexes relatively labile with respect to isomerization and ligand exchange in aqueous solution. Furthermore, high-spin Fe^{3+} has no spin-allowed d–d transitions. Therefore the UV/vis and CD spectra of iron(III) microbial iron chelates arise from the coulombic interaction between the positively charged metal ion and the negatively charged oxygen atoms (charge-transfer transition), which is not as readily interpreted as are ligand-field (d–d) transitions.

Although transitions in high-spin iron(III) complexes are extremely weak, the determination of the metal-center chirality of Fe^{3+} complexes in solution is possible through comparison of the solution and solid-state CD spectra. However, the correlation of the rotary power with left-handed or right-handed helical stereochemistry requires an absolute assignment based on crystal structure data that are usually determined employing the Bijvoet method for anomalous dispersion of Cu-K_α radiation by the Fe^{3+} ion in the crystalline solids. This correlation could be established for triacetylfusarinine and neurosporin.[63,71] The correspondence extends into the other Fe^{3+} complexes and shows that the CD spectra of the iron(III) complexes in solution can be used for determinations of the metal-center chirality. Fe^{3+} complexes will have the Λ configuration (at least predominantly) if the CD

band in the region of the absorption maximum (400–500 nm for hydroxamates) has a positive sign. The visible and CD spectral parameters of siderophores in aqueous solution are summarized in Table 1.

3.3 UV/vis and CD Band Assignments of Chromic Siderophores

An alternative method that enables the classification of geometrical and optical isomers is accomplished by substituting the Fe^{3+} ion with kinetically more inert d^3 Cr^{3+} or d^6 Rh^{3+} ions.[72] Since the substituted ions have almost the same ionic radii and the same charge as Fe^{3+}, their complexes show a high degree of structural similarity with the corresponding Fe^{3+} complexes, as demonstrated by the crystal structures of model compounds.[73,74] The d-electron configurations of Cr^{3+} and Rh^{3+} grant significant CFSE for kinetic inertness and provide well-characterized d–d transitions with distinct UV/vis and CD spectra.

For bidentate ligands with nonequivalent ligating groups, four isomers are possible, Δ-*cis*, Λ-*cis*, Δ-*trans*, Λ-*trans*. Raymond and coworkers have synthesized and separated optical and geometrical isomers of simple hydroxamate and phenolate Cr^{3+} complexes and assigned the absolute configuration of these isomers.[72] Tris(benzhydroxamate)chromium(III), $[Cr(benz)_3]$, was separated into cis and trans geometrical isomers, as confirmed by X-ray structural analyses.[73] Three fractions of optically active tris(*N*-methyl-1-methoxyacetohydroxamato)chromium(III), $[Cr(men)_3]$, were separated by silica gel column chromatography. These were assigned to be a Λ-*cis* fraction, a Δ-*cis* fraction, and a mixture of Λ, Δ-*trans* isomers (Table 2). The cis isomers exhibit a higher dipole moment than the trans isomers. Therefore they bind more strongly to sorbents (e.g. silica gel, ion-exchange resin), yielding bands with lower R_f values compared to trans isomers. This parallels the results obtained for the geometrical isomers of a number of similar compounds.[74–76]

The visible spectra of the Cr^{3+} geometrical isomers exhibit two spin-allowed d–d transitions for octahedral symmetry, namely, ${}^4A_{2g} \rightarrow {}^4T_{1g}$ at higher energy and ${}^4A_{2g} \rightarrow {}^4T_{2g}$ at lower energy. The absorption maximum of the trans isomers is considerably lower at the high-energy transition manifold, and in addition the peak maxima are shifted to higher and lower energy compared to the cis isomers (Table 2). The CD spectrum for *cis*-tris-hydroxamate complexes consists of three bands, due to E_a, A_2, and E_b transitions. The Λ configuration in the model compounds was found to have a positive CD band for the dominant energy transition at 500–600 nm (E_a); the Δ isomer had a negative CD band in this region. For the trans isomer, which has no symmetry (C_1), the E_b transition at high energy is split, providing an additional criterion for differentiating between cis and trans isomers (Table 2). The electronic features are discussed in more detail elsewhere.[9]

Based on these assignments, the absolute configuration of chromium(III) complexes of various siderophores could be determined. The corresponding UV/vis spectral data and CD spectroscopic parameters are shown in Table 2. Whereas chromic desferriferrichromes exclusively show Λ chirality at the metal center, Δ chirality of the coordination octahedron is observed for chromic desferrienterobactin. Chromic complexes of linear chiral ligands such as chromic desferricoprogen and chromic rhodotorulate represent mixtures of Λ and Δ isomers with an overall preference for delta chirality at the metal site, as demonstrated by separation of various geometrical and optical isomers of chromic linear siderophores. Geometrical cis and trans isomers could be separated for linear chromic hydroxamate siderophores, including ferrioxamine B, coprogen, and rhodotorulic acid (Table 2).[9,14,77–80] For the cyclic siderophores, the existence of trans isomers has not been detected. Apparently much larger macrocycle ring dimensions or longer side chains bearing hydroxamate groups are required to allow sufficient flexibility for trans isomer formation.

3.4 Metal-center Symmetry

Derived from X-ray structures, two different models have been presented for the detailed analysis of tris-chelate geometries, and both reach substantially the same conclusion.[81,82] One model describes how close the coordination geometry is to either the trigonally elongated octahedron (trigonal antiprism, D_{3d}) or the trigonal prism (D_{3h}), using shape parameters (which are dihedral angles between trigonal faces sharing common edges of the polyhedron).[83] In the second model, a twist angle is defined as the average of the projection angles of the top and bottom triangular faces spanned by the oxygens and perpendicular to the C_3 or pseudo-C_3 axis. The angle is 60° for an octahedron and 0° for the trigonal prism. The twist angle is a linear function of the ligand bite (the ratio of ring O···O to M–O distance) for a wide range of tris-chelate complexes.

Most structural data are available on the metal centers of hydroxamate siderophores (Figure 6).[26] The observed twist angles range between 36° and 45°. Thus the relative orientations of the octahedral faces formed by the three O(N) and the three O(C) atoms, as described by the twist angle, reflect intermediate structures between the trigonal prism and octahedron. The O···O distance in the bidentate hydroxamate ligand remains constant at 2.55 Å. The (N)–O–Fe–O–(C) angle for hydroxamates is 78°, reflecting the trigonal distortion from the perfect octahedral symmetry (90°). There is not an equal distribution of charges over the two oxygen atoms. The Fe–O–(C) distance is found to be 0.06–0.10 Å longer than the Fe–O–(N) distance in all hydroxamate structures, indicating that the charge on (N)–O is larger than on (C)–O.

The structures of several $[M(catechol)_3]$ complexes are known, including $[Fe(cat)_3]^{3-}$, and all have been found to be pseudo-octahedral. There exists only one crystal structure of an iron(III) tris(catechoylamide), namely of a synthetic compound trivially named bicapped TRENCAM (Figure 7).[84] The

structure analysis shows the coordination geometry around the metal center to be trigonal prismatic, a structure previously unknown for Fe^{3+}. In the structure, shown in Figure 7, the entire catechoylamide group is planar, and the trans configuration of the amide allows a strong hydrogen bond between the amide proton and the coordinated catechol oxygen. The result is a highly stable ligand structure which incorporates three planar catechoylamide groups and six strong amide hydrogen bonds. To accommodate this ligand geometry, the metal ion lies 0.81 Å out of the catechol plane. The molecular and crystallographic site symmetry of the complex is C_{3h}.[84]

3.5 Ligand Denticity and Metal-center Binding Mode

The structure of the metal center is also dependent on the denticity of the ligand. Tetradentate ligands are of particular interest because they are not able to achieve the octahedral coordination geometry in a 1:1 stoichiometry. The dihydroxamate siderophores rhodotorulic acid (RA), bisucaberin (BC) and alcaligin (AL) were analyzed in some detail.[85,86] The binding mode of these complexes is pH-dependent. At low pH (<5) a cationic species of the type $[FeL(H_2O)_2]^+$ was observed. In order to completely encapsulate the metal, a binuclear complex of Fe_2L_3 stoichiometry, which was shown to be formed at near neutral pH, is required. This complex may exhibit either a monobridged or a tribridged binding mode of the bis-hydroxamate ligands.[85,86] At high pH a μ-oxo-bridged alcaligin-complex $[Fe_2L_2O_2]$ is present.[86] Like the bis-hydroxamates, amonabactins, a series of four bis-catecholate siderophores form 2:3 metal:ligand complexes at high pH and in excess of ligand. At lower pH, a 1:1 Fe^{3+}:ligand stoichiometry is found, again like in the corresponding hydroxamate complexes.[87]

3.6 Metal-center Symmetries Based on EPR and Mössbauer Spectroscopy

In Fe^{3+} ions, d–d transitions are both multiplicity- and Laporte-forbidden. Splitting of ^6S is possible due to a second-order spin–orbit coupling of the ^6S manifold with excited quartet spin states or due to higher order effects of the crystal field.[88]

According to Kramers theorem, half-integer spin states like $^6S_{5/2}$ will always be doubly degenerate as long as no strong external magnetic fields are applied. The $^6S_{5/2}$ state splits into three Kramers doublets if the crystal field exhibits a symmetry lower than cubic.

The most common approach to the interpretation of EPR and Mössbauer spectra of siderophores is the spin Hamiltonian formalism. The wavefunctions are parameterized in terms of a few coupling constants that arise in the spin Hamiltonian description of the electronic states. In this approach, the crystal field potential is generally described by a series of spherical harmonics. The corresponding operators are tabulated.[89]

The spin Hamiltonian usually employed for the analysis of siderophores can be represented by equation (1):

$$H = D\left[S_x^2 - \tfrac{1}{3}S(S+1)\right] + E(S_x^2 - S_y^2) + \mu_B \vec{S}\cdot\overleftrightarrow{g}\cdot\vec{B}\,\vec{S}\cdot\overleftrightarrow{A}\cdot I + \frac{1}{4I}(2I-1)QV_{zz}[3I_z^2 - I(I+1)] - g_N\mu_N\vec{B}\cdot\vec{I} \quad (1)$$

$\vec{S}$ and $\vec{I}$ are the electron spin vector operators, respectively, and their projections on the principal axis, $\overleftrightarrow{g}$ and $\overleftrightarrow{A}$ are second rank tensors, $\vec{B}$ is the applied magnetic field, g_N is the nuclear g-factor of the ground and of the excited state, respectively. Q is the quadrupole moment of the excited state; μ_B and μ_N are the Bohr and the nuclear magneton, respectively; D is the zero-field splitting of the Kramers doublets. In trigonal fields the crystal field splitting is given by $\Delta_{CF} = 6D$, separating the Kramers-doublets at a ratio 4:2. E represents the rhombicity and affects the separation of the Kramers doublets. For D = 3E the three Kramers doublets are separated symmetrically by 3.53D which corresponds to a maximal rhombic distortion (symmetries lower than C_3). The ratio E/D is also called the rhombicity parameter λ with $0 \leq \lambda \leq 1/3$.[90] A simulation based on the formalism described in equation (1) is shown in Figure 8.

Based on the spin Hamiltonian of equation (1), EPR and Mössbauer spectra of various siderophores have been analyzed. The parameters obtained are listed in Table 3.[90] All siderophores have some features in common. Isomer shifts and quadrupole splittings are typical for high-spin Fe^{3+}. The internal field is on the order of −55 T. For comparison, the internal field of the isolated Fe^{3+} ion is −63 T, FeF_3 exhibits a value of −62 T, and $FeCl_3$ of −48.6 T. The internal field of siderophores indicates a high degree of ionicity and is typical for an isolated FeO_6 octahedral configuration. The λ-values near 0.333 listed in Table 3 reflect a nearly complete rhombic distortion of the FeO_6 octahedron arising from crystal fields at the nucleus with symmetries lower than C_3. Similarly, ^{13}C NMR spectra of alumichromes show that the hydroxamate carbonyl functionalities are inequivalent, since two carbonyl resonances (161.57 ppm and 161.96 ppm) with a ratio of 2:1 are found.[91,92] These observations are not consistent with a cis geometrical configuration of the metal hydroxamate propellor derived from UV/vis and CD spectroscopy and from crystal structures.

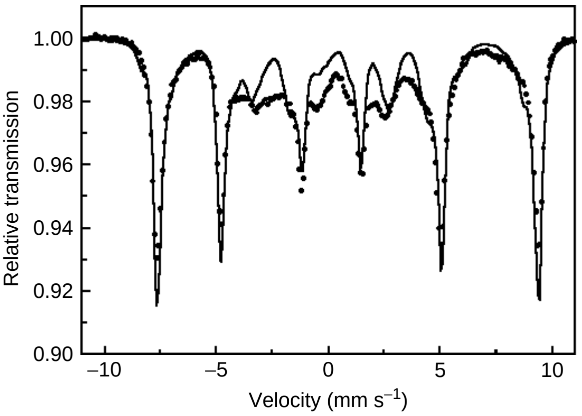

Figure 8 Mössbauer spectrum of a frozen aqueous solution of $[^{57}Fe^{3+}]$-ferrioxamine B (12 mM) employing BSA (100 mM) as a dilutant to minimize spin-spin relaxation. The solid line represents a simulation based on a spin Hamiltonian: line width = 0.35 mm s^{-1}; zero-field splitting, $D = 1.2\,cm^{-1}$; rhombicity parameter, $E/D = 0.33$; $\delta = 0.52\,mm\,s^{-1}$; $\Delta E_Q = -0.84\,mm\,s^{-1}$; asymmetry parameter, $\eta = 1$; and isotropic hyperfine coupling tensor: $A_{xx}/g_N\mu_N = A_{yy}/g_N\mu_N = A_{zz}/g_N\mu_N = -22.1$ T. The simulation does not completely fit the experimental data. This discrepancy is caused by relaxation effects that are not dealt with in the spin Hamiltonian simulation

4 EQUILIBRIUM THERMODYNAMICS OF SIDEROPHORE-IRON BINDING

The formation constants of siderophore complexes define the thermodynamic limits for the conditions in which

[a]Mössbauer analyses have been performed of spectra measured at 4.2 K.

siderophores can compete for iron and extract it from a weaker substrate. Superior propagation conditions will be provided for that organism from which the superior complexing agent was secreted. In addition, these constants are a measure of the siderophore ligand's selectivity for aqueous Fe^{3+} in the presence of competing metal ions and its ability to solubilize Fe and prevent precipitation by hydrolysis. The tenacity of Fe^{3+} binding may determine the mechanism of metabolic turnover of the metal in microorganisms by means of ligand exchange, reductive removal, or ligand destruction.

4.1 Ligand Protonation and Complex Formation Constants

Hydroxamate- or catecholate-containing siderophores are strongly absorbing species with characteristic spectra (see Table 1) which can be utilized for spectrophotometric determination of the complex formation constant. Iron(III) hydroxamates absorb in the visible region, producing a broad absorption band in the 420–440 nm region. Iron(III) catecholates exhibit pH-dependent absorption maxima. Unfortunately, the overall Fe^{3+} ion complex formation constants cannot be determined directly at neutral pH, because the extremely high stability of siderophore complexes precludes direct measurements of the equilibrium of interest, which would yield the desired formation constant for a tris-bidentate siderophore complex, β_{110} (equation (2)).[10,15]

$$Fe^{3+} + L^{n-} \rightleftharpoons FeL^{3-n} \qquad \beta_{110} = \frac{[FeL^{3-n}]}{[Fe^{3+}][L^{n-}]} \tag{2}$$

One method of circumventing this problem is the spectrophotometric measurement of competition for the metal by another thermodynamically well-characterized ligand, typically EDTA. To convert the resultant proton-dependent equilibrium constant into the conventional formation constant, it is necessary to know the ligand protonation constants.[10]

Ligand protonation constants (pK) of the iron-binding groups of siderophores were determined by spectrophotometric and potentiometric titration. Hydroxamic acid-containing siderophores are fairly weak acids with pK_a values ranging from 7.6 to 9.9.[10] Catechols are very weak diprotic acids with widely separated protonation constants (pK_1 between 7.3 and 9.2, pK_2 between 11.5 and 13).[10] In general, the greater the basicity of a chelator, the greater its affinity for Fe^{III}. However, when the pK_a of the ligand is substantially greater than the physiological pH (7.4), proton competition will considerably decrease the concentration of the basic form of the ligand, thus reducing iron binding.

Although the conventional form of tabulation, formation constants are not meaningful alone in judging the relative ability of ligands to compete with one another for Fe^{III} at a given pH. This is due to differences in ligand protonation constants (their number and absolute value), which define the amount of free, uncomplexed, and unprotonated ligand L in aqueous solution. To have a more direct ranking of the ligands under physiologically relevant conditions, so-called pM values have been used. Here pM is defined as $-\log[M(H_2O)_n]^{m+}$, calculated from the constant at pH 7.4, an assumed ligand concentration of 10 μM, and metal concentration 1 μM.[10] Stability constants and pM values of selected siderophores are listed in Table 4. The constants indicate unusually high specificity of the ligands for Fe^{3+}. The reason for this is the high charge and small size of the Fe^{III} ion, which makes it a hard acid (*see* ***Hard & Soft Acids and Bases***). This, in turn, requires the ligand to be a hard base and charged oxygen atoms as occur in catecholates and hydroxamates behave as hard basic ligands.

A comparison of the stability constants of the naturally occurring siderophores uncovers a difference of 17 orders of magnitude between enterobactin ($K \sim 10^{49}$)[93,94] and the most stable hydroxamate complex, ferrioxamine E.[9,10] Using the more comparable pM values, enterobactin remains still eight orders of magnitude more effective than ferrioxamine E. Enterobactin has the highest affinity for Fe^{III} ion of any biological iron chelator tested so far.

The protonation constants K_{MHL} of iron(III) trihydroxamate siderophore complexes are in the range of 1, indicating that these complexes are stable even under very acidic conditions. In contrast, tricatecholate complex structures are strongly pH-dependent. The pH-dependence reflects changes of the iron environment. In enterobactin, the metal is coordinated by three catecholate dianions at pH 7. Raymond and coworkers proposed that with decreasing pH the catecholate oxygens are protonated stepwise concomitant with a bonding shift from catecholate to a salicylate mode of binding, resulting eventually in the neutral complex $[Fe^{3+}(H_3ent)]^0$ (path 1 in Figure 9).[94] For enterobactin and the synthetic analog MECAM, the following complex protonation constants have been evaluated: $K_{MHL} = 4.89$ and 7.08, respectively, $K_{MHL} = 3.15$ and 5.6, respectively.[94,95] Raymond and coworkers corroborated their initial proposal, employing

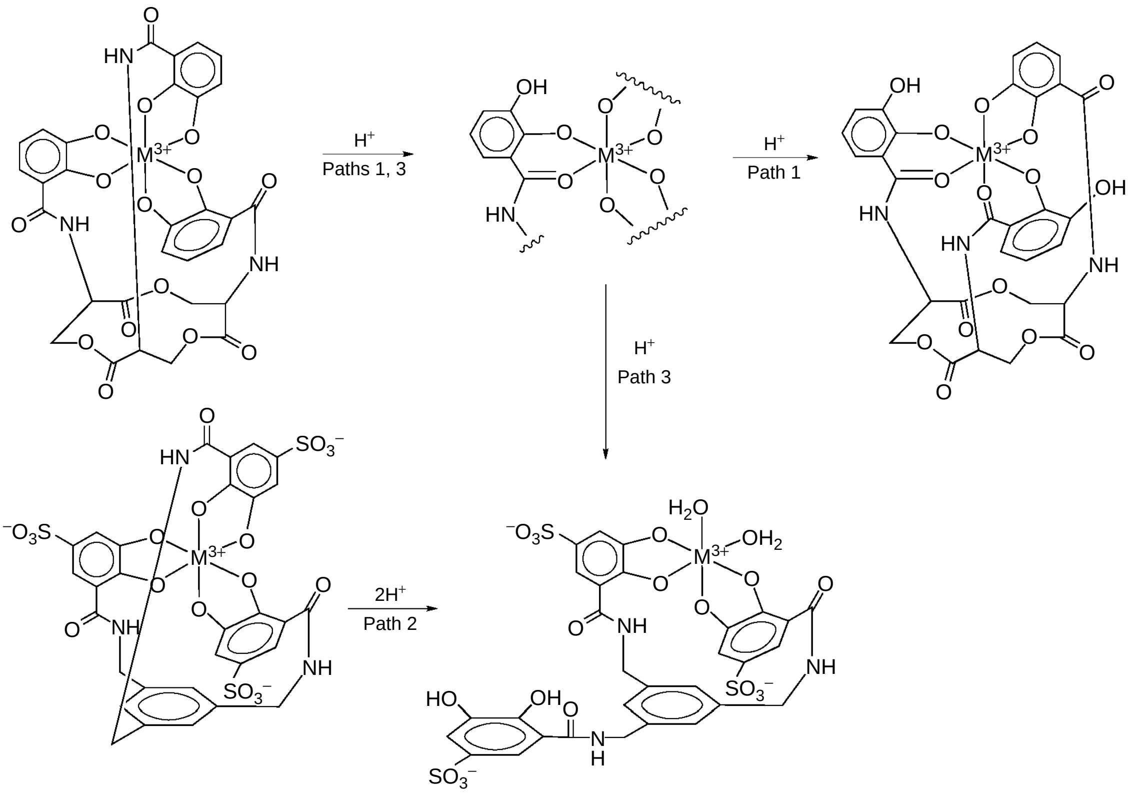

Figure 9 Possible protonation schemes of tris(catecholate) metal complexes. In path 1, the metal complex undergoes a series of two overlapping one-proton steps to generate a mixed salicylate–catecholate coordination. Further protonation results in the precipitation of a tris(salicylate) complex (e.g. enterobactin, MECAM). This differs from path 2, in which a single two-proton step dissociates one arm of the ligand to form a bis(catecholate) chelate. Path 3 incorporates features of paths 1 and 2. In this model, the metal again undergoes a series of two overlapping one-proton reactions. However, unlike the case of path 1, the second proton displaces a catecholate arm, which results in a bis(catecholate) metal complex

spectrophotometric titrations,[94] pH-dependent Mössbauer spectra,[96] an IR study,[97] and a ^{2}H NMR investigation.[98]

4.2 Iron-exchange Kinetics

In early papers on chelate exchange of iron(III) siderophore complexes, it was assumed that the Fe^{III} ion is readily exchanged, due to the known kinetic lability of high-spin Fe^{III}-ion binding. More recent investigations disclosed, however, that ligand exchange reactions are slow and involve stepwise ligand dissociation and protonation, and ternary complex formation.[10,99] From exchange kinetics of the form shown in equation (3)

$$^{55}FeL + L' \rightleftharpoons {}^{55}FeL' + L \quad (3)$$

an approximate linear-free-energy relationship between the equilibrium competition constant and the second-order rate constant for iron removal from ferrichrome, ferricrocin, and coprogen to ferrioxamine B has been derived.[10] Taking triacetylfusarine C as competing ligand, 63% ^{59}Fe was removed from iron(III) citrate after 0.5 h, and even 82% from iron(III) rhodotorulate but only 4% from ferrichrome A.[100] In addition, it was shown that backbone sequence changes in siderophore structures can influence Fe^{3+} lability, but the largest effect is observed on going from a cyclic to an open-chain structure.[101] ^{55}Fe exchange kinetics of the form of equation (4)

$$^{55}FeL + FeL' \rightleftharpoons FeL + {}^{55}FeL' \quad (4)$$

between ferrioxamine B and ferrichrome A were measured at equimolar concentrations (4.0 mM) and 5% excess of desferriferrioxamine B at pH 7.4. The $t_{1/2}$ for exchange is very slow (220 h).[10] In contrast, the exchange reaction between ferrioxamine B and a synthetic tris-catecholate complex exhibits a half-life of approximately 10 hours for equimolar concentrations (1.0 mM) of the competing complexes with no excess free ligand. From a mechanistic point of view, the characteristic feature of siderophore iron-exchange processes is the unraveling of one ligand from the inner coordination sphere, concomitant with complexation by the incoming ligand. This occurs via the formation of a ternary complex between metal ion and entering and leaving ligands. The

general features of these exchange processes conform to ideas formulated in earlier studies of multidentate ligand exchange.[102]

Dissociation of iron from its siderophore complex is a proton driven process and its first step is relatively fast at low pH ($t_{1/2} \cong$ 2-5 ms)[103,104] This step normally involves the dissociation of a bidentate moiety from the fully formed complex ($k_1 = 3.8 \times 10^2\ M^{-1}\ s^{-1}$). Further dissociation is much slower (second-order rate constant $k_3 = 2.3 \times 10^{-2}\ M^{-1}\ s^{-1}$).[105] Proton driven ligand dissociation from tetradentate siderophore complexes (Fe_2L_3) exhibit relatively fast rate constants ($k_3 = 1.5 \times 10^2\ M^{-1}\ s^{-1}$ for alcaligin and $k_3 = 6.8 \times 10^2\ M^{-1}\ s^{-1}$ for rhodoturulic acid).[104] The resulting tetracoordinated complex is relatively stable and requires a drop in pH below 1 for further dissociation. In the case of the hexadentate siderophore ferrioxamine B, dissociation kinetics disclosed an extreme kinetic and thermodynamic stability at physiological pH.[105] In contrast to hexadentate siderophores, tetradentate siderophores can undergo ligand dissociation by multiple pathways. Intermediates of different structures, depending on environmental conditions (pH, Fe:L ratio), have been identified by electrospray ionization mass spectrometry (ESI-MS). The multiplicity of interconvertible species may play a role in cellular recognition, and in the formation of ternary complexes representing a likely prerequisite for biological reduction.[104,106]

Both $\Lambda \rightleftharpoons \Delta$ and cis $\rightleftharpoons$ trans equilibria of siderophore complexes can exist in solution. The chirality of the ligand can impose a preferred metal-center chirality. In addition, the degree of this preference depends on the stereochemical rigidity of the ligand. In principle, the magnitude of the molar circular dichroism can be used as a measure for diastereoisomeric equilibria based on a comparison of the solid-state and solution ellipticity. Nevertheless, predictions of metal-center chiralities require theoretical calculations. For example, empirical-force-field calculations of iron(III) enterobactin show that the Δ orientation at the metal center is more stable than the Λ by 0.5 kcal mol^{-1}, which is consistent with the CD spectra.[107]

In linear siderophores, increasing the chain lengths will obviously cause greater flexibility, resulting in smaller energy differences between both optical and geometrical isomers. These small energy differences allow intramolecular rearrangement reactions of tris-chelate complexes of labile metal ions, such as Mn^{2+}, Fe^{3+}, Al^{3+}, and Ga^{3+}.[108–110] For ferrioxamine B the kinetics of isomerization has been analyzed in detail by NMR spectroscopy.[111] In these experiments, Fe^{III} was substituted by Ga^{III} and Al^{III} to circumvent the problems associated with paramagnetic line broadening. The isomerization reactions were slow enough to allow detection of two geometrical isomers and to measure the rearrangement kinetics by NMR spectroscopy, employing the hydroxamate carbonyls as sensitive probes for metal-center symmetries. The enthalpies of activation ($\Delta H = 53.3$ kJ mol^{-1} in D_2O and 69.7 kJ mol^{-1} in methanol-d_4) are indicative of small activation barriers. The observations favored an intramolecular rearrangement process that involves neither explicit solvent association nor metal–hydroxamate dissociation in the transition state.[111]

4.3 Redox Chemistry of Siderophores

In microbial iron assimilation, one mechanism for the release of iron from siderophores is the enzymatic reduction to the Fe^{II} state. Siderophore stability constants are much lower for Fe^{2+}, which has a lower charge-to-radius ratio. Moreover, ligand exchange reactions for the high-spin Fe^{II} ion are much faster than for the Fe^{III} ion. Stability constants of ferrous siderophores are experimentally difficult to obtain. Limiting pH-independent redox potentials can be utilized, however, to describe the electrochemical and chemical equilibria between fully coordinated Fe^{3+} and Fe^{2+}-siderophore complexes and the uncomplexed $Fe(H_2O)_6{}^{3+}$ and $Fe(H_2O)_6{}^{2+}$, respectively, in a simple model as described in equation (5)[112]

$$E^0_{\mathrm{Fe(III)Sid/Fe(II)Sid}} = E^0_{\mathrm{aq}} - 59.15 \log\left(\frac{\beta^{\mathrm{FeIII}}_{110}}{\beta^{\mathrm{FeII}}_{110}}\right) \tag{5}$$

where E^0_{aq} is the redox potential of hexaaquated iron ($E^0_{\mathrm{aq}} = +770$ mV/NHE).[113] Given the redox potential of the siderophore, and the stability constant of the ferric siderophore complex, the stability constant of the ferrous siderophore complex can be calculated. Based on these considerations Fe^{2+}-siderophore stability constants were determined. Fe^{2+}-siderophores are some 20 orders of magnitude less stable than their Fe^{3+} counterparts.

Table 4 illustrates the redox potentials of various siderophores obtained by cyclic voltammetry. The values of most of the hydroxamates are within the range of typical biological reductants such as NADH-dehydrogenase [−320 mV (NHE)] (Section 5.4). However, the redox potential of tris-catecholate siderophores such as enterobactin and parabactin are considerably more negative than those of hydroxamates. Raymond and coworkers have also measured the redox potentials of Fe^{3+} complexes of synthetic tricatechols and found them to be in the range −0.8 to −1.1 V (NHE).[9,99,114,115] In the case of enterobactin the enormous stability of the Fe^{III} complex, its high specificity for Fe^{3+}, and low affinity for Fe^{2+} result in the Fe^{3+}/Fe^{2+} formal potential being highly negative. The full coordination of Fe^{3+} by all three catechol groups requires the loss of six protons. Thus there is a strong dependence of the stability of the iron(III) enterobactin complex and its reduction potential on pH. The formal electrochemical potentials for $Fe^{III/II}$ enterobactin are (at pH noted) −0.99 (>10.4), −0.79 (7.4), −0.57 (6.0), +0.17 (4.0) V (vs. NHE).[96,116] The redox equilibria have been discussed controversially for some years but there now seems to be agreement on the formulation of the redox chemistry. Below pH 6, protonation of the Fe^{III} complex and dissociation of the Fe^{II} become significant and the electrochemical reaction

is not well defined. Therefore, at pH 4 the potential has been estimated assuming no complexation of the Fe^{II} ion by enterobactin.[96] Mössbauer spectra revealed that, in a methanolic solution, Fe^{III} enterobactin undergoes protonation and a ligand-based redox reaction with the formation of a semiquinone/Fe^{II} couple under acidic conditions.[117] The reaction becomes irreversible if the solution is allowed to stand under aerobic conditions. The mechanism is described as shown in equations (6) and (7)

$$[Fe^{3+}(ent)]^{3-} + nH^{+} \longrightarrow Fe^{3+}[H_n(ent)]^{n-3}(methanol) \quad (6)$$

$$Fe^{3+}[H_n ent]^{n-3} \xrightarrow{H^+} Fe^{2+}[H_n ent]^{n-3} \xrightarrow{O_2} \text{polymeric quinones} + Fe^{2+} \quad (7)$$

5 SIDEROPHORE TRANSPORT IN MICROORGANISMS

Siderophore-mediated iron uptake in microorganisms is both a receptor- and an energy-dependent process.[4,5] Moreover, many receptor–siderophore interactions are very specific.[118–122] Therefore, unraveling the molecular basis of siderophore recognition by the cell continues to represent a major topic of siderophore research. Both the transport mechanisms and the closely related processes of metal release from the complex are of comparable importance. Various excellent books and review articles have been published on iron transport and iron transport agents in microorganisms.[4–6,8,9,123–125] At this point it should be mentioned that recently a series of specific microbial iron transport systems have been discovered which do not require siderophores in order to fulfill their central task of solving the iron-supply problem. These systems include various heme transporters,[126,127] lactoferrin transport[128] and microbial transferrin[129] (*see also* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). In addition, direct mobilization of metals from a mineral surface by membrane proteins might be another strategy of iron acquisition in microbes.[130] Merely salient features of siderophore transport will be presented in the following sections. Within the past two decades our knowledge on bacterial iron transport systems exploded. In particular, the Gram-negative bacterium *E. coli* has been analyzed in great

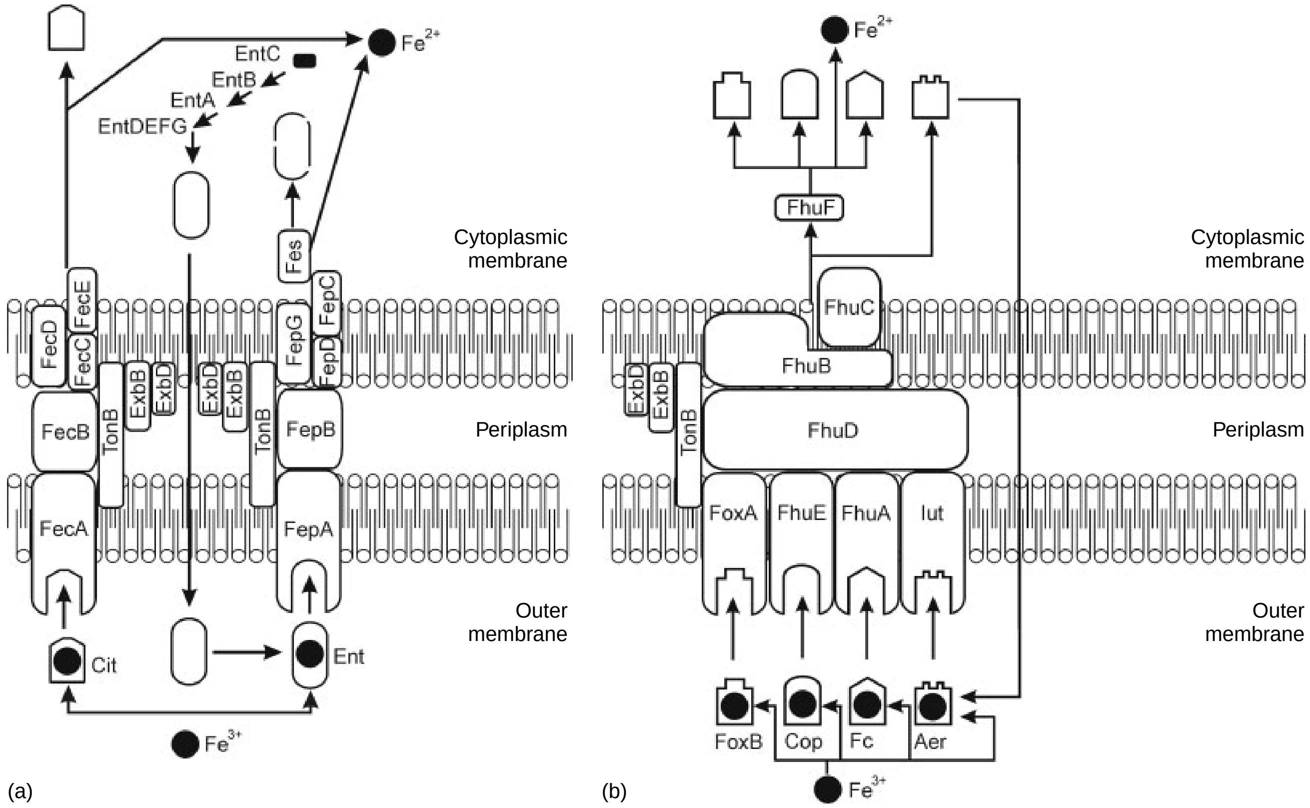

Figure 10 A schematic drawing of the cell envelope of *E. coli* consisting of the cytoplasmic membrane, the periplasm, and the outer membrane. Various proteins are shown, sets of which represent specific siderophore-transport systems. Outer-membrane receptors (OMR) shown here are FepA (enterobactin), IutA (aerobactin), Fec A (Fe^{III} dicitrate), FhuA (ferrichrome), and FhuE (coprogen, Fe^{III} rhodotorulate, and ferrioxamine B). FoxA (ferrioxamine B), is not a receptor of *E.coli*, but of the closely related *Salmonella*. Not shown here are the receptors Fiu and Cir (Fe^{III} $(DHBS)_n$; n indicates 3 possible linear degradation products of enterobactin) and FeO, a transport system for Fe^{II}. Details are discussed in Section 5.1

detail by means of genetic methods. Therefore we shall mainly focus on the model organism, *E. coli*.

Gram-negative bacteria like *E. coli* are surrounded by two membranes, the outer membrane and the cytoplasmic membrane (Figure 10).[131] Between these two layers is the compartment known as the periplasmic space, which may make up 10–40% of the total cell volume, depending on the osmotic strength of the external medium. Solutes from the medium have to diffuse, or be transported, across these three regions to reach the cytoplasm. Pores large enough to allow diffusion of siderophores through the outer membrane pose a threat to the organism, because they would also allow entry of noxious substances like detergents and antibiotics. Therefore, receptor proteins arose parallel to siderophores during the course of evolution exhibiting extraordinary specificities for individual siderophores or a small group thereof. Figure 10 depicts the proteins involved in siderophore transport in *E. coli*. These proteins are essential constituents of the different transport systems.

5.1 Siderophore Receptors

For *E. coli*, seven Fe^{3+} transport systems have been characterized.[5,132] At the level of the outer membrane, these seven transport systems are determined by specific receptors (the corresponding gene products are mentioned in parentheses) which selectively recognize the siderophores enterobactin (FepA), Fe^{III} $(DHBS)_n$ (Fiu and Cir; n indicates 3 possible linear degradation products of enterobactin),[42] aerobactin (IutA), Fe^{III} dicitrate (FecA), ferrichrome and closely related ferricrocin and ferrichrysin (FhuA), and coprogen, Fe^{III} rhodotorulate, and ferrioxamine B (FhuE). In addition, a transport system for Fe^{II} iron has been detected (Feo).[133] Only enterobactin and, in some *E. coli* strains, aerobactin are synthesized by the organism itself. The residual siderophores transported in *E. coli* are xenosiderophores produced by different microorganisms. The enormous metabolic activity aimed at iron acquisition underscores the central role that this metal plays for survival. In general, similar transport systems were identified in other Gram-negative bacteria.[134] In Gram-positive bacteria, which lack an outer membrane, the receptor protein is anchored by a covalently linked lipid. The receptor proteins are synthesized in response to iron limitation in such amounts that they become major outer-membrane proteins with copy numbers between 10 000 and 100 000 per cell.

In the past few years, crystal structures have been published of three of the seven outer-membrane-siderophore receptors from *E.coli*, namely of FepA,[134,135] FhuA,[136–138] and FecA.[139,140] FepA and FhuA represent similar monomeric transmembrane proteins that are composed of 22 antiparallel ß-strands of approximately 70 Å height (Figure 11).[140] The right-handed twist of the β-strands produces an elliptical-shaped barrel with a diameter of 35×47 Å constituting a transmembrane pore.[140] Large extracellular loops extend approx 35 Å (in the case of FepA) above the surface of the outer membrane.[141] These loops are predominantly hydrophilic but contain in addition a large number of aromatic amino acids (Tyr,Phe) and are believed to represent the region of initial siderophore contact. The globular, N-terminal domain of the receptor protein inserts from the periplasmic side into the β-barrel functioning as a plug/cork (Figure 11).

Fortunately, X-ray structures of various FhuA-substrate complexes have been determined recently allowing a more detailed analysis.[142,143] Surprisingly, siderophore binding does not trigger big changes at the extracellular side of the receptor. Some alterations are detectable in the periplasmic loops and very few in the barrel and extracellular loops. Transition from the unliganded to siderophore-liganded conformation induces local and allosteric transitions illustrating an induced-fit binding mechanism. Changes occur primarily in the N-terminal domain. The most visible change is the unwinding of the first helix ($\alpha 1$) in the N-terminal domain.[141] The mode of receptor-binding to ferrichrome and to other ferrichrome analogs discloses that it is the iron chelating hydroxamic acid portion and key groups on the peptide backbone of the siderophore that are preferentially recognized ('binding pocket'). It is noteworthy that this mode of

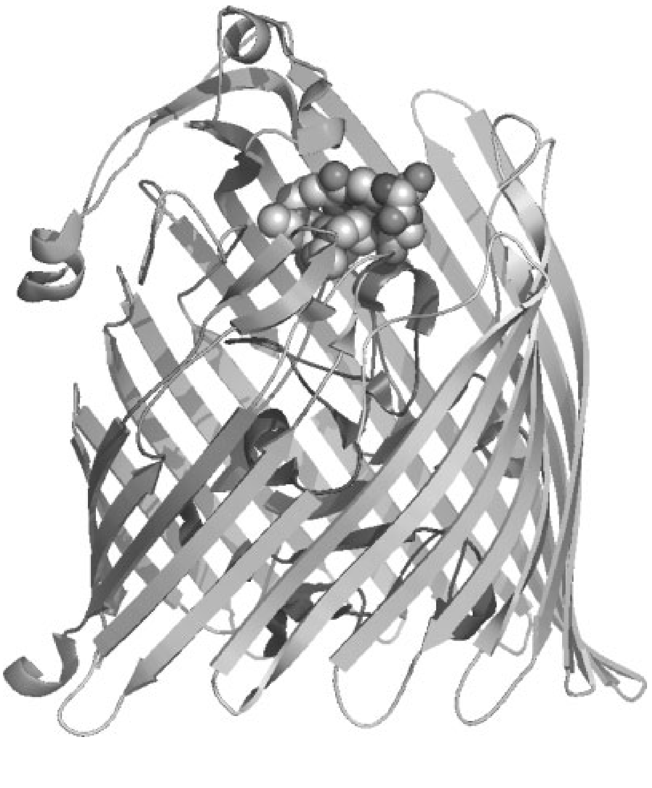

Figure 11 Crystal structure of the OM-siderophore receptor FhuA[136] with the bound siderophore ferrichrome (emphasized by a space filling atom presentation). The plot is based on PDB file 1QFF, taken from the NCBI database using the program PYMOL. Resolution of the structure is 2.70 Å, and the space group is $P6_1$. The upper side of the figure corresponds to the extracellular side of the outer membrane. See Section 5.2 for a detailed discussion

recognition was predicted already 15 years earlier based on siderophore-transport and -inhibition studies employing modified siderophores, siderophore analogs and Fe, Ga, Cr, and Rh complexes thereof (see Section 5.2). Unfortunately, a crystal structure of Fe-ent and of the Fe-ent-FepA complex is still missing. However, a recently published structure of a Fe-ent complex with the human serum protein lipocalin NGAL allows us to imagine what kind of interaction can be expected for the FepA-Fe-ent receptor complex.[144] The crystal structure disclosed a novel type of substrate binding consisting of simple ionic and concomitantly of cation-π interactions. The ionic interaction is achieved by intercalation of positively charged side chains (lysine, arginine) of the NGAL-protein between the ligand catecholates.[144]

The outer-membrane receptors exhibit two functional states. In an unenergized conformation the siderophore binds to the receptor, but is not transported through the membrane. The energized state of the receptors requires a periplasmic protein, named TonB, which serves as a coupling device between the cytoplasmic membrane and the outer-membrane receptors.[145–148] It is assumed that the above mentioned unwinding of helix α1 of the N-terminal domain facilitates the interaction of the outer-membrane siderophore-receptor complexes with TonB. All TonB-dependent siderophore membrane receptors exhibit a pentapeptide consensus sequence, termed the TonB box indicating its involvement in coupling to the TonB protein.[149,150] TonB is anchored in the cytoplasmic membrane, with the rest bridging the periplasmic space.[151] A current model proposes that TonB forms a complex of unknown stoichiometry together with two additional proteins, ExbB and ExbD, stabilizing TonB and increasing TonB activity.[152] In total, the interaction between TonB and TonB-dependent outer-membrane siderophore receptors remains enigmatic. Further intensive research will be required to fully understand the complete process of siderophore outer-membrane transport on a molecular level.[153–157]

5.2 Specificity and Stereospecificity of Siderophore Recognition Probed by Metal and Ligand Substitution

Recognition of siderophores may be dependent on different parts and structural features of the molecule: (a) the molecule as an entity; (b) the geometry and chirality of the backbone; (c) chirality or geometry at the metal center; (d) peripheral groups. As described in Section 5.1, crystal structures of siderophore-receptor proteins are now available. However, the molecular nature of the siderophore-receptor interactions is still not fully understood. In an early approach, the structural elements responsible for specific recognition were traced out by using compounds that are related to the natural siderophore, that is, by employing homologous siderophores, synthetic enantiomers, or synthetic analogs.[118–122] Moreover, diastereoisomers or geometrical isomers might affect such discriminations. Substitution of Fe^{III} iron with kinetically inert ions such as Cr^{3+} or Rh^{3+} enables separation of isomers and studies of their receptor specificity in vivo employing transport and inhibition studies. Based on metal-substituted siderophores and separated geometrical isomers, the Stereospecificity and mechanisms of uptake were studied in *E. coli*,[118,119] *Rhodotorula minuta*,[122] *Streptomyces pilosus*,[77,120] and *Neurospora crassa*.[78,121]

In *E. coli*, the Fe^{III} complexes of some synthetic analogs of enterobactin can act as iron sources and detailed kinetic and inhibition studies enabled a more precise description of the molecular groups essential for recognition by Fep A (Figures 12 and 13).[118,119] Fe-ent carries a Δ absolute configuration at the metal center, and although the synthetic Fe^{III} enantio-enterobactin does not promote growth in *E. coli*,[79] subsequent studies revealed that both enantiomers are transported.[158] Therefore, chirality is not required for receptor-binding. On the other hand, enterobactin uptake is effectively inhibited by the structural analog Fe–MECAM (Figure 12) and Rh–MECAM,[119] indicating that the trilactone backbone is also not required for recognition.

In addition, substrates which are modified at the aromatic rings (MECAMS, LICAMS) or at the amide bond connecting the 2,3-hydroxybenzoyl groups with the backbone

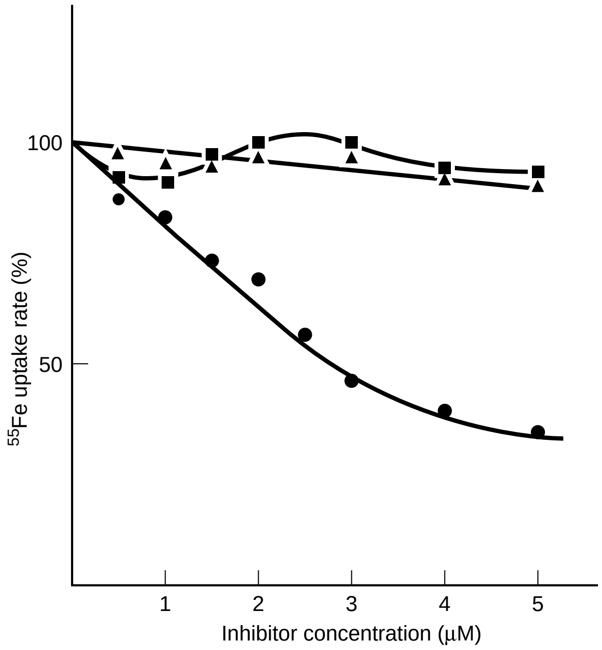

Figure 12 Inhibition of [^{55}Fe]enterobactin uptake in *E. coli* by structural analogs. The initial uptake rate (five minute interval) of [^{55}Fe]enterobactin was determined with and without inhibitor. The synthetic analogs of enterobactin, Fe–MECAM (circles), Fe–TRIMCAM (squares) and Fe–3,4-LICAMS (triangles) were added at various concentrations as potential inhibitors to the transport assay. The [^{55}Fe]enterobactin uptake rate (36 pmol mg^{-1} min^{-1} at 0.5 µM complex concentration) without any inhibitor is defined as 100%. Only Fe MECAM is an efficient inhibitor of Fe-enterobactin uptake. See text for discussion[118]

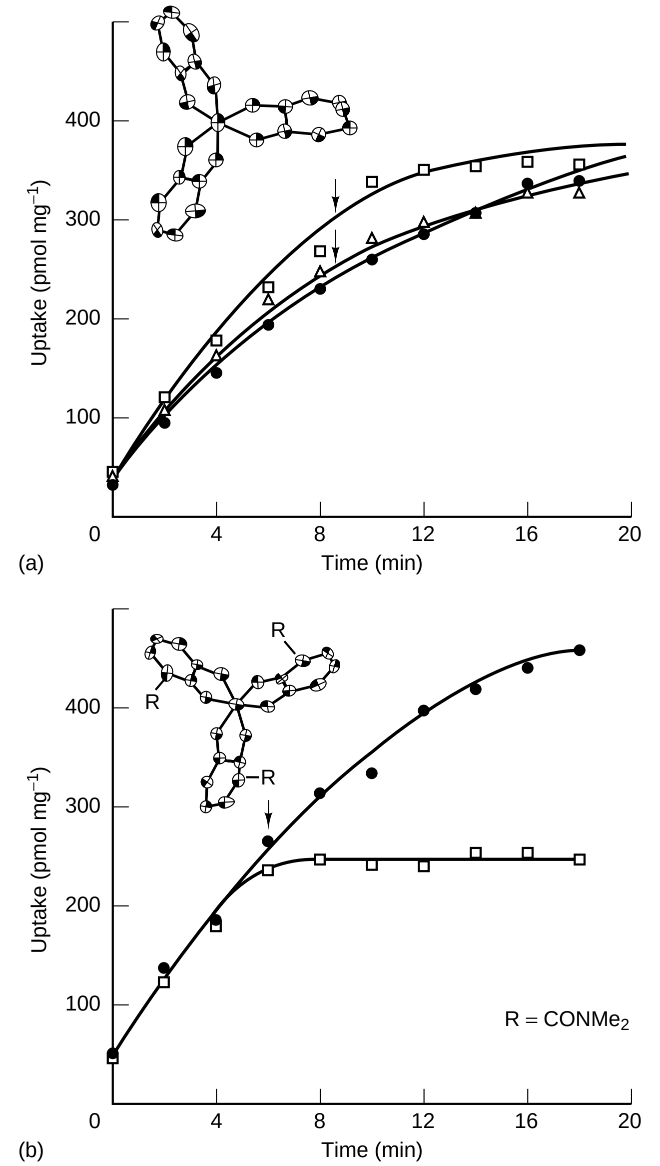

Figure 13 (a) Inhibition of 2 µM [^{59}Fe]enterobactin by $[Rh(cat)_3]^{3-}$. Control (closed circles) represents uptake of 1 µM label with no inhibitor added. Inhibition experiments: $K_3[Rh(cat)_3]^{3-}$ added at $t = 6$ min in 10-fold excess (open squares) or 100-fold excess (open triangles). (b) Inhibition of 2 µM [^{59}Fe]enterobactin by $[Rh(DMB)_3]^{3-}$. Control (closed circles) represents uptake of 1 µM label with no inhibitor added. $K_3[Rh(DMB)_3]^{3-}$ added at $t = 6$ min in 50-fold excess (open squares). (Reprinted with permission from Ref. 120. © 1988 American Chemical Society)

(TRIMCAM) are ineffective inhibitors (Figures 12 and 13).[118] From these experiments, it was concluded that the part of the molecule recognized by the receptor is the metal-binding end, but the ligand to which these functionalities are attached is not important in receptor recognition. Actually, an unsubstituted triscatechol iron center and the amide linkage is essential for recognition. These studies clearly show that modified siderophores and synthetic models are excellent tools in determining specificity of siderophore uptake at the molecular level.

Stereospecific recognition in *R. minuta* was probed with separate Λ-*trans*, Δ-*trans*, and Δ-*cis* chromium(III) RA as well as with synthetic enantio-RA.[80] The RA uptake system discriminates between RA and its enantiomeric form. It also discriminates between Λ-*trans* and Δ-*trans* isomers of $Cr_2(RA)_3$, as shown by inhibition of Fe^{III} RA uptake[80] and, finally, changes in the backbone have only little effect on uptake rates.[122] In *S. pilosus* the racemic C-*cis,cis*, N-*cis,cis*, and trans isomers of Cr^{3+} desferriferrioxamine B (see Table 2) inhibited equally well the ^{55}Fe-ferrioxamine B uptake, suggesting that no differentiation between cis and trans geometrical isomers occurs in this system.[77] Coprogen is the species-specific siderophore synthesized by *Neurospora crassa*. For Cr^{3+} desferricoprogen, two fractions were separated by HPLC, a cis complex (20% excess Λ) and a mixture of trans complexes (20% excess Δ) (see Table 2).[78] Although this separation of optical and geometrical isomers was not complete, inhibition studies suggest a predominant recognition of the Δ-*trans* isomers. In summary, these investigations revealed that the metal-center chirality and the shape of the metal-center portions of siderophores are of central importance for molecular recognition by receptors in the cell envelope.

5.3 Transport Mechanisms

After Fe^{3+} siderophores have docked at the binding pocket of the outer-membrane receptors of *E. coli*, translocation into the periplasmic space is mediated by the TonB complex. Once released into the periplasm, siderophores are rapidly bound by the specific periplasmic binding proteins FhuD (hydroxamate siderophores),[159] FepB (enterobactin),[160] and FecB (ferric dicitrate).[161] FhuD, for example, exhibits a broad substrate specificity for a variety of hydroxamate siderophores including ferrichrome, coprogen, aerobactin, ferrioxamine B, shizokinen, rhodotorulic acid, and the antibiotic albomycin. The dissociation constants of FhuD with these siderophores range from 0.3 to 5.4 µM.[162,163] X-ray structures of FhuD and FhuD-siderophore complexes[164–166] explain this broad substrate specificity. Ferrichrome bound to FhuD is exposed at the protein surface thus enabling fewer constraints to ligands than a deep cavity does.

The siderophore-loaded periplasmic siderophore-carrier proteins eventually transfer the siderophores to so-called ABC-Transporter systems (from ATP-binding cassette)[167–169] consisting of two proteins, one to span the membrane acting as a permease and a second one which can hydrolyze ATP to provide the energy for transport. The transmembrane permeases are FhuB for hydroxamates, FepDG for enterobactin, and FecCD for ferric dicitrate. The corresponding ATP-hydrolyzing proteins at the cytoplasmic side of the cytoplasmic membrane are named FhuC, FepC,

and FecE. Ferric siderophores are released from the transport system at the cytoplasmic side of the cytoplasmic membrane. Eventually, iron is rapidly released from the siderophore complex via reduction (details in Section 5.4) The molecular mechanism of siderophore transport across the cytoplasmic membrane is not yet fully understood.[170] A completely different iron transport mechanism has been suggested for an OM-transport of pyoverdin via the FpvA receptor in *Pseudomonas aeruginosa*.[171] The ligand exchange step occurs at the cell surface and involves the exchange of iron from a ferric pyoverdin to an iron-free pyoverdin strongly bound to the receptor FpvA. This mechanism suggests an increase of the iron uptake rate, with increasing concentration of iron-free siderophore. A similar transport system has been identified in the fresh water bacterium *Aeromonas hydrophila*.[172] However, in contrast to *Pseudomanas aeruginosa*, the *Aeromonas* receptor recognizes and transports an extremely broad range of siderophores, with chelating groups as varied as catecholate, hydroxamate, or hydroxopyridoxinate.

In fungal systems, only little is known about the number and spatial organization of the proteins of the siderophore-transport systems. Employing the modern methods of molecular biology some information is now available on yeasts and Ascomycetes.[173–176] Most is known on the siderophore transporters from *Saccharomyces cerevisiae* because it is the only fungus the whole genome of which is known. The yeast transporter family–as far as it is known–includes Taf1 (triacetylfusarinine C), Arn1 (ferrichromes), Enb1 (enterobactin), and Sit1 (ferrioxamine and ferrichrome transporter).[177]

In general, two different types of siderophore-transport mechanisms are operative in fungi.[8–10,178] One major path comprises transport across cell membrane(s) into the cytoplasm. In the cytoplasm, Fe^{III} is removed from the complex by a specific or unspecific ferrireductase and Fe^{II} is transferred to an intracellular Fe^{II} carrier, the structure of which has not yet been determined. Finally the metal-free siderophore is resecreted for additional solubilization–assimilation cycles. Coprogen transport into the ascomycete *Neurospora crassa* and ferrichrome transport into the yeast *Ustilago sphaerogena* are typical representatives of this mechanism. The most prominent feature of the second transport mechanism is the lack of membrane permeation by the iron complex. The extracellular siderophore complex releases the metal to a membrane-associated iron shuttle system either by ligand exchange or by reduction. A ligand exchange mechanism was found for Fe^{III} rhodotorulate transport in *Rhodotorula pilimanae*[122] (Figure 14) and a reductive removal is typical of the ferrichrome A transport in *U. sphaerogena*.

In principle, redox-relevant aspects of transport mechanisms can be determined employing Ga^{III}, Rh^{III} and Cr^{III} desferrisiderophores. The redox potentials of these metal-substituted siderophores are outside the range observed for

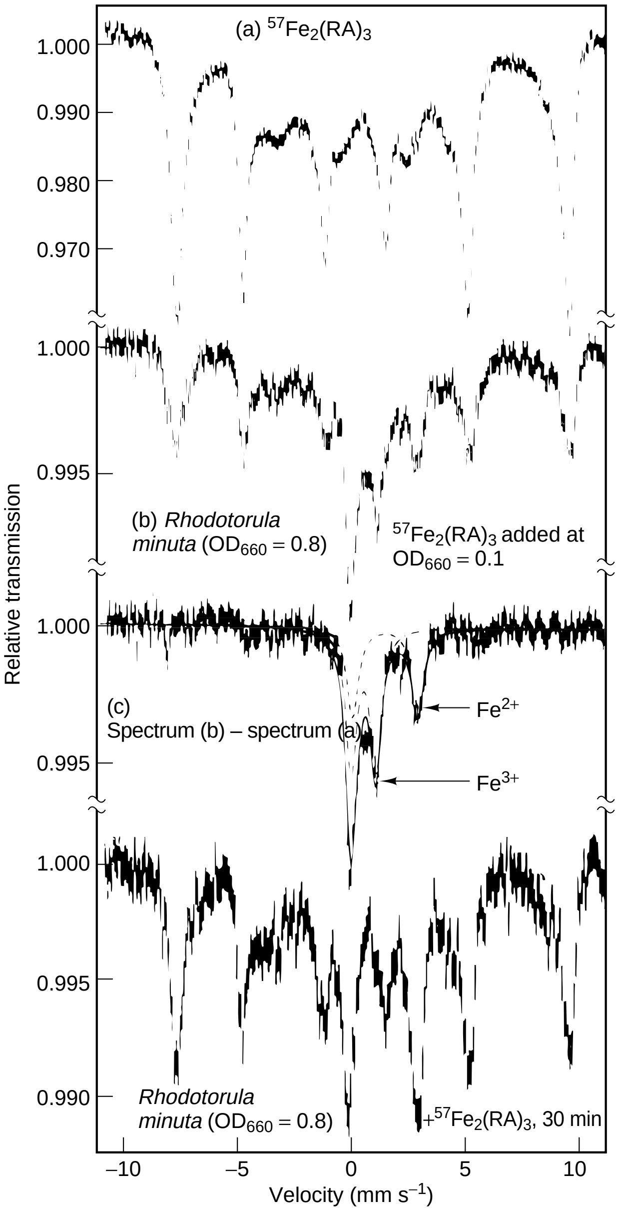

Figure 14 Mössbauer spectra of the frozen aqueous siderophore solution of [^{57}Fe]rhodotorulate, $Fe_2(RA)_3$, (a), and of the yeast *R. minuta* (b–d) at 4.2 K in a magnetic field $H_{app} = 20$ mT perpendicular to the γ-rays. Spectrum (b) corresponds to frozen *R. minuta* cells, grown in a salt medium supplied with 15 μM $^{57}Fe_2(RA)_3$ and harvested at $OD_{660} = 0.85$. The spectrum exhibits various components. The magnetically split subspectrum is due to $Fe_2(RA)_3$ (a), as can be demonstrated by subtraction (c). This indicates that $Fe_2(RA)_3$ is present in the cell. However, the metal is exchanged at the membrane level as shown by uptake studies with Cr- and Ga-substituted RA. (c) shows the residual spectrum (b) after stripping. Only two species can be observed. This metabolic pattern is similar to those found in Gram-negative bacteria.[177,179] Part (d) represents the Mössbauer spectrum of *R. minuta* at $OD_{660} = 0.8$ grown in iron-depleted medium. $^{57}Fe_2(RA)_3$ (15 μM) was added for 30 min. The $^{57}Fe_2(RA)_3$ contribution is 68% of the absorption area; the residual contribution is solely due to an Fe^{2+} high-spin species which seems to be the first iron metabolite after uptake

biological reductants. If these complexes show lack of intracellular accumulation, this could imply a reductive step during uptake. If Ga is transported and Cr is not, the uptake process should involve a ligand exchange step because Ga^{III} complexes are kinetically labile.[77,80] Detailed information on transport mechanisms and steps of iron metabolization have also been derived from in vivo Mössbauer spectroscopy (Figure 14).[179–182,183]

5.4 Reductive Removal of Iron from Siderophores In Vivo

Siderophores exhibit an affinity for Fe^{2+} that is some 20 orders of magnitude lower than for Fe^{3+}.[103] The kinetics of ligand exchange of high-spin Fe^{2+} are much faster than for high-spin Fe^{3+}.[184] Therefore, reduction of ferric siderophores accompanied by ligand exchange is an excellent mechanism for intracellular iron release. In fact, one main route of bacterial iron acquisition includes active transport of ferric siderophores across cell membranes, followed by intracellular iron removal from the siderophore carrier via reduction.[180,182,185,186] The deferrated siderophore is rapidly excreted.[186] Many flavin reductases show the property of reducing a broad spectrum of $[Fe^{3+}]$-siderophores in vitro. However, surprisingly it is not known which enzymes reduce the $[Fe^{3+}]$-siderophore in the cell.[185] Moreover, a substantial number of trihydroxamate-siderophores possess very negative redox potentials well below −320 mV at neutral pH precluding reduction via NADH or NADPH. In a very recent investigation, the Fe_2S_2-protein, FhuF, of *E. coli* has been identified as a siderophore reductase exhibiting a redox potential $E_{1/2}$ of −310 ± 25 mV vs NHE.[187]

Although the redox potential of FhuF is in the same range as NADH, FhuF is capable of reducing ferrioxamine B (see Table 4) in vitro and in vivo.[187] In fact, it has been postulated that it is the redox potential of the ternary reductase-ferric-siderophore complex rather than the redox potential of the free ferric siderophore that is important when considering reduction as a process involved in iron release.[188] In general, one has to bear in mind that a thermodynamically unfavorable process can nevertheless be driven if steady-state conditions are applied. In addition, the pH could influence the redox potential of a siderophore. For example, the midpoint potential of ferrioxamine B is −468 mV at pH 7.4, but increases to −180 mV at pH 4.5.[189]

A different strategy of intracellular iron release was found for the catechol siderophores enterobactin and parabactin. The pH 7 redox potential values for these siderophores are beyond the range of normal physiological reducing agents (see Table 4). This suggests that cellular iron release may occur by a reductive mechanism only after chemical transformation of the Fe^{III} siderophore to a form with an appropriate redox potential; an alternative process would be a significant drop in pH (e.g. in the acidic periplasm) to bring about an increase in Fe^{III} siderophore redox potential. In fact, an esterase was found in the cell extracts of *E. coli* that cleaves the ester backbone of Fe^{III} enterobactin.[190] In addition, it was demonstrated that the redox potential of the hydrolysis product $Fe(DHBS)_3$ (dihydroxybenzoylserine = DHBS) is −350 mV and within the range available from biological reductants (Table 4). Therefore, a mechanism of enterobactin-mediated iron uptake was proposed which involved an initial ester cleavage to metabolize iron. However, uptake studies with synthetic analogs which lack ester units and which are not susceptible to hydrolysis showed growth response of *B. subtilis* and of *E. coli* (see Figure 9).[191] Thus the esterase mechanism for in vivo iron release from Fe^{III} enterobactin became uncertain. An in vivo Mössbauer study of ^{57}Fe(ent) and ^{57}Fe(MECAM) uptake in the *aro*$^-$ mutant *E. coli* K12 RW193 has helped to address this problem.[192] Whereas both Fe(ent) and Fe(MECAM) are taken up as the intact complex, the rates of metabolic utilization are drastically different (70% of enterobactin-bound iron within 140 min, but only traces after two hours of Fe(MECAM) uptake). This is clear evidence for a merely slow, that is, nonspecific, utilization of MECAM-bound iron. Above all, this finding substantiates the esterase mechanism of iron removal from enterobactin. Since no appreciable amounts of $Fe(DHBS)_3$ could be detected in the enterobactin experiments, any esterase activity and reductive ligand exchange must be closely correlated. The positive growth promotion with Fe(MECAM) uptake must be interpreted as being due to a small amount of nonspecifically metabolized complex which is still sufficient for normal growth rates of *E. coli*.[192] Although the existing data provide a consistent model, there continues to be confusion on this subject. Even a recent major microbiolical review[193] incorrectly assigned the major route of iron release from enterobactin.

Another illustration of a ligand-degradation process may be seen in the case of parabactin. Parabactin also has too negative a redox potential for iron removal via a reductive mechanism. However, upon hydrolysis of the oxazoline group of parabactin to produce parabactin A the redox potential is shifted to a more positive value that is within the physiological range for Fe^{III} reduction (Table 4). Therefore, in vivo oxazoline ring cleavage followed by Fe^{III} reduction may be involved in metabolic iron removal in *Paracoccus denitrificans*.

Finally, it has to be pointed out that the formation of bulk ‘free’ $Fe_{aq}{}^{2+}$ in the cytoplasm of microorganisms is not to be expected in vivo under ‘healthy’ conditions. $Fe_{aq}{}^{2+}$ is Fenton-active and thus deleterious to cells. Therefore, it is likely that the ferrous iron is bound by a chaperone-like structure or other novel structural elements to enable sheltered intracellular transfer of this ion. In fact, an oligomeric sugar phosphate was detected in *E. coli*[194] that binds ferrous iron (cytoplasmic concentration: approximately 500 μM) intracellularly released from ferrichrome (*E. coli*[182]) or ferrioxamine E (*Pantoea agglomerans*[180]). This compound was named ferrochelatin.[195]

5.5 Siderophore Uptake Regulation

The genes coding the proteins of siderophore-transport systems and the enzymes of siderophore biosynthesis and a variety of additional genes scattered through the chromosome are regulated by the iron requirement of the organism. A protein, named Fur (*f*erric *u*ptake *r*egulation) has been identified which is responsible for the transcriptional regulation of these genes (*see* ***Metalloregulation***). The *fur* gene product acts as a classical repressor requiring Fe^{2+} as an activator.[196–198] When the internal iron concentration is high, Fur forms a complex with Fe^{II} iron, exhibiting a strong binding affinity to DNA sequences (fur boxes) in the promoter regions of all genes which are negatively regulated by iron.[199] The Fur binding prevents transcription of these genes. The crystal structure of Fur from *P. aeruginosa* uncovered a functional dimer, each subunit exhibiting an N-terminal DNA-binding domain and a C-terminal dimerization domain.[199] Two metal centers were found, a Zn^{2+}-, and a Zn^{2+}/Fe^{2+}-binding site.[199,200] The Zn-binding site probably plays an important role in maintaining the integrity of the structure. At the second site Zn is exchangeable with Fe^{2+} and hence represents the regulatory site. Binding of ferrous iron leads to local conformational changes, which in turn probably alter the DNA-binding of the DNA-binding domain. Under conditions of iron deficiency, Fe^{II} iron is removed from Fur, the binding affinity to the DNA recognition sequences is lost, and Fur-dependent genes are transcribed. In addition, it has been demonstrated by in vivo Mössbauer spectroscopy that very high intracellular levels of Fe^{II} iron are maintained even under extreme growth conditions in *fur*$^{-}$ mutants, whereas wild-type strains show high levels of Fe^{III} iron.[182,201] Therefore it has been concluded that *fur* also regulates the oxidation state of the main components of iron metabolism in *E. coli*. It is now well established that a major subclass of Fur-like proteins is mainly involved in cellular iron homeostasis (*see****Metalloregulation***). But in addition, it can function in acid tolerance and protection against oxidative stress.[202–205]

6 ADDITIONAL FUNCTIONS OF SIDEROPHORES

6.1 Siderophores as Iron-storage Compounds

The predominant class of intracellular iron-storage compounds is represented by ferritin in eukaryotes and bacterioferritin in prokaryotes (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). In various in vivo Mössbauer spectroscopic studies on siderophore uptake in fungi, it was realized that siderophores can also function as intracellular iron-storage compounds.[179,181,206] In the ascomycete *Neurospora crassa*, the transport siderophore coprogen represents an intracellular transient iron pool. A major part of coprogen-bound iron is transferred to a second siderophore, ferricrocin, which represents the long-term iron-storage form in this fungus.[206] Spores of *N. crassa* and of *Aspergillus ochraceus* are also lacking in ferritin-like iron-storage proteins. Rather, ferricrocin constituted 47% of the total iron content in *N. crassa*. In spores of *A. ochraceus*, 74% of the iron content was bound by ferrichrome-type siderophores.[181] It is safe to conclude that these siderophores are iron-storage peptides in spores. In view of the large siderophore iron-storage pools in spores, the intracellular accumulation of ferricrocin in mycelia seems to warrant an iron pool sufficiently large for sporulation. In the heterobasidiomycetous yeast *R. minuta*, the major intracellular iron pool is Fe^{III} rhodotorulate, and in the smut fungus *U. sphaerogena*, ferrichrome is found.[207] Again, no ferritins or bacterioferritins could be detected. From this the conclusion was drawn that, in various Ascomycetes and Heterobasidiomycetes, intracellular siderophores replace ferritins as iron-storage compounds. This further extends the biological role of siderophores. Whether genes for ferritin or bacterioferritin are present in these organisms remains an open question. However, ferritins definitely do not play a significant role in iron storage of these fungi.

6.2 Siderophores in Medicine

In the treatment of β-thalassemia and certain other anemias, periodic whole blood transfusions are required.[208–211] Since there is no specific physiological mechanism for the excretion of iron in man, continued transfusion therapy leads to a steady buildup of iron in the body and to deposition of iron in a number of organs, resulting in tissue damage and premature death. These iron excesses, as well as the primary iron overload diseases such as hemochromatosis and hemosiderosis, and accidental iron poisoning, require the removal of iron from the body, especially from the liver. The current drug of choice for the treatment of transfusional iron overload is the trihydroxamate siderophore desferrioxamine B. The long-term treatment with desferrioxamine B is generally well tolerated but it has two major drawbacks: lack of oral efficacy and short lifetime in the serum. Because of these limitations, there has been a wide search for new drugs with increased efficacy. Ideally, such an agent should be orally active and resistant to degradation or metabolism in the gastrointestinal tract, the bloodstream, the liver, and the kidneys. Furthermore, the drug should be effective at concentrations much lower than the gram amounts per day presently used for desferrioxamine B, should show a relatively long retention time in the body, and should have no adverse side effects. The design of such drugs continues to use siderophores as a principal model.[210–212]

Desferrioxamine B has also found therapeutic application for various pathological conditions due to aluminum overload.[213–215] Accumulation of this toxic metal is frequently observed in chronically dialyzed patients who have lost the ability to clear via renal excretion. Desferrioxamine B has also been recommended for the diagnosis of such an overload state.

For improved contrast enhancement for magnetic resonance imaging, different paramagnetic ions like Mn^{2+}, Fe^{3+}, and Gd^{3+} have been used. Gd^{3+} is particularly well suited as a contrast agent in diagnostic medical MRI due to its high magnetic moment and favorable electronic relaxation rate, However, Gd^{3+} is highly toxic at concentrations required for MRI. Therefore, chelators are required that prevent release of the free cation in vivo. Again, siderophores and their synthetic analogs serve as principal models for such chelators.[216]

As with almost any organism, iron is an essential nutrient for *Plasmodium falciparum*, the parasite causing malaria. In a series of investigations the antimalarial activities of various iron chelators were scrutinized. Some of these iron chelators exhibit activity in vitro and in animals with experimental plasmodial infections.[217] In particular, desferrioxamine B, the only chelator that is widely available for use in humans, has clinical antimalarial activity. The same siderophore was shown to inhibit growth of *Trypanosoma brucei*, another protozoic parasite causing sleeping sickness in human bloodstream.[218] However, in order to assess a siderophore or iron-chelator based therapy, extensive further investigations are required in this field. There might also be some therapeutic potential for siderophores and synthetic iron chelators in the treatment of cancers.[219,220] One strategy is aimed at the antineoplastic activity of siderophores.[221] A second strategy is focused on chelators for the clearance of non-transferrin-bound iron in serum which occurs in cancer therapy as a result of some chemotherapies.[222]

It has been shown in early inhibition studies as well as in recent crystal structures (see Sections 5.1 and 5.2) that the backbone portion of siderophores is not predominantly involved in receptor interactions; the carbon skeleton is partially solvent exposed instead. To this portion of the molecule, antibiotics may be attached. The resulting mixed compounds would be actively taken up into the cell, where the antibiotic portion of the molecule can kill the cell.[223] Indeed, the naturally occurring antibiotics albomycin and ferrimycin utilize this route for action. This ‘Trojan horse’ concept led to the synthesis of a series of siderophore-antibiotics.[224–226] Given the growing resistance, for example, of *Mycobacterium tuberculosis* and certain strains of *Pseudomonas* against antibiotic drugs currently at hand, there is an urgent need for completely new classes of antibiotics. The above mentioned approach might turn out to be of importance in the battle against pathogenic microbes and deserves therefore further intensive investigations.

6.3 Siderophore-transport Systems and Virulence

The relationship between siderophore production and bacterial growth rates has led to the belief that siderophore production contributes to bacterial virulence.[227,228] Reduced virulence of mutants deficient in siderophore production have been reported for *Yersinia pestis*, the causative agent of bubonic plague[229] and *Vibrio vulnificus*, a cholera-related pathogen associated with septicaemia arising from eating infected shell fish. It has frequently been noted that one of the host’s responses to infection is a reduction in serum iron levels, termed hypoferemia of infection. Under these conditions, the iron transport systems of the invading microorganism are expressed.[230,231] Indeed, antibodies against enterobactin and the enterobactin receptor have been detected in vertebrate serum. Very recently, it was discovered that a member of the human lipocalin-protein family, NGAL, binds Fe-enterobactin tightly (see Section 5.1).[144] NGAL is a potent bacteriostatic agent under iron-limiting conditions. Therefore, NGAL very likely participates in the antibacterial iron depletion strategy of the innate immune system. Also very important was the finding that certain invasive strains of *E. coli*, responsible for infections in vertebrates, harbor plasmids that enhance their virulence. One set of proteins encoded by these plasmids was identified as the transport system for the mixed-ligand siderophore aerobactin. It has been demonstrated in various studies that the ability to synthesize and transport aerobactin enhances virulence of bacteremic strains. Iron is not only an essential nutrient for invading microorganisms but may also serve as a regulatory signal influencing the expression of a variety of virulence factors. It is likely that iron, like calcium and constant temperature, is one of the environmental signals which serve to regulate the expression of genes required for survival and virulence in the host. There are several bacterial toxins that are derepressed under the conditions of low-iron stress typically found in a host. These include exotoxin A in *Pseudomonas aeruginosa*, the phage-mediated diphtheria toxin in *Corynebacterium diphtheriae*, the tetanus toxin of *Clostridium tetani*, and the shiga toxin of *Shigella dysentheriae*.

6.4 Other Applications of Siderophores

Siderophores have been found to bind effectively to actinides, such as Th, U, Np, and Pu.[232–234] Siderophores and other naturally occurring ligands may therefore affect actinide mobility in waste repositories and in the environment and may also be used to treat radioactive waste prior to storage or to decontaminate soils and water[234–236] Siderophores and siderophore analogs have also been investigated for possible medical use in the decorporation of actinides from the body,[232] while simple hydoxamates may have uses in the reprocessing of nuclear fuel.

1 INTRODUCTION

Lead has been known to man since antiquity, and must have been of not inconsiderable value by the second millennium BC, since the earliest known reference to it is as part of a tribute brought back to Pharaoh Thutmosis III (ca. 1500 BC) when his victorious army returned from Mesopotamia. However, its use in pottery glazes predates this by several thousand years. The use of lead in water piping and plumbing was extensive in ancient times, giving rise to the terminology used today. Unfortunately, in present times lead is associated most strongly with its toxic effects. Initially these arose from the use of lead piping for supplies of potable water, or, in ancient times, from the use of lead acetate ('sugar of lead') to sweeten food! In the past few decades, the major origin of lead toxicity has been from motor vehicle exhaust emissions resulting from the use of tetraethyllead as an 'anti-knock' agent. Other sources include the use of 'surma' (a preparation made from lead sulfide) in certain ethnic communities.

The extreme toxicity of lead results from the manifold modes of activity. In the stable state, $\geq$90% of total body lead is stored in the skeleton. Lead appears to have the capacity to seek out areas of active bone formation, where it occupies lattice interstices or exchanges with calcium in the bone apatite structure, although only ca. 0.65% of bone calcium is exchangeable. Lead in this form can be slowly released back into the bloodstream with the obvious consequences of chronic damage to major organs and soft tissue. At the chemical level, lead is capable of interrupting most of the steps in heme synthesis and porphyrin metabolism. In addition, it can inhibit the activity of many enzymes including ATPase, carbonic anhydrase, acetylcholine-esterase, and acid phosphatase, and also interfere with protein synthesis by interaction with transfer-RNA. Acute lead poisoning, which usually arises from the accidental ingestion of a soluble lead salt, is characterized by an intense thirst and metallic taste in the mouth, a burning abdominal pain, vomiting, diarrhea, hemolysis, renal damage with ologuria, shock, and coma. Chronic poisoning, due usually to accumulation of small quantities of lead in the body by either inhalation, ingestion, or skin absorption, has somewhat different symptoms. Early symptoms can be anorexia, constipation, headache, weakness, development of a black or blue line on the gums, and anemia. There may be accompanying vomiting, irritability with paralysis in more advanced cases, and renal damage. Encephalopathy with visual disturbance, persistent vomiting, ataxia, delirium, and convulsions may develop, especially in children. Organolead(IV) compounds have a specific action on the nervous tissues, leading to mental disturbance and convulsions. Treatment is usually by sequestering the lead using a strongly chelating agent such as D-penicillamine, EDTA and its salts (known usually as edetates), or BAL (British anti-Lewisite, dimercaptopropanol). Initial treatment commonly involves disodium calcium edetate in order to prevent hypocalcemia in conjunction with dimercaptopropanol, followed by longer-term treatment with D-penicillamine. Dimercaptopropanol functions by successfully competing for lead associated with the SH groups of proteins, forming stable complexes. Both edetate salts and D-penicillamine chelate lead, forming stable complexes, which are excreted in the urine.

At 13 ppm, lead is by far the most abundant of the heavier metals. This is due in large part because ^{206}Pb, ^{207}Pb, and ^{208}Pb arise as the stable end products of natural radioactive decay sequences. The most important ore is galena (PbS), but several other ores are known [cerussite ($PbCO_3$), anglesite ($PbSO_4$), pyromorphite ($Pb_5(PO_4)_3Cl$), and mimesite ($Pb_5(AsO_4)_3Cl$)]. The extraction of lead from galena involves roasting to give PbO, which is then reduced using coke and limestone or using fresh galena. The initial product contains many impurities (Cu, Ag, Au, Zn, Sn, As, and Sb), all of which can be removed prior to final purification by electrolytic methods. Most of the lead produced is used in batteries with the remainder used for solders, sheeting and tubing, cable sheathing, pigments and chemicals, and tetraethyl- and tetramethyllead. Lead compounds are widely used as pigments, as ceramic glazes ($PbSi_2O_5$), in lead crystal glass, and as stabilizers in poly(vinyl chloride) plastics for nonfood use (lead soaps). Red lead (Pb_3O_4) and Ca_2PbO_4 are used

as primers for iron and steel. Lead chromate ($PbCrO_4$) is the yellow pigment used in paints for road markings and, in conjunction with iron, blue pigments in green paints. Other lead-based pigments include red–orange $PbMoO_4$, yellow PbO, and white $2PbCO_3{\cdot}Pb(OH)_2$. Increasingly important are electroactive lead ceramic materials.

2 GENERAL TRENDS

Lead metal is soft, malleable, and ductile, and low melting (mp 327 °C, bp 1751 °C). It is very dense (11.342 g cm^{-3} at 20 °C) with a typically metallic face-centered cubic structure. The electrical resistivity is very low (20×10^{-6} Ω cm at 20 °C). Finely divided lead is pyrophoric but the reactivity is greatly reduced by the formation of a thin coherent protective layer of oxide, oxocarbonate, sulfate or chloride, depending upon the ambient atmosphere. Such coatings render the metal quite inert; hence the use of lead in the handling of hot concentrated sulfuric acid. Reactivity with mineral acids is generally very slow, although lead reacts with concentrated nitric acid, giving lead(II) nitrate and oxides of nitrogen. Lead metal and lead-containing solders react with organic acids such as acetic acid, which precludes storage of acidic foodstuffs such as citrus fruits and tomatoes in cans with solder seams. Direct reaction of lead metal with other elements at room temperature is restricted to fluorine (giving PbF_2), although chlorine, and the chalcogenides oxygen, sulfur, selenium, and tellurium, react on heating.

Inorganic compounds of lead are far more abundant in the +2 oxidation state than in the +4 state. This is a manifestation of the greater stability of the +2 state with respect to the +4 state, and is related to the *Inert Pair Effect* seen quite generally for the heavier posttransition metal p-block elements. The effect is not so much a result of low ionization energies [for lead: 715.4 (1st), 1450.0 (2nd), 3080.7 (3rd), and 4082.3 (4th) kJ mol^{-1}], rather than that the energy required to involve the s electrons is not compensated by the energy released by the formation of additional bonds. Obviously this is a rather simple view, and in practice many other factors (structure, bonding type, enthalpies of solvation, entropy effects) are also involved. It is notable, however, that in the organometallic chemistry of lead, the abundance of compounds is the converse, that is, many more organolead(IV) compounds are known.

The electronegativity of lead differs little from germanium and tin [Pauling 1.9 (cf. tin and germanium 1.8)], being somewhat lower than for carbon (2.5). Elemental radii are rather large [r(IV)(covalent) 146 pm, r(IV)('ionic' six-coordinate) 78 pm, r(II)('ionic' six-coordinate) 119 pm]. These data are only approximate guidelines, and actual values will depend upon the particular structure and bonding present in the compound under study. Nevertheless, it is to be expected that in lead(IV) compounds the bonding will be covalent in character with well-defined geometries. In contrast, in bivalent lead compounds the much larger size of the ion will make the metal center much softer and the metal–ligand bonding will be more electrostatic in character. This coupled with the large size of the metal will lead to higher coordination numbers and a greater variety of coordination geometries.

Table 1 Bond energy data

Bond	Compound	Bond energy (kJ mol^{-1})
Pb–F	PbF_4	331
Pb–F	PbF_2	394
Pb–Cl	$PbCl_4$	243
Pb–Cl	$PbCl_2$	303
Pb–Br	$PbBr_2$	260
Pb–C	$PbMe_4$	205
Pb–C	$PbEt_4$	130
Pb–H	Me_3PbH	259
Pb–Pb	Me_6Pb_2	230

Few bond energy data are available for lead (Table 1), and are rather subjective. They do, however, follow expected trends, for example, bonds to halogen are strongest with fluorine and decrease with increasing size of the halogen; bonds to carbon, hydrogen, and lead are quite weak.

3 COORDINATION GEOMETRIES

The variety of coordination geometries exhibited by lead is illustrated in Table 2, which contains examples of the principal types found. The list is extensive with coordination numbers ranging from one to twelve, but is by no means comprehensive. Many irregular coordination geometries of high coordination number are observed. The only example of multiple bonding between lead and an electronegative element are the matrix-isolated species PbO and PbO_2.

In contrast to the lighter congeners of group 14, the stability of the +II oxidation state[1] is greater than of the +IV state. Compounds in the +III state, that is, the radical species $R_3Pb{\bullet}$, are normally only transiently stable intermediates except when the R group is bulky, as in ${\bullet}Pb[CH(SiMe_3)_2]_3$. Such radicals can have extremely long lifetimes.[2]

Few compounds of the type PbX_4 (X = electronegative ligand) are stable with respect to reductive elimination to the corresponding PbX_2 compound (hence the utility of some lead(IV) compounds as synthetic reagents for oxidation reactions; see Section 7). Lead compounds with oxidation state +IV are much more common when lead–carbon bonds are present. Tetrahedral four-coordination is only observed for lead in R_4Pb (R = organic group) and R_nPbX_{4-n} derivatives which are either sterically crowded or in which the ligand X is weakly electronegative and a poor donor. Coordination

Table 2 Coordination geometries of lead compounds

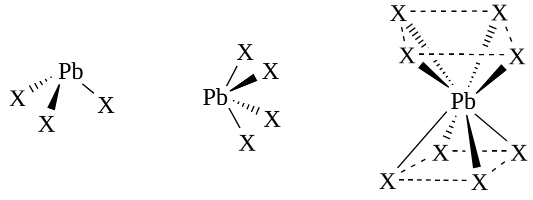
Coordination number	Geometry	Examples
1	Diatomic	PbO[a]
2	Linear	PbO_2,[d] $(C_5H_5)(CO)_2MnPbMn(CO)_2(C_5H_5)$
2	Bent	Lead(II) halides[a,c]
		$Pb[OC_6H_2Me(t\text{-}Bu_2)]_2$
		$Pb[N(SiMe_3)_2]_2$
3	Trigonal planar	$Pb(EPh)_3^-$ (E = S, Se)
3	Pyramidal	PbX_3, $PbX_2{\cdot}L$, $Pb(SPh_3)$, plumbyl radicals, R_3Pb[b]
4	Tetrahedral	R_4Pb, Ph_3Pb SAr, R_6Pb_2
4	Square pyramidal	PbO, phthalocyaninatolead(II)
4	Pseudotrigonal bipyramidal[e]	$[Pb_4(OSiPh_3)_6]O$, $Pb[(Ph_2P)_2(SiMe_3)_2]_2$
5	Trigonal bipyramidal	$Me_3Pb(O_2CMe)$, Me_3PbN_3, Ph_3PbOH, Ph_3PbCl, R_3PbX_2
6	Octahedral	Ph_2PbCl_2, $Me_2Pb(OMe)_2$, $Ph_2PbX_4^{2-}$, $Ph_2PbX_2.2L$, $[Pb(antipyrine)_6]^{2+}$, PbS, PbSe
7	Pentagonal bipyramidal	$[Ph_2Pb(O_2CMe)_2]_2{\cdot}H_2O$
8	Hexagonal bipyramidal	$[Ph_2Pb(O_2CMe)_3]^-$, $Pb(SCN)_2(C_{12}H_{26}N_2O_4)$
8	Dodecahedral	$Pb(O_2CMe)_4$
8	Square antiprismatic	$Pb(O_2CC_6F_5)_2{\cdot}2MeOH$, 34 $Pb(O_2CH)_2{\cdot}4SC(NH_2)_2$
9	Trifacially capped trigonal prismatic	$PbCl_2$, $PbBr_2$
10	Various	$Pb(SCN)_2(C_{18}H_{36}N_2O_6)$
		$Pb_3(PO_4)_2$
12	Various	$Pb(NO_3)_2$, $PbSO_4$

[a]Matrix-isolated species. [b]Unstable intermediates. [c]In the gas phase. [d]In solution. [e]One equatorial coordination site occupied by the metal(II) lone pair.

numbers higher than four are achieved wherever possible. When the lead atom is bonded to three organic groups, coordination saturation is invariably reached at five as a trigonal bipyramid. For compounds with one or two bonds to carbon, coordination saturation is usually achieved at six in an octahedral or distorted octahedral geometry, but some examples with coordination numbers of seven or eight have been characterized.

Two factors combine to lend a greater diversity in the stereochemistry for bivalent lead compounds: the increased radius of lead(II) compared with that of lead(IV) and the presence of a nonbonding pair of electrons.[3] When the nonbonding pair of electrons occupies the isotropic 6s orbital as in, for example, the complex cations $[Pb\{SC(NH_2)_2\}_6]^{2+}$,[4] $[Pb(antipyrine)_6]^{2+}$,[5] and various trispyrazolylmethane derivatives,[6] or when they are donated to conductance band levels as in the binary lead selenide and telluride or the perovskite ternary phases $CsPbX_3$ (X = Cl, Br, I),[7,8] the metal coordination is regular. However, in the majority of compounds an apparent vacancy in the coordination sphere is observed, which is usually ascribed to the presence of the nonbonding pair of electrons in a hybrid orbital and cited as evidence for a stereochemically-active lone pair. Being large and soft, metal–ligand bonding is electrostatic in nature and the demands of the ligands determine in large part the particular stereochemistry adopted in any particular case.

Examples of compounds exhibiting the two-coordinate 'bent' or 'V'-shaped geometry are relatively uncommon, and only when the two ligands are very bulky do they occur under ordinary conditions. The preferred coordination geometries for lead(II) are pyramidal three-coordination (**1**) and four-coordination based upon a distorted pseudotrigonal bipyramid (**2**), where the stereochemically-active lone pair occupies an equatorial coordination site. Much higher coordination numbers in a variety of geometries are also abundant. Square-antiprismatic eight coordination (**3**) is quite common. Several other types of coordination numbers from 7 to 12 are also observed, many of which are irregular.



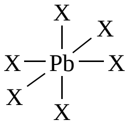
(**1**) (**2**) (**3**)

4 LEAD HALIDES AND COMPLEX HALIDES

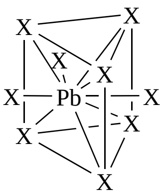
Lead forms binary halides in both oxidation states, although the tetrahalides, PbX_4, are generally much less stable than their bivalent analogs, PbX_2. Lead(IV) fluoride is the only halide of lead which is stable under ordinary conditions. It is a crystalline solid with a melting point >600 °C and obviously

has a fluorine-bridged polymeric structure. Lead(IV) chloride is described as a yellow oil and can be obtained by the action of concentrated sulfuric acid on pyridinium hexachloroplumbate. Like tin(IV) chloride it is covalent and tetrahedral, soluble in solvents such as chloroform and carbon tetrachlorade, and fumes in air. However, it is reported to decompose explosively to give $PbCl_2$ and chlorine. Much more stable are salts of the complex anions $[PbX_6]^{2-}$ (X = halide), many of which have been characterized. The two lower congeners, $PbBr_4$ and PbI_4, are of very low stability or do not exist at all. In contrast, the bivalent lead halides, PbX_2, are stable crystalline solids which can be obtained by treating any soluble lead(II) salt with halide anions, whereby the insoluble halide is precipitated. Many mixed halides, for example, PbFX (X = Cl, Br, I), and a wide range of ternary halides, for example, $CsPbX_3$,[9] Cs_4PbX_6 (X = Cl, Br, I)[10] and $[CuPbBrIL_2]_2$ (L = 2-dimethylaminoethanol),[11] have also been isolated. Many of the lead(II) halides exhibit photo and electrical properties.

Structurally, lead(II) halides only adopt monomeric molecular structures under special circumstances. Isolated molecules of the lead(II) halides (C_{2v} geometry) are only found in the vapor phase or in low-temperature rare gas matrices.[12] In the solid, variants of close-packed lattices are formed with distortions arising because of the metal nonbonding pair of electrons. The basic structural unit is usually recognizable as a trigonal bipyramid, where the metal forms three quite short bonds with angles of ca. 90°, but additional bonds or contacts are often present leading to distorted pseudotrigonal bipyramidal, octahedral (**4**), or facially capped trigonal prismatic (**5**) coordination geometries.[13]



(**4**)



(**5**)

The prototype lattice adopted by most lead(II) halides is the $PbCl_2$ lattice, which is also found for $PbBr_2$. In this layer-type lattice, the metal is surrounded by nine halogen atoms as in (**5**) from three different layers, six at the apices of a trigonal prism and three in facially capping positions. The coordination is, however, far from regular, and the metal forms three short bonds (the typical $\{MX_3\}$ structural unit) together with four additional close contacts. A further two halogen atoms are at even longer distances. However, PbF_2 crystallizes with a cubic fluorite lattice at normal temperatures, but also forms an orthorhombic modification with the $PbCl_2$ lattice structure. Lead(II) iodide crystallizes with the hexagonal anti-CdI_2 lattice in which the metal atom is surrounded octahedrally by six iodine neighbors, although a large number of modifications are known which differ in the layer sequence.[14–16]

The structure of the hydrate $3PbBr_2{\cdot}2H_2O$ is also based upon the $PbCl_2$-type structure. The lead atom is surrounded by a trigonal prism of bromine atoms, with bromine atoms, water molecules, or vacancies in the facially capping sites.[17] In the basic lead chloride, Pb(OH)Cl, the lead atom is surrounded by five chlorine atoms and three hydroxyl groups in a polyhedron best described as a strongly distorted square antiprism.[18] ^{207}Pb NMR can be used to distinguish the halide from the oxyhalide.[19]

The cesium salts $Cs[PbX_3]$ (X = Cl, Br, I) exhibit two crystal modifications, one in which the coordination at the lead atom is distorted octahedral and a second perovskite phase in which the lead has ideal octahedral coordination.[7–10] Similarly, the tetramethylammonium salts $[MeNH_3][PbX_3]$ and $[MeNH_3][Pb_nSn_{1-n}X_3]$ (X = Cl, Br, I) also have the cubic perovskite lattice.[20] All three series with the perovskite structure are intensely colored and exhibit electrical conductivity because of the population of lattice conduction bands by the lead nonbonding electrons.[21] Regular octahedral coordination is very common with the iodides, presumably largely due to steric reasons, there being little room for lone pair stereoactivity, and is found in orthorhombic $RbPbI_3$ and the hydrates $KPbI_3{\cdot}2H_2O$, $NH_4PbI_3{\cdot}2H_2O$, and $RbPbI_3{\cdot}2H_2O$, which all comprise double chains of edge-sharing $[PbI_6]$ octahedra held together by the cations and all, in the case of the hydrates, water molecules.[22,23] Lead(II) chloride iodide has a distorted trigonal bipyramidal geometry.[24]

Of current interest because of their potential as electronic materials are layered perovskite-type lead iodide compounds of general composition $(RNH_3)_2(MeNH_3)_{n-1}Pb_nI_{3n+1}$, of which representative examples are $(Ph(CH_2)_2NH_3)_2PbI_4$ and $(Me(CH_2)_8NH_3)_2(MeNH_3)Pb_2I_7$.[25]

5 LEAD PSEUDOHALIDES

Lead(II) cyanide, $Pb(CN)_2$, a yellowish white powder, lead(II) cyanate, $Pb(NCO)_2$, as white needles, and lead(II) thiocyanate, $Pb(NCS)_2$, also as white needles, have all been known for a long time. Like the lead halides, the pseudohalides also form complexes with donor molecules (e.g. $Pb(NCS)_2{\cdot}L_2$, L = phen, terpy)[26,27] and complex anions (e.g. $[Bu_4N][Pb(N_3)_6]$).[28] In general, the coordination of the lead(II) pseudohalides and their complexes is irregular with a high coordination number for lead.

6 OXIDES AND OTHER CHALCOGENIDES

Lead forms several binary oxides and a large number of ternary oxides, several of which have important electronic

and other technological applications. Lead monoxide, PbO, forms two modifications, a red, tetragonal modification (litharge) stable at room temperature and a yellow, orthorhombic modification (massicot) stable at temperatures above ca. 490 °C. These oxides are of considerable interest because they exhibit photoactivity over a wide range of electromagnetic radiation wavelengths and are used in the manufacture of ceramic silicate glasses and porous electrodes in lead acid batteries. Tetragonal lead(II) oxide forms a layer-lattice structure with square pyramidal coordination and equal lead–oxygen distances. The metastable orthorhombic modification has a similar, but more loosely bound layer structure with two short and two longer lead–oxygen distances. The structure of both modifications can be visualized as a face-centered cubic array of lead atoms, as in lead metal, swelled and distorted by the introduction of double layers of oxygen atoms between each second layer of lead atoms. However, whereas the lead and oxygen layers in litharge are flat, the [100] sheets in massicot are strongly corrugated, producing significant differences in both the thickness and separation of the layers.[29]

Like SnO_2, maroon-colored PbO_2 exhibits the rutile structure with the lead atom in almost ideal octahedral coordination.[30] A second black, orthorhombic modification of PbO_2 is formed at high pressures.[31] PbO_2 is a good oxidizing agent, and in air decomposes on heating to give, via intermediate compositions of $Pb_{12}O_{19}$, $Pb_{12}O_{17}$, and Pb_3O_4, ultimately PbO. The black, vitreous monoclinic sesquioxide, Pb_2O_3, can also be obtained by decomposing PbO_2 or PbO at 580–620 °C under a pressure of oxygen (1.4 kbar). The mixed valence oxide Pb_3O_4, made by heating PbO at 450–500 °C, consists of chains of edge-sharing ($Pb^{IV}O_6$) octahedra linked by pyramidal [$Pb^{II}O_3$] units, and finds commercial application as a pigment and a primer. The two intermediate oxides, $Pb_{12}O_{19}$ and $Pb_{12}O_{17}$, both form defect fluorite structures with ordered anion vacancies. Materials with nonstoichiometric intermediate compositions can also be formed in which the anion defects are quasi-random in nature.[32,33]

Many ternary and mixed oxides of lead with both lead(II) and lead(IV) are known. These are usually obtained by heating stoichiometric mixtures of PbO or PbO_2 with the appropriate metal oxide, hydroxide, or carbonate. A variety of structural types are observed and some examples are given here. Potassium, rubidium, and cesium orthoplumbates, M_4PbO_4 (M = K, Rb, Cs), all contain isolated [PbO_4] tetrahedra, as does Rb_3NaPbO_4.[34–36] The structure of the 'metaplumbate', Li_2PbO_3, is a variant of the NaCl-type lattice, with octahedrally coordinated lead,[37] whilst the diplumbate, $K_2Li_2[Pb_2O_8]$,[38] and the triplumbates, $M_2Li_{14}[Pb_3O_{14}]$ (M = K, Rb, Cs),[39] contain the discrete [Pb_2O_8] and [Pb_3O_{14}] units, respectively. Sodium plumbate(II), Na_2PbO_2, has a layer lattice, although the analogous silver salt contains infinite $[PbO_2]_{2\infty}{}^{\infty-}$ chains.[40]

Several ternary oxides are electroactive.[41] The mixed ion lead oxides $PbFe_{2n}O_{3n+1}$ ($n = 6$, 5, 2.5, 1, 0.5) are ferrimagnetic but not as commercially attractive as $BaFe_{12}O_{19}$. Structurally characterized Ce_5Pb_3O orders ferrimagnetically at Tc = 46 K.[42] However, several ternary oxides with the perovskite structure have become extremely important. The most important of these are lead titanate, $PbTiO_3$ (PT) (ferroelectric below 490 °C),[43] lead zirconate, $PbZrO_3$ (PZ) (ferroelectric below 230 °C),[44] lead hafnate, $PbHfO_3$ (antiferroelectric below 215 °C),[45,46] mixed lead titanate zirconate (PZT),[47] $PbTi_xZr_{1-x}O_3$, lanthanide-doped PZT,[48,49] $Pb(Fe_{1/2}Nb_{1/2})O_3$ (PFN),[50,51] and $Pb(Mg_{2/3}Nb_{1/3})O_3$ (PFN). These materials are characterized by large dielectric constants, PFN having a magnitude of 2000 at 60 Hz. Related materials such as the tungsten bronze-type lead niobate, $PbNb_2O_6$ (ferroelectric up to 560 °C), the perovskite lead magnesium niobate, $Pb(Mg_{1/3}Nb_{2/3})O_3$, and lead zinc niobate, $Pb(Zn_{1/3}Nb_{2/3})O_3$, also find important applications.

Mixed-metal oxide halides such as $Pb_3Te_2O_6X_2$ and $Pb_3Te_2O_4X_2$ (X = Cl or Br) are interesting structurally as well as having potential utility as ion exchange and optical materials.[52] However, no simple hydroxide of lead exists. Hydrolysis of lead(II) salts yields oxolead ions of which many types, depending on the conditions, particularly the pH,[53] have been isolated and characterized crystallographically. The $[Pb_4(OH)_4]^{4+}$ cation, in which the lead atoms occupy the corners of a slightly distorted tetrahedron with the hydroxyl groups capping each face, is present in crystals of $[Pb_4(OH)_4]_3(CO_3)(ClO_4)_{10}\cdot 6H_2O$,[54] $[Pb_4(OH)_4](ClO_4)_4$,[55] and $[Pb_4(OH)_4][O_2C_6H(NO_2)_3\text{-}2,4,6]$.[56] The homologous $[Pb_6O(OH)_6]^{4+}$ cation is present in the α- and β-modifications of $[Pb_6O(OH)_6](ClO_4)_4\cdot H_2O$[57,58] and in $[Pb_6O(OH)_6](ReO_4)_4\cdot H_2O$,[59] the latter being obtained by heating ReO_3, PbO, and water at 523 K. This cation is made up of three [Pb_4] tetrahedra sharing common faces, with the unique oxygen atom located at the center of the central tetrahedron rather like in the structure of the neutral molecule $Pb_4O(OSiPh_3)_6$.[60] The six hydroxyl groups are located above each of the six unshared faces of the two terminal tetrahedra. From neutral solutions the hydrated oxide formulated variously as $3PbO\cdot H_2O$ or $Pb_3O_2(OH)_2$ but actually $Pb_6O_4(OH)_4$ can be isolated.[61] This contains the adamantane-like [Pb_6O_8] cluster as the central feature in which the eight faces of a slightly distorted octahedron of lead atoms are capped by oxygen atoms. Adjacent {$Pb_6O_4(OH)_4$} units are linked by a network of hydrogen bonds. Like the thallium compound $TlPb_8O_4Br_9$, the mixed lead oxide bromide $Pb_9O_4Br_{10}$ contains the {Pb_8O_4} core.[62] While the nucleus of this structural unit is a {Pb_4O_4} cube similar to that found in $[Pb_4(OH)_4](ClO_4)_4$, the overall structure may be considered as four {Pb_4O} tetrahedra similar to that in $Pb_4O(OSiPh_3)_6$ fused together. The bromine atoms are located around the periphery of the {Pb_8O_4} cluster. In bis[hydroxylead(II)] 5,5′-azotetrazolediide the hydroxylead cation has an infinite one-dimensional structure in which the lead atoms have the three-coordinated pyramidal structure, although there are two

additional weak interactions with nitrogen atoms from the anions.[63]

Lead(II) sulfide (black), selenide (gray), and telluride (white) all adopt the cubic NaCl-type structure. PbS is an intrinsic semiconductor which can develop either n-type or p-type properties depending upon the level of impurities or stoichiometric imbalance. All three compounds are photoconductors, and are widely used in photoelectric cells and as IR detectors.[64] Many ternary and even more complex sulfides are known, many as minerals, for example, $PbSnS_2$ (teallite), $AgPbAsS_3$ (marrite), $PbAgSbS_3$ (freislebenite), $Pb_2Bi_2S_5$ (cosalite), and the plagionite series, $Pb_{3+2n}Sb_8S_{15+2n}$ ($n = 0-3$).[13] Binary lead(IV) chalcogenides do not exist.

7 CARBOXYLATES AND OXYACID DERIVATIVES

Apart from lead(IV) acetate, $Pb(O_2CMe)_4$, and lead(IV) trifluoroacetate, $Pb(O_2CCF_3)_4$, both of which have found extensive use as selective oxidizing agents in organic synthesis, lead(IV) sulfate, $Pb(SO_4)_2$, essentially all lead derivatives of oxyacids and organic acids contain bivalent lead. The lead nitrate oxalate hydrate, $Pb_2(NO_3)_2(C_2O_4).2H_2O$, provides another example.[65] Many are well known, for example, lead(II) acetate, $Pb(O_2CMe)_2$, $Pb(NO_3)_2$, $PbSO_4$ (used for the gravimetric determination of sulfate), $PbSeO_4$, $PbCO_3$ (the mineral cerussite), and a multitude of phosphates, phosphites, and hypophosphites. Many basic salts, for example, the basic carbonate $2PbCO_3{\cdot}Pb(OH)_2$ once widely used as a white pigment, and basic phosphates of which many have been reported, and mixed halide carbonates, $PbX_2{\cdot}PbCO_3$ (X = Cl, Br), and halide phosphates (lead apatites), $3[Pb_3(PO_4)_2]{\cdot}PbX_2$ (X = F, Cl, Br, I, OH), are known. The nitrate and acetate are very soluble in water, in which they can be made from PbO and the appropriate acid, and are used widely for the preparation of other lead compounds. The nitrate has a highly symmetric structure in which the arrangement of lead ions is face-centered cubic with the nitrate anions in between. In contrast, lead(II) nitrite monohydrate, $Pb(NO_2)_2{\cdot}H_2O$, has a very irregular structure with two lead atoms in two types of coordination. Both have contacts to seven nitrite oxygen atoms and one water oxygen atom, but they differ in the number of contacts to nitrogen atoms: in one case there are contacts to two and in the other only to one nitrogen.

A number of lead salts of the halogen oxyacids are known including the chlorite, $Pb(ClO_2)_2$, chlorate, $Pb(ClO_3)_2$, bromate, $Pb(BrO_3)_2$, iodate, $Pb(IO_3)_2$, and perchlorate, $Pb(ClO_4)_2{\cdot}3H_2O$. The latter, like the nitrate, is extremely soluble in water and so serves as a useful source of soluble Pb^{2+} cations. One note of caution, however, concerns the bromate. If preparation is attempted using lead(II) acetate, the highly dangerous double salt $Pb(BrO_3)_2{\cdot}Pb(O_2CMe)_2$, may be formed which *explodes violently at 165 °C* but can also *detonate at room temperature on impact.*

Lead(IV) acetate is obtained from Pb_3O_4 and glacial acetic acid as an air-sensitive crystalline solid. The mode of action of lead(IV) acetate as a synthetic reagent has been well documented.[66] Many types of substrate (alcohols, diols, phenols, oximes, alkenes, amines, diamines, carboxylic acids, cyclopropanes, etc.) can undergo reaction. The initial step is invariably the formation of a tris(acetato)lead(IV) derivative of the substrate. Further reaction usually involves homolysis of the intermediate Pb–O bond although heterolysis may occur depending on the reaction conditions and the substrate. Two examples are shown here: oxidation of a carboxylic acid (Scheme 1) and the cyclization of an alcohol (Scheme 2). The former follows a free-radical chain process forming radicals, R•, or carbocations, R^+. Products can be formed from either. Primary R• radicals abstract hydrogen from solvent, giving the corresponding RH. The carbocations can react in a variety of ways, losing H^+ to form an alkene, reacting with acetic acid to form an ester, reacting with the solvent or another functional group within the molecule, or undergo rearrangement.

The structures of lead(II) carboxylates and their complexes are quite varied and are characterized by intermolecular association and high coordination numbers at lead.[67,68] Both bridging and chelating carboxylate groups are found. A few illustrative examples are described here. The simplest, lead(II) formate, $Pb(O_2CH)_2$, has a three-dimensional polymeric structure in which adjacent lead atoms are bridged by formate groups. Both oxygen atoms of each ligand form bonds to two different lead atoms, and therefore each formate group links four neighboring lead atoms. The resulting stereochemistry at lead is that of a distorted dodecahedron, with the lead forming three short bonds and five longer bonds to oxygen. No vacancy in the coordination polyhedron is apparent, and hence the bivalent lead lone pair in this case is not stereochemically active and is confined to the 6s orbital.

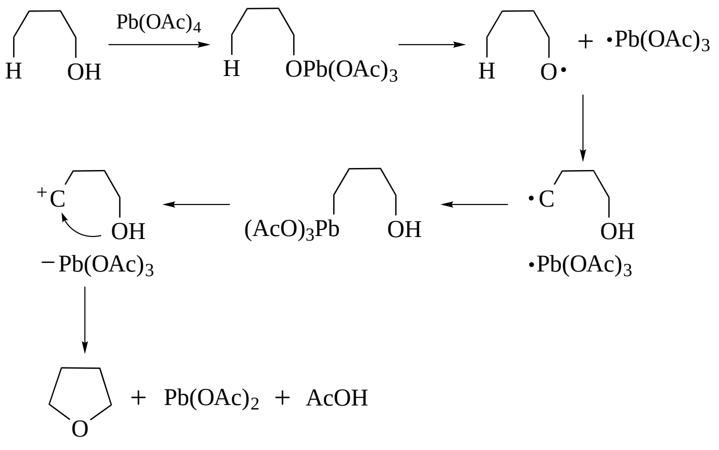
$$Pb(OAc)_4 + RCO_2H \longrightarrow Pb(OAc)_3OCOR \text{ (or } Pb(OAc)_2(OCOR)_2\text{)}$$

$$Pb(OAc)_3OCOR \longrightarrow {\bullet}Pb(OAc)_3 + R{\bullet} + CO_2$$

$$R{\bullet} + Pb(OAc)_3OCOR \longrightarrow R^+ + {\bullet}Pb(OAc)_2OCOR + OAc^-$$

$${\bullet}Pb(OAc)_2OCOR \longrightarrow Pb(OAc)_2 + R{\bullet} + CO_2$$

Scheme 1



Scheme 2

The other common type of eight coordination, square antiprismatic, is exhibited by lead(II) bis(pentafluorophenylbenzoate bis(methanol) solvate. Each lead atom is coordinated by two symmetrically chelating carboxylate groups and the two methanol solvate molecules. One oxygen atom of each carboxylate group is also bonded to an adjacent lead atom, thus forming a one-dimensional chain. The resulting square-antiprismatic stereochemistry is distorted in such a way that the four upper oxygen atoms are more opened out than the lower four, suggesting stereochemical activity for the lead lone pair.

Both lead(II) acetate trihydrate[67,69] and the pyridine complex of lead(II) benzoate have one-dimensional chain structures, but are quite different in nature. The lead atoms in the former again have a distorted square-antiprismatic coordination, but in this case only one acetate group participates in bridging, symmetrically chelating the lead atom and forming longer bonds to both of the adjacent lead atoms in the chain. The other acetate group exhibits anisobidentate coordination. The coordination polyhedron is completed by three water molecules at rather long Pb–O distances.

The lead(II) benzoate–pyridine complex is only seven coordinate. Nevertheless, the relationship of the coordination polyhedron to square antiprismatic is quite apparent, with one site unoccupied. The square base of the antiprism is formed by contacts to adjacent lead atoms by the bridging carbonyl oxygen atoms of the benzoate groups, and is nearly planar. The three upper sites are occupied by the two nonbridging oxygen atoms of the benzoate groups and the pyridine nitrogen atom. The bridging in the chain is thus similar to that in $Pb(O_2CC_6F_5)_2\cdot 2MeOH$, with each carboxylate group chelating one lead whilst bridging to an adjacent lead atom. The two types of bridging do, however, differ in that in the pentafluorobenzoate complex, each of the two carboxylate groups bridges to different adjacent lead atoms in the chain, whilst in $Pb(O_2CPh)_2\cdot py$, both groups bridge to the same lead. The question of possible stereochemical activity for the lead lone pair in this case is quite interesting. The four oxygen atoms of the square base of the antiprism are significantly opened out such that the lead is almost coplanar with the four oxygen atoms, suggesting lone pair–bond pair repulsion. However, if the stereochemistry is examined more closely, it can be seen that the pyridine ring is oriented in such a way as to largely occupy the vacant site, although at a large enough distance from lead so as to preclude both Pb···N and Pb···ring interactions.

The stereochemistry exhibited by (phenanthroline)lead(II) acetate dihydrate is very unusual. Each lead atom is chelated by the phenanthroline and the two acetate groups, giving a $[(phen)Pb(O_2CCH_3)_2]$ unit, the geometry of which is highly distorted. The origin of the distortion appears to be due to the formation of weakly bound dimers, of which there are two different types in the crystal and which are interlinked by a system of hydrogen bonds involving the water molecules. The two halves of each dimer unit are held together by very weak carboxyl bridging and possibly a weak Pb–Pb interaction. The Pb–Pb distances in the two dimers are 4.05 and 3.73 Å (cf. Pb–Pb distance in lead metal, 3.50 Å). Quite notably, of all the structures described here, this complex exhibits the weakest carboxyl bridging yet has the shortest Pb–Pb distance.

8 SOLUTION STUDIES

In solution, lead compounds invariably participate in equilibria involving a variety of species. Two methods have been employed for investigations in this area, potentiometry[53] and ^{207}Pb NMR.[70] The latter is quite convenient, and with $I = 1/2$, abundance = 21.1%, and sensitivity = 9.13×10^{-3} (cf. ^{13}C, sensitivity = 1.59×10^{-2}), ^{207}Pb is relatively easy to observe. Since the chemical shift range is very large (ca. 4000 ppm), very subtle changes in the electronic distribution about lead may be detected. The simplest parameters to vary in solution are the concentration of

the solute and the pH. Advantages of the NMR method are that solutions of solvents other than water may be investigated and at solute concentrations much higher than those customary for potentiometry. Typical results are illustrated here.

Lead-207 NMR spectra invariably exhibit a single line indicative of the presence of equilibria which are rapid on the NMR timescale.[70] More recently, the first two-dimensional ^{207}Pb-^{1}H heteronuclear multiple-quantum correction (HMQC) NMR spectra have been reported for Pb(II)-EDTA complexes in solution.[71] The chemical shift observed for aqueous solutions of lead(II) perchlorate occurs at extremely high field (−2880 ppm at infinite dilution) and corresponds to the hydrated lead(II) cation, $[Pb(H_2O)_n]^{2+}$. The efficient shielding of the lead nucleus is most probably a result of the localization of the lead(II) lone pair in the isotropic 6s orbital, and that the shift is essentially invariant with concentration indicates that this is the only species present at all concentrations. The chemical shifts of aqueous lead(II) nitrate solutions are also at very high field, but in this case exhibit concentration dependence varying from −2961 ppm at 1 mol dm^{-3} to −2854 ppm at 0.01 mol dm^{-3}. At low concentrations the predominant species is again the hydrated lead(II) cation, but at higher concentrations the equilibrium (shown in equation 1) occurs with an association constant, K, of 1.23 dm^{-3} mol^{-1} at 25 °C. Large changes in chemical shift are observed for aqueous solutions of lead(II) acetate. In the concentration range 0.25–1.0 mol dm^{-3}, the variation in chemical shift is relatively small (−1429 to −1370 ppm), but at concentrations of less than 0.1 mol dm^{-3}, the chemical shift moves rapidly to higher field, reaching a value of −1956 ppm at a concentration of 0.01 mol dm^{-3}. In this case, the equilibrium involves the dissociation of an acetate ligand from the neutral hydrated bis(acetato)lead(II) (equation 2)

$$[Pb(H_2O)_n]^{2+} + NO_3^- \rightleftharpoons [Pb(NO_3^-)(H_2O)_m]^+ \qquad (1)$$

$$[Pb(O_2CMe)_2(H_2O)_p] \rightleftharpoons [Pb(O_2CMe)(H_2O)_q]^+ + {}^-O_2CMe \qquad (2)$$

with a dissociation constant of 0.014 mol dm^{-3} at 25 °C. By varying the temperature, thermodynamic quantities for the equilibrium, $\Delta H_{298} = -14.2$ kJ mol^{-1}, $\Delta G_{298} = 10.5$ kJ mol^{-1}, and $\Delta S_{298} = -82.9$ J K^{-1} mol^{-1}, may also be accessed. Unlike potentiometry, NMR can be used to study equilibria in nonaqueous media. Lead(II) pentafluorobenzoate is insoluble in water but freely soluble in THF, and in this solvent the chemical shift change from −1258 ppm at 0.3 mol dm^{-3} to −959 ppm at 0.06 mol dm^{-3} corresponds to an equilibrium between monomer and dimer solution species with an association constant of 0.14 mol dm^{-3} at 25 °C.

Using potentiometry,[53] several oxolead species have been shown to be present in aqueous solutions of lead(II) nitrate, depending on the pH and the concentration of solute. At low pH (<6) the principal species is the $[Pb(OH)]^+$ cation, but as the pH increases more associated species including $[Pb_3(OH)_4]^{2+}$, $[Pb_3(OH)_5]^+$, $[Pb_4(OH)_4]^{4+}$, and $[Pb_6(OH)_8]^{4+}$ are present, the more associated species being more abundant at higher pH levels. In general, solutions involve a complex series of equilibria, the positions of which are dependent on a number of variables.

9 LEAD(II) ALKOXIDES

Poorly characterized insoluble, polymeric lead(II) alkoxides of formula $[Pb(OR)_2]_n$ have been reported to form via the decomposition of trimethyllead methoxide (R = Me) or by substitution of dicyclopentadienyllead(II) or lead(II) salts such as the iodide or nitrate (R = Me or t-Bu).[72,73] The most general method for the synthesis of lead(II) alkoxides is by the protolysis of $Pb[N(SiMe_3)_2]_2$ by the appropriate alcohol, and two well-defined lead(II) alkoxide polymers have been characterized, lead(II) isopropoxide and lead(II) 2-methoxyethoxide.[74] Both are isostructural in the solid, and comprise one-dimensional chains with bridging alkoxide groups and pseudotrigonal bipyramidal coordination at lead. However, by increasing the steric bulk of the organic group the aggregation can be broken down completely, and red monomeric, 'V'-shaped lead(II) 2,6-di-t-butylphenoxide has been obtained by substitution of $PbCl_2$ and also by protolysis of $Pb[N(SiMe_3)_2]_2$ using the corresponding phenol. In between these two extremes, a variety of aggregation numbers are found.[75] Stirring PbO with Me_3SiOH in THF affords $Pb(OSiMe_3)_2$ which is dimeric in benzene[76] (cf. the adamantane-like cluster $Pb_4O(OSiPh_3)_6$ which is obtained by the reaction of $Pb(C_5H_5)_2$ and Ph_3SiOH).[60] Dimeric $[Pb(O\text{-}t\text{-}Bu)_2]_2$ is formed together with the cluster $Pb_4O(O\text{-}t\text{-}Bu)_6$ by the reaction between $Pb[N(SiMe_3)_2]_2$ and t-BuOH in dilute pentane at −70 °C, but $Pb_4O(O\text{-}t\text{-}Bu)_6$ is the only product when the reaction is carried out at higher concentrations or temperatures.[77] Similar oxoalkoxide clusters are obtained by metathesis between lead(II) acetate and NaO-i-Pr or NaO-t-Bu. By contrast, the reaction of $PbCl_2$ with three equivalents of NaO-t-Bu affords the sodium plumbate $Na_2Pb_2(O\text{-}t\text{-}Bu)_6$, which reacts with $PbCl_2$ to give trimeric $Pb_3(O\text{-}t\text{-}Bu)_6$.[78] This compound, which has also been obtained by the alcoholysis of $Pb[N(SiMe_3)_2]_2$,[74] has an unusual structure with nonequivalent lead atoms, with the central six-coordinated lead being bridged to the two three-coordinated lead atoms by alkoxide groups. Many variations of this structural type have been synthesized starting either from $Pb_3(O\text{-}t\text{-}Bu)_6$, $Na_2Pb_2(O\text{-}t\text{-}Bu)_6$, or $PbI_2\cdot$dioxane.[78,79] For example:

$$\frac{2}{3}Pb_3(O\text{-}t\text{-}Bu)_6 + M(O\text{-}t\text{-}Bu)_2 \xrightarrow[M = Ca, Sr, Ba]{} Pb(O\text{-}t\text{-}Bu)_3M(O\text{-}t\text{-}Bu)_3Pb \qquad (3)$$

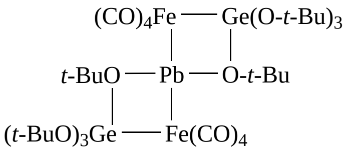
$$2PbI_2\cdot dioxane + 3Ca(O\text{-}t\text{-}Bu)_2 \longrightarrow Pb(O\text{-}t\text{-}Bu)_3Ca(O\text{-}t\text{-}Bu)_3Pb + 2CaI_2 \qquad (4)$$

$$\mathrm{Na_2Pb_2(O\text{-}\mathit{t}\text{-}Bu)_6 + MCl_2 \xrightarrow[\mathrm{M = Cd,\ Mn,\ Zn}]{} 2NaCl + Pb(O\text{-}\mathit{t}\text{-}Bu)_3M(O\text{-}\mathit{t}\text{-}Bu)_3Pb} \quad (5)$$

$$\mathrm{\frac{2}{3}Pb_3(O\text{-}\mathit{t}\text{-}Bu)_6 + \frac{1}{2}[Ge(O\text{-}\mathit{t}\text{-}Bu)_2]_2 \longrightarrow Pb(O\text{-}\mathit{t}\text{-}Bu)_3Pb(O\text{-}\mathit{t}\text{-}Bu)_3Ge} \quad (6)$$

$$\mathrm{Pb_3(O\text{-}\mathit{t}\text{-}Bu)_6 + [Sn(O\text{-}\mathit{t}\text{-}Bu)_2]_2 \longrightarrow Sn(O\text{-}\mathit{t}\text{-}Bu)_3Pb(O\text{-}\mathit{t}\text{-}Bu)_3Sn} \quad (7)$$

All are structurally similar, and lead can occupy either the central or terminal position depending on the composition and the method of synthesis. These mixed alkoxides form complexes with $Fe_2(CO)_9$, for example, $[(CO)_4Fe–Sn(O\text{-}t\text{-}Bu)_3Pb(O\text{-}t\text{-}Bu)_3Sn–Fe(CO)_4]$ in which the stannylene behaves as the donor towards iron, and (**6**) where the $[Fe(CO)_4]$ unit bridges the lead and germanium atoms.[80] Many of these compounds, $Pb_2Zn_2(C_2H_3O_2)_4(C_3H_7O_2)_4$[81] and $Pb_4Zr_2(O^iPr)_{16}$,[82] for example, are being explored as precursors to ceramic materials.



(**6**)

10 LEAD THIOLATES, DITHIOPHOSPHATES, DITHIOXANTHATES, AND DITHIOCARBAMATES

Lead(II) thiolates, $Pb(SR)_2$, are crystalline compounds readily obtained by the addition of the appropriate thiol to lead(II) acetate in ethanol.[83] Their particular use is as thiol transfer reagents[84] (equation 8).

$$\mathrm{2Me_2GeX_2 + Pb(SR)_2 \xrightarrow[\mathrm{X = Cl,\ Br}]{} Me_2(RS)GeX + PbX_2} \quad (8)$$

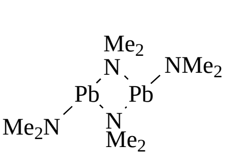
With excess thiolate anion, complex tris(thiolate) anionic species such as $[Pb(SPh)_3]^-$ can be formed.[85]

The $\{S_2E\}$ group in lead(II) dithiophosphates, $Pb[S_2P(OR)_2]_2$, dithioxanthates, $Pb[S_2COR]_2$, and dithiocarbamates, $Pb[S_2CNR_2]_2$, all function as chelating ligands towards lead.[13,86] The distorted pseudotrigonal bipyramidal geometry is common, but other geometries occur as the nature of the organic group changes and additional intermolecular Pb – S contacts are formed. Tetraethylammonium tris(ethylxanthato)lead(II), lead(II) bis(*O*,*O*′-diisopropyldithiophosphate) D-penicillaminatolead(II), and lead(II) ethanedithiolate have structures based on a pseudopentagonal bipyramidal geometry at lead.[13,85] However, in the first the apparent vacant coordination site (presumably occupied by the lead lone pair) is one of the axial sites, whereas in the others the coordination vacancy is one of the equatorial sites. The lead(II) dithiophosphates and xanthates readily form complexes with nitrogen donor ligands, for example, $Pb(S_2COPr)_2·py$, $Pb[S_2P(OEt)_2]_2·en$, $Pb[S_2P(OEt)_2]_2·bipy$, and $[Pb\{S_2P(OEt)_2\}_2]_2·en$, the structures of which are often complex and involve intermolecular Pb – S interactions.[87] One example exemplifying this observation is the oxygen-centered cluster $Pb_5O(SR_F)_8·2C_7H_8$ [R_F = 2,4,6-Tris(trifluoromethyl)phenyl].[88] It contains a central Pb_3O unit with Pb–O distance averaging 2.205 Å.

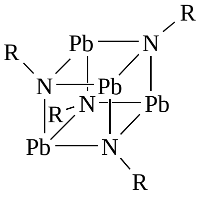
11 COMPOUNDS CONTAINING BONDS TO NITROGEN OR PHOSPHORUS

Lead(II) compounds of the general composition $Pb(NR_2)_2$ may adopt monomeric or dimeric structures depending on the nature of the organic group. Synthesis is usually by substitution of lead(II) chloride using the appropriate lithium amide. The simplest amido derivative, lead(II) dimethylamide, most probably has the dimeric structure (**7**) like the tin analog.[89] It is soluble in aprotic organic solvents and may be recrystallized from *n*-hexane at low temperature. However, it is very thermally unstable and even at −20 °C it slowly turns black and deposits a metallic mirror. The more bulky amide $Pb[NCMe_2(CH_2)_3CMe_2]_2$ still decomposes below 0 °C, but the monomeric amides, $Pb[N(CMe_3)(SiMe_3)]_2$ and $Pb[N(SiMe_3)_2]_2$ and the cyclic compound $Pb(N\text{-}t\text{-}Bu)_2)SiMe_2$ are stable under ambient conditions.[90–92] $Pb[N(SiMe_3)_2]_2$ has the monomeric ‘V’-shaped structure in both the crystal and the gas phase, although the NPbN bond angle is different (91(2)° in the gas phase and 103.6(7)° in the solid). The monomeric amidoplumbylenes are colored ($Pb[N(CMe_3)(SiMe_3)]_2$ (red), $Pb[N(SiMe_3)_2]_2$ (deep yellow), $Pb(N\text{-}t\text{-}Bu)_2)SiMe_2$ (yellow) and thermochromic, becoming very pale colored at −196 °C. Unlike the tin and germanium analogs (which afford very long-lived metal-centered $\cdot MR_3$ radicals), photolysis of the lead amides only results in the formation of a lead mirror. Reaction of $Pb[N(SiMe_3)_2]_2$ with transition metal complexes leads to either insertion or complexation.[93] Thus with $[\{Pd(\eta\text{-}C_3H_5)Cl\}_2]$ the lead(II) amide functions as a two-electron donor, cleaving the chloride bridge and forming the complex $[\{Pd(\eta\text{-}C_3H_5)Cl\}\{Pb[N(SiMe_3)_2]_2\}]$. With *trans*-$[\{Pt(\mu\text{-}Cl)Cl(PEt_3)\}_2]$, however, the product is *trans*-$[\{Pt(\mu\text{-}Cl)\{PbCl[N(SiMe_3)_2]_2\}(PEt_3)\}_2]$. Treatment of the monomeric amidoplumbylenes $Pb[N(SiMe_3)_2]_2$ and $Pb(N\text{-}t\text{-}Bu)_2SiMe_2$ with primary amines results in the formation of $\{Pb_4N_4\}$ cubane structures, for example, (**8**).[94] Reaction of $Pb(N\text{-}t\text{-}Bu)_2SiMe_2$ with $Me_2Si(NMeH)_2$ gives polymeric (**9**), and with $Sn_3(N\text{-}t\text{-}Bu)_4H_2$ a mixture of the mixed cubane cages (**10**)–(**12**).[95]

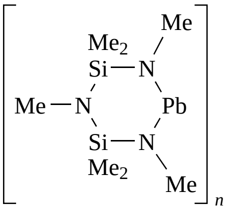
The most stable type of compounds with Pb–N bonds are those with pyrazolylborate ligands.[96] This type of complex



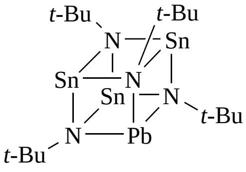
(7)



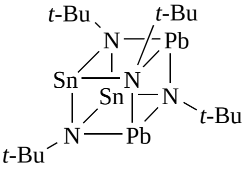
(8)



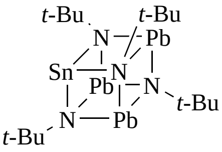
(9)



(10)



(11)



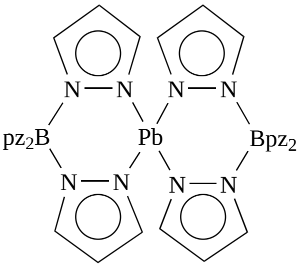
(12)

with two bis-, tris-, or tetrakis(pyrazolyl)borate ligands coordinated to lead(II) are readily prepared by the addition of aqueous solutions of $PbCl_2$ to solutions of the ligand salt (equation 9).

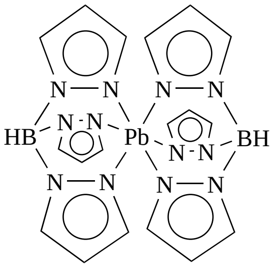
$$2K[H_nB(pz)_{4-n}] + PbCl_2 \xrightarrow[n=0-2]{} [H_nB(pz)_{4-n}]_2Pb + KCl \quad (9)$$

Similarly, the mixed compounds are obtained by addition of one equivalent of the ligand salt to solutions of $PbCl_2$. Unlike the Pb–N bonded complexes described above, the pyrazolylborate complexes are all air stable, high-melting solids. The stability is most probably derived from the chelating nature of the ligands. Typical structures are illustrated in (**13**)–(**15**). The coordination geometry at lead in $(Bpz_4)_2Pb$ is that of a distorted pseudotrigonal bipyramid with the lead lone pair occupying an equatorial site (**13**). In $(HBpz_3)_2Pb$ both ligands are terdentate, forming a six-coordinate monomeric structure (**14**). The geometry about lead is best described as based on a capped octahedron with the lone pair located in the capping position of a triangular face. The lead is again six coordinate in $[HB(3,5\text{-}Me_2pz)_3]_2Pb$ (**15**). However, in this case the geometry about lead is a trigonally distorted octahedron in which the lone pair is clearly stereochemically inactive. The difference in structure between (**13**) and (**15**) can be attributed to steric effects. The mixed $(HBpz_3)PbCl$ compound (**16**) adopts the pseudotrigonal bipyramidal geometry.

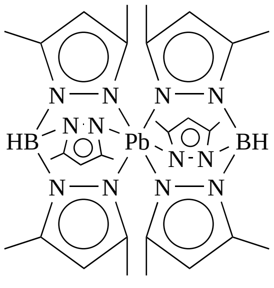
The only compounds containing lead–phosphorus bonds are $Pb[(Ph_2P)_2CH]_2$ and $Pb[(Ph_2P)_2C(SiMe_3)_2]_2$, formed as orange crystals from $PbCl_2$ and the appropriate lithium salt



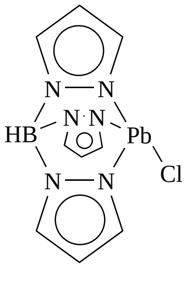
(13)



(14)

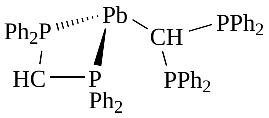


(15)

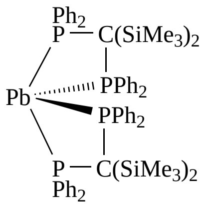


(16)

in THF. $Pb[(Ph_2P)_2CH]_2$ is highly unusual in that each of the two ligands has a different mode of coordination to the lead. One has the expected unidentate *C*-coordination while the other functions as a chelating diphosphino ligand, resulting in pyramidal coordination at lead as in (**17**). $Pb[(Ph_2P)_2C(SiMe_3)_2]_2$ has the distorted pseudotrigonal bipyramidal structure (**18**) with a stereochemically-active lone pair. In solution both compounds are fluxional.[97,98]



(17)



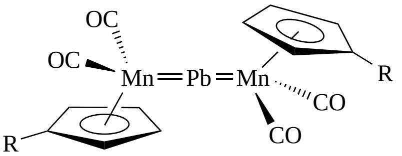
(18)

12 COMPOUNDS WITH LEAD–TRANSITION METAL BONDS

Lead forms a number of organolead compounds containing Pb–TM bonds similar to those formed by its group 4 congeners, although the range is less extensive. Examples include $Ph_2Pb\{Mn(CO)_5\}_2$, $Ph_3PbRe(CO)_5$, $Ph_2Pb\{Co(CO)_4\}_2$, $(PPh_3)_2Pt(PbPh_3)_2$, $Fe(CO)_3(PbEt_3)_2$, and $[(CO)_4FePbEt_2]_2$. Reaction of these compounds with elemental halogens results in cleavage of the Pb–M bonds.[99]

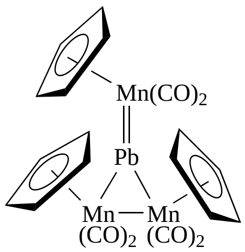
There are several nonorganometallic examples of neutral or anionic compounds in which the lead is bonded

to transition metal atoms. The simplest of these are the complexes $(C_5H_4R)(CO)_2Mn{=}Pb{=}Mn(CO)_2$ (R = H, Me) (**19**) which are obtained from $(C_5H_4R)(CO)_3Mn$ and $PbCl_2$ and contain essentially linearly coordinated lead. The Pb–Mn bond distances are significantly shortened (20–25 pm) compared to typical Pb–Mn bond distances and are consistent with truly Pb=Mn double bond character.[100] A similar linear arrangement is found[101] in the anion $[Pb\{Pt(C_6F_5)_4\}_2]^{2-}$ and also probably in $[Pb\{Fe(CO)_4\}_2]^{2-}$.[102] Treatment of $Pb[N(SiMe_3)_2]_2$ with the molybdenum hydrides $Mo(R)(CO)_3H$ (R = C_5H_5, C_5Me_5, $C_5H_3(SiMe_3)_2$) in THF affords the THF adducts $Pb\{Mo(R)(CO)_3\}_2{\cdot}THF$.[103] Solvent free complexes result from evacuation. Both types have three-coordinated lead, the solvate via THF coordination but in $Pb\{Mo(C_5Me_5)(CO)_3\}_2$ by dimer formation and carbonyl oxygen-to-lead coordination.

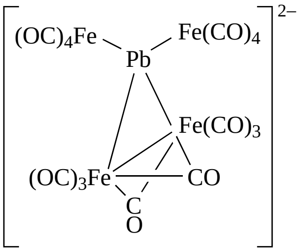


(**19**)

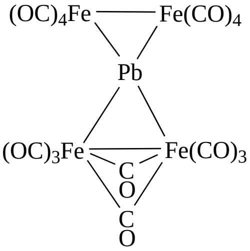
Examples of lead in three-coordinated trigonal planar and four-coordinated tetrahedral environments have also been characterized. Reaction of $(C_5H_4R)(CO)_2Mn{=}Pb{=}Mn(CO)_2$ (C_5H_4R) with excess $(C_5H_4R)(CO)_2(THF)Mn$ gives (**20**),[104,105] while a number of Pb–Fe bonded complexes including anionic $[Pb\{Fe(CO)_4\}_2]^{2-}$ and $[Pb\{Fe(CO)_4\}_3]^{2-}$ (**21**) and neutral (**22**) result from the reaction of simple lead salts with $Fe(CO)_5$ under various conditions.[102,106,107]



(**20**)



(**21**)



(**22**)

13 METALLIC CLUSTERS

Reduction of lead or lead alloys in liquid ammonia or amines gives polyatomic metal anions. Thus dissolution of the lead alloy $NaPb_{1.7-2}$ in ethylenediamine in the presence of a polydentate crypt ligand such as $[N\{(C_2H_4)O(C_2H_4)O(C_2H_4)\}_3N]$ affords the red crystalline compound $[Na(crypt)]_2{}^+[Pb_5]^{2-}$, which contains the trigonal bipyramidal $[Pb_5]^{2-}$ anion.[108] The emerald green species $[Pb_9]^{2-}$, which is stable in liquid ammonia solution, has not so far proved amenable to isolation via crypt-complexed cations. The mixed *nido*-$[Sn_{9-x}Pb_x]^{4-}$ ($x = 0$–9), $[Sn_{8-x}Pb_xTl]^{5-}$ ($x = 1$–4), and $[Pt(PPh_3)_zPb_9]^{4-}$ anionic species have been identified by NMR in solution.[109,110] Other anions prepared similarly include tetrahedral $[Pb_2Sb_2]^{2-}$[111] and trigonal bipyramidal $[Pb_2Se_3]^{2-}$ and $[Pb_2Te_3]^{2-}$.[112] Direct fusion of various elemental combinations at 700 °C leads to the formation, and in most cases production of single crystal of the cluster anions $[M_3M'][Pb_4]$ (where M = Cs, Rb, K; M′ = Na, Li). The structures are either noncapped square antiprism or tricapped trigonal prism.[113] A wide range of binary metal-lead cluster anions can be detected after laser ablation of the metals (Ti, Cr, Mn, Fe, Co, Ni, Zn,[114] Cu, Ag, Au[115]) and Pb. It is proposed that the units $[MPb_4]^-$ and $[MPb_5]^-$ are the building blocks to the $[M_xPb_y]$ cluster (albeit with M no greater than four).

Lead: Organometallic Chemistry

Hemant K. Sharma & Keith H. Pannell
University of Texas at El Paso, El Paso, TX, USA

Based in part on the article Lead: Organometallic Chemistry by R. Bruce King which appeared in the Encyclopedia of Inorganic Chemistry, First Edition.

1 Introduction 1
2 Divalent Lead 1
3 Tetravalent Lead 6
4 References 7

1 INTRODUCTION

Organometallic chemistry of lead is less developed in comparison with that of lighter group 14 elements, owing to low thermal and photochemical stability of organoplumbanes. In the early 1920s, tetraalkyl lead chemistry led to two major discoveries: thermal generation of free radicals and antiknock additives for gasoline;[1,2] however, the development of lead chemistry is clearly hampered by the environmental hazard associated with lead.

A number of reviews dealing with organoplumbanes have been published,[3–12] however, and the purpose of this contribution is to overview the advances in organometallic chemistry of lead in the last decade for both divalent lead, R_2Pb, and tetravalent lead, $R_{4-n}PbX_n$.

2 DIVALENT LEAD

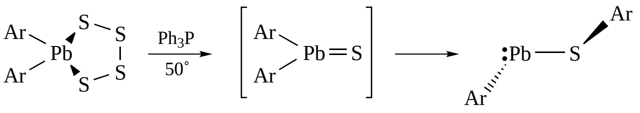
2.1 Plumbylenes

Simple dialkyl/diphenyl lead compounds, R_2Pb, are postulated as reactive intermediates in the synthesis of R_4Pb and $R_3Pb-PbR_3$ compounds. These R_2Pb species are usually unstable and highly reactive and undergo disportionation/oligomerization in the absence of stabilizing substituents on the lead atom. In general, low-valent R_2E compounds are kinetically stabilized by introducing sterically demanding substituents onto group 14 element (E = Si, Ge, Sn, Pb) and the synthetic methods for plumbylenes are restricted mainly to nucleophilic substitution of divalent lead halides and amides with organolithium or Grignard reagents[13–29] (equation 1), and the first dialkylplumbylene, $:Pb[CH(SiMe_3)_2]_2$, was obtained by Lappert in 1973,[13] from the reaction of $PbCl_2$ with $[(Me_3Si)_2CH]_2Li$ in low yield according to equation (2).

$$PbCl_2 + 2ArMgBr \longrightarrow :PbAr_2 + 2MgBrCl \qquad (1)$$

$$PbCl_2 + 2[(Me_3Si)_2CH]_2Li \longrightarrow :Pb[CH(SiMe_3)_2]_2 + 2LiCl \qquad (2)$$

Other synthetic methods are less known. For example, an aryl (arylthio)plumbylene has been obtained by unusual 1,2-aryl migration from cyclic five-membered tetrathiaplumbane by desulfurization with a triphenylphosphine[30] along with other products at high temperature according to equation (3). Presumably, the reaction occurs through the plumbathione $Ar_2Pb{=}S$ intermediate.



(3)

Another interesting dialkylplumbylene in which the lead atom is a central part of a seven-membered ring[22] with a C–Pb–C angle of 117.2° has been synthesized by nucleophilic substitution of $PbCl_2$ (Figure 1).

An unusual spectroscopic feature of the cyclic plumbylene is ^{207}Pb NMR chemical shift at $\delta 10\,050$ ppm in C_6D_6, the largest downfield shift reported for a lead compound. In general, the strong downfield chemical shift values for plumbylenes are consistent with low-coordination numbers and are in the range of (4000 – 10 500 ppm).

Significant developments have been made in the low-valent lead chemistry in the last decade and a number of thermally stable heteroleptic plumbylenes including those in which one of the organic group is replaced either by halide or sulfur have been synthesized and structurally characterized.[28–30] Plumbylenes containing heteroatoms F, N, S, and O as pendent groups are stabilized by intramolecular Pb–heteroatom interactions.[23–29] The plumbylenes, RPbX, exist as halogen-bridged dimers and trimers in the solid state (Figure 2) and provide useful reagents for the transfer of 'PbR' moiety. The X-ray diffraction studies show that the plumbylenes exist as a V-shaped monomer in the solid state and show little tendency of dimerization.

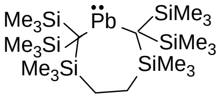


Figure 1 Cyclic plumbylene

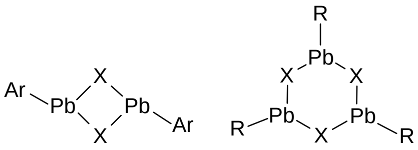

Figure 2 Halogen-bridged plumbylenes

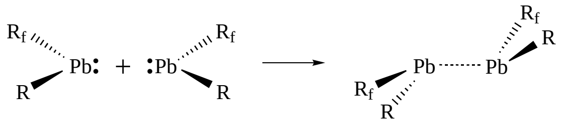
2.2 Plumbylene Dimers and Diplumbenes

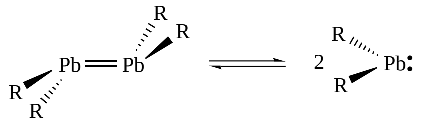
Theoretical calculations on the possibility of forming the parent diplumbene $H_2Pb{=}PbH_2$ suggested it was stable and would exhibit a bond length of 2.95–3.00 Å.[31] Several groups have attempted to synthesize such species with a series of surprising results that are very dependent upon the substituents on lead. For example, the dimerization of the heteroleptic plumbylenes R_fRPb, R = $SiMe_3$ and R_f = 2,4,6-trifluoromethylphenyl or 2-*t*-butyl-4,5,6 trimethylphenyl (equation 4),



(4)

led to interesting species with very long Pb···Pb internuclear distances.[32,33] The Pb–Pb distances of 3.370(1) Å and 3.537(1) Å were much longer than predicted for the parent diplumbene but the observed *trans*-bent configuration, with angles of 40.8° and 46.5°, respectively was in the expected range continuing the progressively nonplanar trend noted for the species from Si=Si to Ge=Ge to Sn=Sn. Dimerization of the corresponding divalent species can be thought to occur through donor–acceptor interaction between electron pair in 6s orbitals and empty 6p orbitals of two singlet plumbylenes (Figure 3).

The question whether or not these compounds are truly diplumbenes is complicated, since other systems with much shorter Pb–Pb bonds have been isolated. Indeed the first thermally stable diplumbene was obtained from the low-temperature reaction of $PbCl_2$ with the bulkier aryl Grignard reagent TipMgBr (Tip = 2,4,6-triisopropylphenyl).[34] The resulting compound had a short Pb–Pb separation of 3.0515(3) Å, only marginally longer than the calculated bond distance for $H_2Pb{=}PbH_2$, and *trans*-bent angles of 43.9° and 51.2°. The material was obtained as light and air-sensitive red crystals, and whereas in the solid state a diplumbene formulation is appropriate, in solution it readily dissociates into plumbylenes (equation 5).



(5)

Further studies on the system showed that the size of the lead substituents is crucial. For example the reaction of the less bulky 2,4,6-triethylphenyl Grignard reagent with $PbCl_2$ in THF gave an unusual product in which two plumbylenes were stabilized by the weak interactions with Br atoms of a bridging $MgBr_2$ species[35] (Figure 4).

With the even less bulky mesityl Grignard reagent, the reaction with $PbCl_2$ produced another Pb–Pb dimeric species stabilized by two terminal $MgBr_2$ molecules (Figure 5). The Pb–Pb separation in the dimer was found to be 3.3549(6) Å.[36]

The above substituent effects fail to address the question about the steric requirements for the dimerization of plumbylenes, and the reaction conditions such as solvent and temperature play a dominant role in the outcome of the reactions.

Heteroleptic diplumbenes even shorter Pb–Pb bond lengths from 2.903–2.9899(5) Å can be obtained by the substituent exchange between two homoleptic plumbylenes,[12,36] equation (6), Sisyl = $(Me_3Si)_3Si$, presumably formed by initial formation of the symmetrical diplumbene.

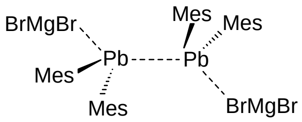

Figure 5 Plumbylene dimer stabilized by two molecules of $MgBr_2$

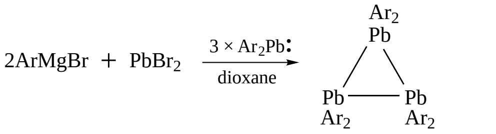
2.3 Cycloplumbanes

To further complicate the chemistry, the reaction between 2,4,6-triethylphenyl magnesium bromide and $PbBr_2$, which in THF gave the product illustrated in Figure 4, in dioxane at low temperature yielded the first thermally stable triplumbacyclopropane,[37] equation (7).

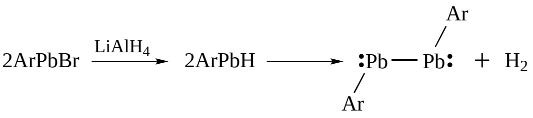


(7)

The average Pb–Pb bond length of 3.184 Å in this cyclotriplumbane is significantly longer than the single Pb–Pb bond of $Ph_3Pb–PbPh_3$, 2.844(4) Å,[38] and the aryl lead substituents are twisted by about 37° from their ideal positions. The long Pb–Pb bonds suggests that the three-membered ring is held together by weak Pb–Pb interactions in contrast to other homonuclear ring systems of group 14 elements in which the bond distances between E–E bonds indicate normal single bonds.

2.4 Diplumbyne

The first example of a species that could be thought of as a diplumbyne[39] was synthesized by the reduction of ArPbBr with $LiAlH_4$; presumably the dimerization occurs through transient ArPbH, equation (8).



(8)

($Ar = 2,6\text{-Trip}_2\text{-}C_6H_3$)

However, close examination suggests it is better thought of as a diplumbylene. For example, the Pb–Pb bond of 3.1881(1) Å, which is significantly longer than the single Pb–Pb bond $Ph_3Pb–PbPh_3$,[38] and a *trans*-bent geometry with a Pb–Pb–C angle of ∼90° indicate the lone pairs essentially remain in the 6s orbitals of each lead atom. However, stable germanium and tin analogs of alkynes have also been isolated. They also exhibit a *trans*-bent geometry and possess much shorter E–E distances, and both experimental and theoretical studies suggested an E–E bond order of approximately two.

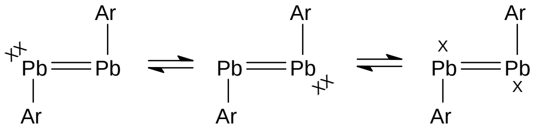


Figure 6 Bonding representations for $(ArPb)_2$

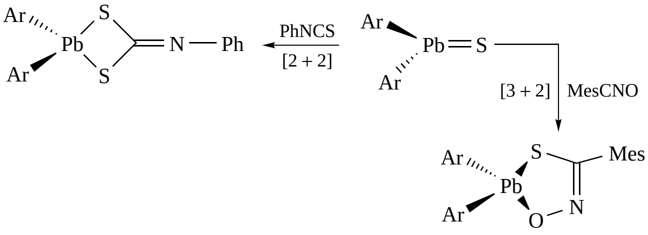
More recent studies have suggested that a more appropriate formulation of the $(ArPb)_2$ compounds may be envisaged in terms of a ‘‘diradicaloid’’ species:[40] (Figure 6)

2.5 Plumbathiones

Plumbathiones, the compounds containing Pb=S, have not been isolated yet, but as noted above, they were synthesized in situ, equation (3), and were trapped with mesitylisocyanates and phenylisothiocyanates to give [3 + 2] and [2 + 2] cycloaddition products,[41] equation (9).



(9)

2.6 Low-valent Lead Cations

The study of carbocations analogs of group 14 elements (Si, Ge, Sn, Pb) have received attention owing to their intermediacy in number of chemical transformations. The cations of group 14 have been isolated by inter- or intramolecular stabilization of the cationic center through donor ligands or by coordination through the solvent. Donor-free cations of Si, Ge, and Sn have recently been isolated and characterized.[42] The reaction of decamethyl plumbocene $(C_5Me_5)_2Pb$ with tetrafluroboric acid led to the isolation the η^5-bonded lead cation, $[Me_5C_5Pb]^+$, equation (10).[43]

$$(C_5Me_5)_2Pb + HBF_4 \longrightarrow [Me_5C_5Pb]^+[BF_4]^- + C_5Me_5H \quad (10)$$

The X-ray analysis of the salt displays the dimeric nature of the cation bridged by the fluorine atoms of the tetrafluroborate anion. Recently, Power *et al.* synthesized a one-coordinated lead cation by abstracting methyl group from an arylmethyl plumbylene with tris(pentafluorophenyl)boron in toluene at room temperature,[44] equation (11).

$$\text{Ar-Pb-Me} + (C_6F_5)_3B \longrightarrow [\text{Ar-Pb}]^+[(C_6F_5)_3MeB]^- \quad (11)$$

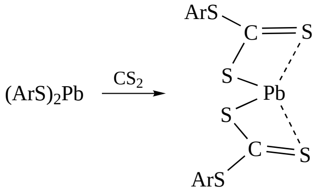
The X-ray analysis of the cation shows a weak interaction with the solvent but no close interactions between the lead and the anion. In general, the Lewis acidity of the cations is displayed by ready adduct formation with pyridine and bipyridine and the ^{207}Pb NMR resonance at 8974 ppm is consistent with low coordination of lead.

2.7 Reactivity of Plumbylenes

The reactivity of plumbylenes shows them to be useful precursors for the synthesis of various tetravalent organolead compounds. A limited number of reports show that the diarylplumbylenes inserts into MeI, CBr_4, $(PhX)_2$, X = S, Se to give corresponding tetravalent lead derivatives[8,18–20] (Scheme 1).

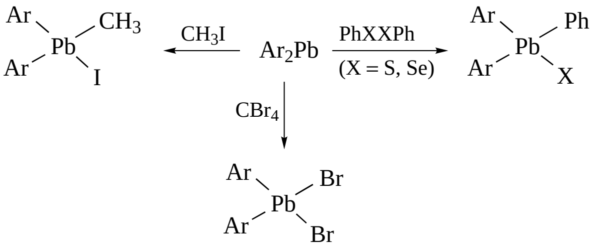
The reaction of less hindered diarylplumbylenes with elemental sulfur, S_8, gives three different types of Pb-S heterocycles, whereas the reaction of highly crowded diaryl plumbylenes gives only the aryl substituted polysulfides[20] (Scheme 2).

An interesting plumbylene stabilized by intramolecular Pb···S interactions is obtained by the double insertion of carbon disulfide into Pb–S bonds of bis(arylthio) plumbylene[45] according to equation (12).

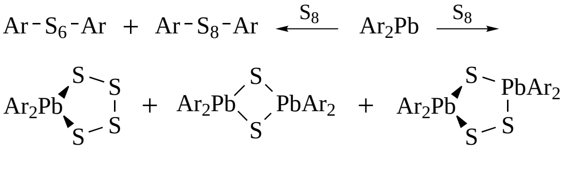


(12)

Thermally stable cyclic carbenes can act as electron donors to plumbylenes to form Zwitterionic adducts,[46,47]



Scheme 1 Formation of tetravalent lead compounds from plumbylenes



Scheme 2 Reactions of diaryl plumbylenes with S_8 showing the formation of plumbathione hetrocycles and aryl polysulfides

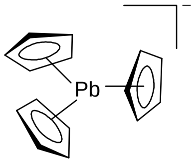


Figure 7 Structure of paddle-wheel η^5-Cp_3Pb anion

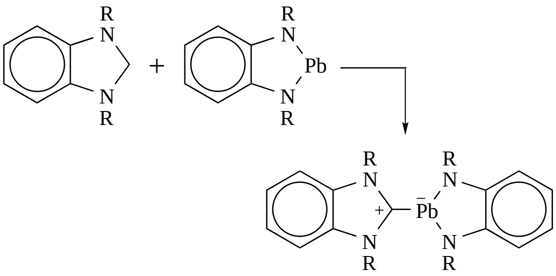
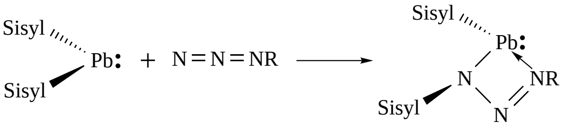
equation (13).



(13)

In the solid state, the adducts are monomeric and the three-coordinate carbene C atom is essentially planar and the Pb atom is pyramidalized with a relatively long carbene C–Pb bond, 2.586(7) Å. In solution, the adducts dissociate to free carbenes and plumbylenes.

Plumbylenes also form stable 1:1 adducts with alkylisonitriles, phosphines, and amines.[12] In an attempt to synthesize a lead imine, the reactions of bis (sisyl)plumbylene with arylazide provided an unusual four-membered heterocyclic plumbylene as shown in equation (14).



(14)

(Sisyl = $(Me_3Si)_3Si$, R = Ad)

The crystal structure revealed the pyramidal geometry around lead atom with two unequal Pb–N bonds of 2.344(7) Å and 2.372(6) Å. Similar chemistry was observed with aryl isocyanates.

2.8 Plumbocene

Plumbocene, $(\eta^5\text{-}C_5H_5)_2Pb$, (Cp = $\eta^5\text{-}C_5H_5$), was first reported by Fischer and Grubert from the reaction between Cp^-Na^+ and $Pb(NO_3)_2$ in 2:1 molar ratio in DME.[48] It is thermally unstable and monomeric in gas phase and has different structural motifs in the solid state because of flexibility of the metal-Cp bonding. The known polymorphs of plumbocene are cyclic hexamer, helical, sinusoidal, and zigzag chains bridged by the cyclopendienyl ring.[49]

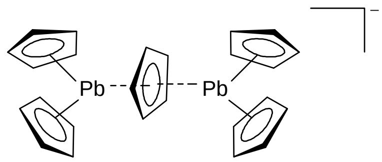


Figure 8 Structure of $[Cp_5Pb_2]^-$ anion showing bridging Cp

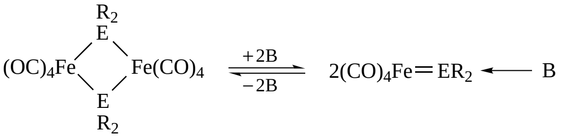
Plumbocenes exhibit rich reaction chemistry.[49–54] They undergo nucleophilic addition of Cp^- anions to produce $(\eta^5\text{-}Cp_3Pb)^-$ paddle-wheel anions containing trigonal-planar Cp_3Pb units.[50,51] The structure of the $(\eta^5\text{-}Cp_3Pb)^-$ is shown in Figure 7.

Multidecker anions are obtained if the nucleophilic addition of Cp^- anion is carried in the presence of crown ethers. For example, the oligomeric mixed salt $\{[Cp_5Pb_2]^-[Cp_9Pb_4]^-[Li(12\text{-crown-}4)_2{}^+]_2\}$ was obtained from the reaction between Cp_2Pb and CpLi in the presence of 12-crown-4.[53] The $[Cp_5Pb_2]^-$ anion, Figure 8 is formed predominantly under a broad range of different reaction conditions.

There are no close interactions between cations and anions in multinuclear complexes and this factor, along with the solvation of cations by crown ethers or cryptands, is responsible for the formation of multidecker anions in which the Cp_2Pb units are linked through bridging $\mu\text{-}\eta^5$-Cp ligand. The multidecker anion $[Cp_9Pb_4]^-$ could be thought of as the $[Cp_5Pb_2]^-$ anion bridged by two additional Cp_2Pb units, as shown in Figure 9.

2.9 Transition Metal Plumbylene Complexes

Compounds that contain bonds between lead (II) and transition metals are rare. Dimeric group 14 bridged complexes $[R_2EM(CO)_4]_2$ (M = Mn and Fe) were obtained from the reaction of $[M(CO)_4]^{2-}$ $2Na^+$ with R_2PbX_2 in THF.[55–58] In the presence of donor solvents like pyridine, THF, DMF, and acetonitrile, these complexes undergo reversible cleavage of the metal-group 14-element bond to yield base-stabilized plumbylene metal complexes,[58] equation (15).



(15)

Two spectroscopically characterized examples of base-free plumbylene complexes are $(CO)_5MoPb\{N(SiMe_3)_2\}_2$ and $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)Pb\{N(SiMe_3)_2\}_2]_2$.[59] A simple route to obtain Mo-Pb(II) complexes involves the amine elimination reaction shown in equation (16).[60]

$$2[Cp^*Mo(CO)_3H] + Pb[N(SiMe_3)_2]_2 \longrightarrow [Cp^*Mo(CO)_3]_2Pb + 2HN(SiMe_3)_2 \quad (16)$$

Bis-metallaplumbylenes containing three-coordinate lead complexes $[\{Cp^*Mo(CO)_3\}_2Pb(THF)]$ and an unusual bridging carbonyl dimeric complex $\{(Cp^*Mo(CO)_3)PbCp^*Mo(CO)_2(\mu\text{-}CO)\}_2$ were structurally characterized.[60] Plumbylene complexes of group 6 metals (M = Cr, Mo, W) were synthesized by reacting $(FcN)_2Pb$ (Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$, N = CH_2NMe_2) with metal carbonyls.[61] The M–Pb bond distances of 2.7157(4) Å, Cr; 2.8531(13) Å, Mo; and 2.8497(3) Å for W indicate some degree of π-bonding in these complexes. The geometry around Pb is distorted trigonal bipyramidal owing to Pb-N close interactions, whereas the transition metal is in a distorted octahedral environment.

In an attempt to synthesize M≡Pb triple bond complexes, Power *et al.* obtained metallaplumbylenes of the type L_nM-Pb-Ar (M = Cr, Mo, W and Ar = 2,6 $Trip_2C_6H_3$) of group 6 metals by salt elimination, as shown in equation (17).[62]

$$[(\eta^5\text{-}C_5H_5)M(CO)_3]^-Na^+ + ArPbBr \longrightarrow (\eta^5\text{-}C_5H_5)(CO)_3M\text{-}Pb\text{-}Ar + NaCl \quad (17)$$

The M≡Pb triple bond complexes were not obtained because of the inert pair effect of $6s^2$ electrons and the larger size of the lead atom, which decreased the steric protection, thus preventing the CO elimination. The special feature of these metallaplumbylene complexes is the relatively long M–Pb bonds: 2.9092(9) Å Cr; 2.9845(7) Å, Mo; 3.0055(6) Å for W, and bent geometry at lead with M–Pb–C angles is in the range of 108.6(2)–113.58(9)°. These complexes can be best described as having primarily M–Pb single bond character with lone pair of electrons localized at the lead atom.

A lead allene analog of Mn, $CpMn(CO)_2$=Pb=$Mn(CO)_2Cp$, was prepared from the reaction of the thermally labile Mn complex $CpMn(CO)_2(THF)$ with $PbCl_2$ as a reddish-brown air- and light-sensitive complex.[63,64]

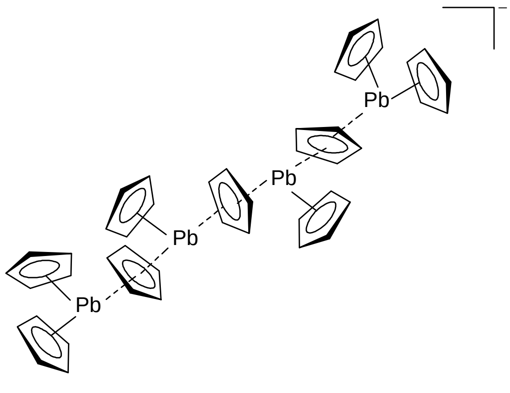


Figure 9 Structure of multidecker $[Cp_9Pb_4]^-$ anion

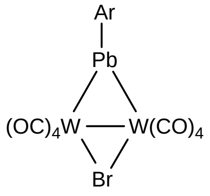


(Ar = 2,6-$Trip_2$-C_6H_3)

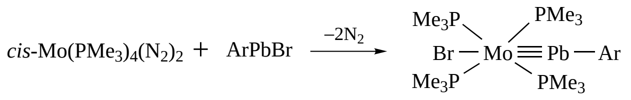
Figure 10 Bridging plumbylene tungsten complex

2.10 Transition Metal Plumbylyne Complexes

An unusual bridging plumbylyne complex was obtained in poor yield from the reaction of $W(CO)_5{\cdot}THF$ with bromoplumbylene, ArPbBr. Since the Pb atom is a three-electron donor to the metals, it may be regarded as a plumbylyne ligand, Figure 10.[28]

The structure of the complex exhibits two Pb–W bonds at 2.7517(3) Å and 2.7423(3) Å which are markedly shorter than Pb–W single bonds. The geometry around lead is distorted trigonal with acute W–Pb–W angle of 70.177(8)°. These features demonstrate some degree of double bond character between Pb–W bonds.

Recently, a first complex containing a M≡Pb triple bond has been reported and this was obtained by the reaction Mo dinitrogen complex with aryl lead bromide in toluene at ambient temperature according to equation (18).[65]



(Ar = 2,6-$Trip_2$-C_6H_3)

(18)

The complex is air sensitive but thermally stable. The Mo–Pb bond of 2.55 Å is very short and the almost linear geometry, Mo–Pb–C bond angle 177.8(2)°, clearly indicates the formation of a Mo≡Pb triple bond.

3 TETRAVALENT LEAD

3.1 Lead Oligomers

A well known reaction in lead chemistry is the synthesis of Ph_3Pb–$PbPh_3$ from phenyl Grignard reagent and lead (II) halides. The mechanism for this reaction is presumed to involve the formation of diphenylplumbylene, which then oligomerizes and disproportionates to hexaphenyldilead and metallic lead. However, repeating the above reaction at low temperature led to the isolation of unexpected oligomeric lead anion, $:[Pb(PbPh_3)_3]^-$.[66] The four Pb atoms in the anion form trigonal pyramid with Pb–Pb bonds of about 2.98A, which are significantly longer than the Pb–Pb bond in hexaphenyldilead, and the Pb–Pb–Pb angles are compressed to an average value of 93°.

3.2 Acylplumbanes

Thermally stable acylplumbanes were isolated by using bulky mesityl substituents on the lead using the simple reaction of Mes_3PbLi with acyl chlorides (R = Me, Ph), equation (19).[67]

$$Mes_3PbLi + RCOCl \longrightarrow Mes_3PbCOR \qquad (19)$$

The photochemistry of the acylplumbanes, which involves cleavage of both the Pb-acyl and Pb-mesityl bonds, is less developed in comparison with acylsilanes, which exhibit a rich vein in photochemistry.

3.3 Intra Group 14 Bonds

Attempts to synthesize lead derivatives of E = Si, Ge, and Sn with direct Pb–E bonds are unsuccessful owing to the low stability of the Pb–E bond, which is prone to undergo decomposition because of 1,2-alkyl/aryl migrations from the lead atom.[68,69] By using aryl groups on lead and the bulky substituents $E(SiMe_3)_3$ (E = Si, Ge), the migration of aryl groups from lead to group 14 element can be suppressed, thereby stabilizing the Pb–E bond and facilitating the isolation of intra group 14 derivatives. Both symmetrical and unsymmetrical aryl lead-aryl/sisyl (sisyl = $(SiMe_3)_3$) group 14 compounds were obtained by salt-elimination reactions, equation (20).[70–73]

$$Ar_3PbLi + Ar'_3EX \longrightarrow Ar_3Pb\text{–}EAr'_3 + LiX \qquad (20)$$
$$(E = Si, Ge, Sn)$$

3.4 Transition Metal-lead Complexes

The first transition metal-lead compounds were reported in 1941;[74] in general they are prone to decompose thermally, and this process is accelerated in the presence of light. A recent comprehensive review is available.[75]

The salt-elimination reaction involving the use of a transition metallate and organo-lead halides has been widely used to form metal-lead complexes, equation (21), and a range of such derivatives has been prepared for many metals: Cr,[76–78] Mo,[76–78] W,[76–78] Mn,[55,56,79] Re,[79] Fe,[57,78,80,81] Os,[82] Co,[83] Rh,[84] and Ir.[84]

$$[(CO)_5Mn]^-Na^+ + Me_3PbCl \longrightarrow [(CO)_5Mn]PbMe_3 + NaCl \qquad (21)$$

Highly reduced metal anions $[M(CO)_n]^{3-}$ (M = Mn, Re; $n = 4$; M = Co, $n = 3$) react with two equivalents of Ph_3PbCl

to provide anionic complexes that were isolated as crystalline tetraammonium salts, equation (22).[85,86]

$$[Co(CO)_3]^{3-}3Na^+ + 2Ph_3PbCl + NH_4Cl \longrightarrow (NH_4)[Co(CO)_3(PbPh_3)_2] \quad (22)$$

Complexes of Pd and Pt were synthesized by the reaction of *cis* or *trans*-$[ML_2Cl_2]$ (M = Pd or Pt; L = PEt_3 or $AsEt_3$) with triphenyllead lithium, equation (23). The red solution produced yellow crystalline solids of *trans*-$[ML_2(PbPh_3)_2]$ complexes.[87] These complexes are thermally stable.

$$[Pt(PEt_3)_2Cl_2] + [Ph_3Pb]^-Li^+ \longrightarrow trans\text{-}[Pt(PEt_3)_2(PbPh_3)_2] + 2LiCl \quad (23)$$

Oxidative addition of the relatively weak Pb–Pb, Pb–C, and Pb–Cl bonds to metal-centers is a useful reaction for the formation of Pb–M bonds, equations (24 and 25).[88–90]

$$(Ph_3P)_4Pt + Ph_3Pb\text{–}PbPh_3 \longrightarrow [(Ph_3P)_2Pt(PbPh_3)_2] + 2Ph_3P \quad (24)$$

$$(Ph_3P)_4Pt + Ph_4Pb \longrightarrow [(Ph_3P)_2Pt(PbPh_3)(Ph)] + 2Ph_3P \quad (25)$$

Addition of PbR_2 to a benzene solution of the iron complexes $CpFe(CO)_2X$ (X = I, Br or Cl) resulted in the formation of four-coordinated functionalized Fe-Pb complexes, via insertion chemistry, that is, $[CpFe(CO)_2(PbR_2X)]$.[91]

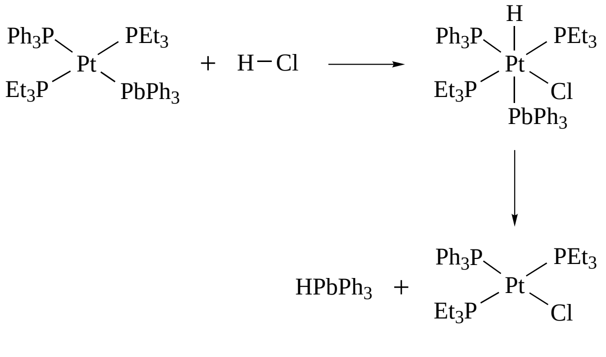
Another interesting approach for the synthesis of transition metal-lead bonds is the reaction of metal hydrides with R_3Pb–X.[92]

3.5 Reactivity of Transition Metal-lead Complexes

Metal-lead complexes can undergo the cleavage of Pt–Pb bond with halogens and halogen acids[88,93] (Scheme 3).

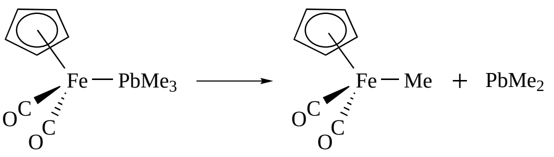
On the other hand, halogenation of the binuclear Mn complex $[Mn(CO)_5]_2PbPh_2$ with Cl_2 or Br_2 cleaves the Pb–C bond rather than the Mn–Pb bond to produce halogenated Mn-Pb derivatives, equation (26), X = Cl, Br.[56]

$$[(CO)_5Mn]_2PbPh_2 + 2X_2 \longrightarrow [(CO)_5Mn]_2PbX_2 + 2PhX \quad (26)$$



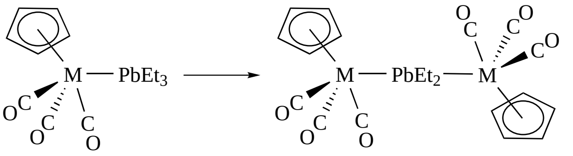
Scheme 3 M–Pb bond cleavage with halogen acid

There are several reports concerning the thermal and photochemical reactivity of triorganolead metal complexes. In general, they eliminate plumbylenes, R_2Pb, with a concurrent transfer of the organic radical to the metal center. Such chemistry is reported for platinum, iron, and molybdenum *inter alia*. A typical reaction is outlined in equation (27).[77,81,88,90]



(27)

Related disproportionations were also observed in Mn[55] and Fe[94] complexes; for example, the $Mn(CO)_5$-$PbEt_3$ complex in THF gave the *bis*-Mn complex $[Mn(CO)_5]_2PbEt_2$, equation (28).



(28)

3.6 ^{207}Pb NMR Spectroscopy of Transition Metal-lead Complexes

^{207}Pb NMR spectroscopy is a valuable method for studying transition metal-lead bond in solution. It is evident that the variations in chemical shift values with respect to the transition metal are large, for example, ^{207}Pb NMR of $[Fe(CO)_4]_4Pb$ exhibits a resonance at 3587 ppm.[57] The trends in chemical shift values are consistent with the trends observed in ^{29}Si and ^{119}Sn NMR spectra of the corresponding transition metal complexes where a comparison is possible.

Since this article was written, several notable developments in organolead chemistry have been reported. New diplumbenes,[95] a W-Pb triple bond,[96] a tri(trisbiphenylplumbyl)lead anion,[97] and new lead clusters[98] have been obtained.

Glossary

Chromophore: central atom and coordination sphere responsible for d–d and charge–transfer transitions in complex or crystal
Perturbation theory: mathematical technique for determining the effect on state energies and wavefunctions of small perturbations, for example, electric or magnetic fields

1 INTRODUCTION

The transition elements are characterized by the occurrence of stable oxidation states in which the nd subshell is partly filled. For example, the most familiar compounds of iron can be classified as containing Fe^{II} or Fe^{III}. These are deemed to contain Fe^{2+} and Fe^{3+} ions, whose ground states (*see Ground State*) are $3d^6$ and $3d^5$ respectively (*see* d^n *Configuration*). In contrast, stable oxidation states exhibited by the main group elements nearly always correspond to empty or filled subshells. The consequences of partly filled nd subshells largely determine the physical and chemical properties that characterize the transition elements. Ligand field theory (LFT) is a valuable tool for analyzing these properties, by focusing attention on the partly filled subshell. In particular, LFT recognizes that the subshell will lose its fivefold degeneracy when the atom or ion is placed in any chemical environment, that is, the five nd orbitals will no longer all have the same energy and their precise occupancies have to be scrutinized.

LFT has an important place in the historical development of inorganic chemistry. Its elegance attracted a large proportion of the 'new wave' of inorganic chemists who revolutionized the subject in the 1950s and 1960s. Inorganic chemistry texts[1–14] give elementary accounts; advanced general treatments are found in monographs.[15–32] References to more specialized reviews and articles are made in the text.

LFT has been applied to the splitting of the 4f and 5f orbitals in compounds of the lanthanides and actinides respectively.[33] This article deals only with applications to d-block chemistry.

2 CRYSTAL FIELD (CF) APPROACH

The term *Crystal Field Theory* (CFT) is often used almost interchangeably with LFT. Strictly speaking, CFT refers to an early version of what most inorganic chemists now understand to be LFT. The name is derived from the title of a classic 1929 paper by Bethe,[34] 'The Splitting of Terms in Crystals'. This shows how the methods of group theory can be used to determine what happens to the degeneracy of a spectroscopic state (term) when a free atom or ion is placed in a chemical environment having less than spherical symmetry. Bethe's approach was quickly taken up by physicists who were interested in the quantum mechanical theory of *Paramagnetism* in compounds of the transition elements. CFT was 'rediscovered' in the early 1950s by inorganic and physical chemists who extended its applications to spectroscopic, structural, thermodynamic, and kinetic properties of transition-element complexes. As discussed in Section 3, it was clear by the late 1950s that CFT, in its purest form, was untenable. However, it remains useful to this day for qualitative purposes, and, with some adjustments, can be applied to quantitative treatments of spectroscopic and magnetic observations. Thus, LFT encompasses a broader approach, which acknowledges the shortcomings of CFT while recognizing its value.

2.1 The Five d Orbitals in a Free Atom or Ion

Here, we look at the atomic orbitals (AOs) that constitute the partly filled subshell; we are dealing for the moment with free atoms/ions, as observed in the gas phase. An AO is a function of the coordinates of just one electron, and is the product of two parts: the radial part is a function of r, the distance of the electron from the nucleus and thus has spherical symmetry; the angular part is a function of the x, y, and z axes and conveys the directional properties of the orbital. The notation nd indicates an AO whose l quantum number is 2; we have five nd orbitals corresponding to $m_l = 2, 1, 0, -1$, and -2. Solving the Schrödinger equation, we obtain the angular wavefunctions as equations (1–5).

$$d_2 = (x + iy)^2 \quad (1)$$

$$d_1 = z(x + iy) \quad (2)$$

$$d_0 = \left(\tfrac{1}{2}\right)(2z^2 - x^2 - y^2) \quad (3)$$

$$d_{-1} = z(x - iy) \quad (4)$$

$$d_{-2} = (x - iy)^2 \quad (5)$$

These are acceptable for many purposes, but the complex number $\sqrt{i}$ $(= -1)$ makes them difficult to visualize. Given a set of solutions to the wave equation, which we find inconvenient, it is always permissible to transform these into an equal number of new functions obtained by taking linear combinations of the original ones, provided that orthogonality is upheld, that is, the overlap integral $\int \psi_i \psi_j \, d\tau \ (i \neq j)$ is always zero. (This procedure is utilized in other familiar situations, for example, in the construction of hybrid orbitals, and of MOs as linear combinations of AOs; *see **Molecular Orbital Theory***.) Eliminating i from equations (1–5) by equations (6–9),

$$\left(\frac{1}{2}\right)(d_2 + d_{-2}) = x^2 - y^2 \quad (6)$$

$$\left(\frac{1}{2i}\right)(d_2 - d_{-2}) = 2xy \quad (7)$$

$$\left(\frac{1}{2}\right)(d_1 + d_{-1}) = 2xz \quad (8)$$

$$\left(\frac{1}{2i}\right)(d_1 - d_{-1}) = 2yz \quad (9)$$

we have a set of mutually orthogonal functions labeled in terms of angular functions $d_{x^2-y^2}$, d_{xy}, d_{xz}, and d_{yz}; d_0 is retained as in equation (3) and relabeled as d_{z^2}. These are the familiar d orbitals, although other formulations are possible. In a free atom/ion, they are of equal energy (fivefold degenerate). As discussed in Section 4.2, the spectroscopic states of a d^n atom/ion differ in energy by amounts expressible as interelectron repulsion parameters.

2.2 CF Splitting of d Orbitals in Cubic Systems

Here we examine the d orbitals of an atom/ion in an octahedral or tetrahedral environment; these symmetries are called *cubic* because of their relationship to the cube, having three equivalent spatial directions. Symmetry arguments show that the fivefold degeneracy of an nd subshell cannot persist if the atom is in chemical combination. Even in cubic molecules and crystals, there can be no orbital degeneracy greater than three. Where the three axes are nonequivalent, there can be no orbital degeneracies at all.

2.2.1 Octahedral ML_6

Octahedral six-coordination is the most common chemical environment for the transition elements (*see **Coordination Numbers & Geometries***). Apart from the great number of octahedral complexes, the formally ionic oxides and halides usually adopt structures in which the cation is in an octahedral site. LFT is equally applicable to a complex species such as CrF_6^{3-} and to the binary halide CrF_3. For spectroscopic purposes, we say that CrF_3 and complex fluorides such as $KCrF_4$, K_2CrF_5, and K_3CrF_6 all contain the octahedral $Cr^{III}F_6$ chromophore (i.e. 'color-bearer'). Likewise, $[Cr(NH_3)_5OH]Cl_2$ contains the $Cr^{III}N_5O$ chromophore.

In the simplest CF approach, the ligands are represented by negative point charges. No covalency is explicitly considered, so that the bonding is deemed to be ionic; this may seem unduly simplistic, but CFT does not purport to be a theory of bonding in compounds of the transition elements. In a quantitative treatment, the array of point charges around the central ion is formulated as an electrostatic potential, the crystal field, whose effect on the nd subshell can be calculated by means of perturbation theory. Here we give only a qualitative treatment.

The energy of an orbital is a nebulous concept, having meaning only when an electron is in it. The effect of a negative potential field, whatever its symmetry, upon a d orbital must be to raise its energy relative to that in the free atom/ion. In quantitative treatments, the potential is divided into a spherically symmetric part (whose effect is to raise equally the energies of all five d orbitals) and a symmetry-dependent part; the latter will determine the splitting of the fivefold degeneracy. Let us place the six-point charges representing the ligands on the x, y, and z axes as shown in Figure 1. An orbital whose electron density is concentrated along the axes will be destabilized more than one that avoids the ligands/point charges. Thus, in Figure 2, we see that an electron in $d_{x^2-y^2}$ will experience a stronger field than one in d_{xy}. It should be obvious from the equivalence of the x, y, and z axes that d_{xy}, d_{xz}, and d_{yz} are equally affected and are triply (or threefold) degenerate; less obviously, $d_{x^2-y^2}$ and d_{z^2}, higher in energy than $d_{xy,xz,yz}$, are doubly (twofold) degenerate. This is best shown by symmetry arguments (there are several texts that deal with symmetry/*Group Theory*).[35–47] The effect of any symmetry operation upon a nondegenerate function is either to leave the function unchanged, or to change its sign everywhere. The effect of a symmetry operation upon any member of a degenerate set of functions may be:

a) to leave the function unchanged
b) to change its sign everywhere
c) to transform the function into one of its degenerate partners
d) to transform the function into a linear combination of two or more members of the degenerate set.

To say that the x, y, and z axes are equivalent in the O_h point group (which denotes octahedral symmetry; *see **Symmetry Point Groups***) is to assert that there exist symmetry operations that interchange these axes. Thus, if we rotate the octahedron in Figure 1 and 2 by 120° about the axis that joins the centroids of the triangular faces defined by ligands 125 and 346, we are performing the symmetry operation C_3 which transforms $x \rightarrow z$, $z \rightarrow y$ and $y \rightarrow x$. Thus, the function $(x^2 - y^2)$ becomes $(z^2 - x^2)$ and $(2z^2 - x^2 - y^2)$

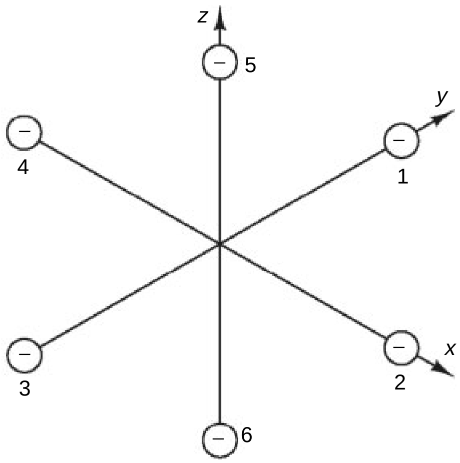

Figure 1 Six negative point charges located at ligand positions for an octahedral complex, providing the crystal/ligand field

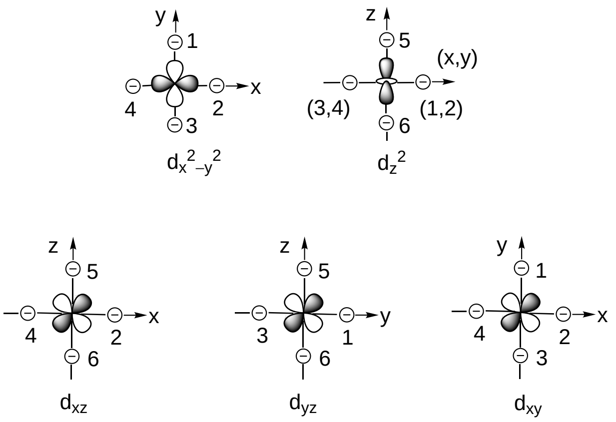

Figure 2 The five d orbitals in octahedral symmetry, with point charges as in Figure 1. Shaded areas indicate positive amplitude

becomes $(2y^2 - z^2 - x^2)$. From equations (10) and (11), we see that the $d_{x^2-y^2}$ and d_{z^2} orbitals are equivalent since under C_3, each is transformed into a linear combination of itself with its partner. We thus arrive at the CF splitting diagram shown in Figure 3.

$$(z^2 - x^2) = \left(\frac{1}{2}\right)(2z^2 - x^2 - y^2) - \left(\frac{1}{2}\right)(x^2 - y^2) \tag{10}$$

$$(2y^2 - z^2 - x^2) = -\left(\frac{3}{2}\right)(x^2 - y^2) - \left(\frac{3}{2}\right)(2z^2 - x^2 - y^2) \tag{11}$$

It is conventional to depict only the splitting owing to the nonspherical component of the field; the orbital energies are shown relative to the situation in a spherical field. Perturbation theory requires that the sum of the energies of the orbitals in an octahedral field must be equal to the

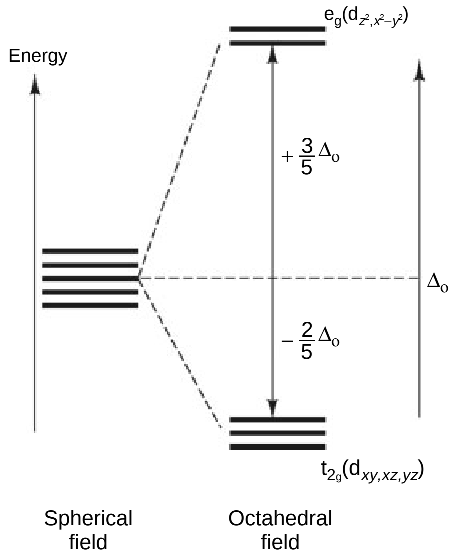

Figure 3 Splitting of d orbitals in octahedral symmetry

orbital energy in the spherical field, so that a ‘center-of-gravity’ rule applies. The splitting Δ_o is thus shown so that the twofold-degenerate d_{z^2} and $d_{x^2-y^2}$ are destabilized by $(3/5)\Delta_o$, while the threefold-degenerate $d_{xy,xz,yz}$ are stabilized by $(2/5)\Delta_o$, both relative to a spherical field. The labels e_g and t_{2g} are group-theoretical symbols, which specify the symmetry properties of the functions (more precisely, they designate irreducible representations of the O_h point group).

This diagram makes it possible to specify the occupancies of the d orbitals more precisely than would be the case if fivefold degeneracy remained, or if the orbitals were split unpredictably. For example, an octahedral complex of Cr^{III} is deemed to contain Cr^{3+} ions having the ground-state configuration $[Ar]3d^3$. We can predict from Figure 3 that the three electrons will occupy the t_{2g} orbitals; we can further assert that, to minimize interelectron repulsion energy, each of the t_{2g} orbitals is singly occupied with the electrons all having the same spin. Thus, the ground state of an octahedral Cr^{III} complex has the configuration $(t_{2g})^3$; the allocation of the three electrons to different t_{2g} orbitals, with spins parallel, specifies the ground state. In the case of an octahedral Mn^{III} complex (Mn^{3+} has the ground-state configuration $[Ar]3d^4$), the situation is less straightforward. Briefly, the ground state might be derived from $(t_{2g})^4$ (minimizing the orbital energy) or from $(t_{2g})^3(e_g)^1$ (which minimizes the interelectron repulsion). This issue is discussed in more detail in Section 4.3.4.

2.2.2 *Tetrahedral ML_4*

Tetrahedral coordination geometry is far less common than octahedral, except where the central cation is d^0 or d^{10} (of little interest in LFT).

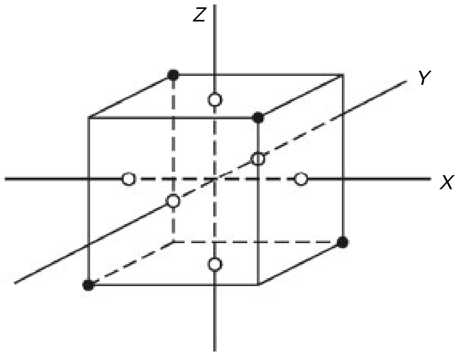

Figure 4 Relationship between octahedral and tetrahedral arrangements of point charges in the Cartesian axis system

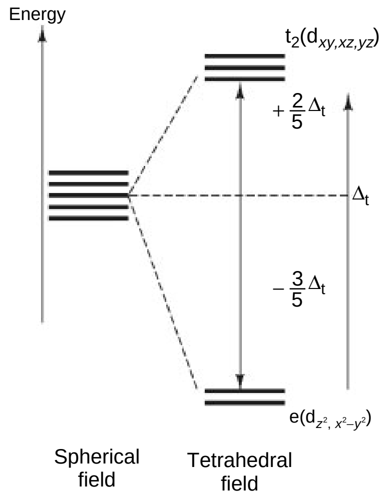

Figure 5 Splitting of d orbitals in tetrahedral symmetry

The most convenient coordinate system for a tetrahedral species is that shown in Figure 4. Qualitative inspection shows that, as in the octahedron, $d_{xy,xz,yz}$ are a threefold-degenerate set, given the equivalence of x, y, and z. The d_{z^2} and $d_{x^2-y^2}$ orbitals are likewise twofold-degenerate. However, inspection will show that the d_{z^2,x^2-y^2} pair (labeled 'e' in the notation appropriate to the tetrahedral point group T_d) interact less with the applied field than the $d_{xy,xz,yz}$ orbitals (labeled t_2; the subscripts g and u in O_h signify, respectively, symmetry or antisymmetry with respect to a center of symmetry but are inappropriate for T_d; a tetrahedron has no center of symmetry). Thus, we arrive at the splitting diagram shown in Figure 5. The splitting is smaller than that for the octahedron: the tetrahedral t_2 orbitals obviously point less directly at the ligands than do the octahedral e_g. Electrostatic calculations give $\Delta_t = (4/9)\Delta_o$, which agrees with the experimental data (Section 2.3).

2.3 The Magnitudes of Cubic CF/LF Splitting Parameters

The splitting parameters are usually found experimentally from d–d spectra, that is, the electronic transitions between the states arising from the d^n configuration, perturbed by the ligand field (Sections 4 and 5). Meanwhile, we consider the magnitudes of LF splittings.

The splitting parameters obtained from d–d spectra are usually expressed in cm^{-1}, or sometimes kK (kilokaysers, $1\,kK = 1000\,cm^{-1}$). Most Δ_o values are in the range $7000–40\,000\,cm^{-1}$, that is, in the near-IR, visible, and near-UV. A selection of experimental values is collected in Table 1. A number of generalizations can be made.

Table 1 LF splittings Δ_o and Δ_t for selected octahedral and tetrahedral systems

1. The splitting increases with increasing oxidation number of the central atom. This can be explained in electrostatic terms by noting that the ionic radius of (say) Co^{3+} is smaller than that of Co^{2+}; according to the CF model, Δ_o and Δ_t are proportional to r^{-5}, where r is the distance between the central atom and the donor atom/point charge. Since r is typically about 7–8% shorter for an M^{III} complex compared to M^{II} with the same ligands, we expect Δ to be 40–50% greater for M^{III}.
2. Splittings for complexes of the 4d and 5d elements are much greater than for those of the 3d elements. This is not easily explained by the CF model.
3. For a given set of ligands, the variation of Δ for M^{II} and M^{III} across each series is irregular and has no simple explanation.
4. The dependence of Δ_o or Δ_t on the ligands follows a fairly constant sequence for all central atoms, viz. $I^- < Br^- < Cl^- < F^- < H_2O < NH_3 < NO_2^- < CN^- < CO$. This is the *Spectrochemical Series*. There is a clear correlation between the position of a ligand in the spectrochemical series and the position of the donor atom in the Periodic Table, thus C > N > O > F > Cl > Br > I. No simple electrostatic interpretation is available.

3 DEFICIENCIES OF THE CRYSTAL FIELD MODEL

While there is abundant evidence from magnetic and ESR data, as well as from electronic spectroscopy (Section 4), to support qualitatively the d-orbital splittings predicted by the simple CF model for cubic complexes, the model is clearly inadequate. Electrostatic calculations of Δ_o fail to account for the experimental order of magnitude, and sometimes even the sign! An even more serious objection is raised by experimental evidence suggesting that a purely ionic description of the bonding in transition-element compounds is inappropriate.

3.1 Evidence for Covalency in d-Block Chemistry

Here we set out some of the experimental evidence, which forces us to reexamine the electrostatic, ionic approach inherent in CFT.

1. ESR measurements suggest that unpaired electrons, which (in CF language) are in pure d orbitals on the central atom/ion, are appreciably delocalized over the ligands. This can be explained in terms of MO theory (*see* ***Molecular Orbital Theory***); the 'd electrons' are now in MOs, which have considerable ligand character.
2. NMR measurements likewise reveal the delocalization of unpaired electrons over the ligands.
3. The *Nephelauxetic Effect* (Section 5) provides evidence for the donation of electron density from ligand to central atom/ion (as suggested by the usual theories of covalent bonding in complexes) and for the delocalization of electrons which, in the CF approach, should be localized in central atom d orbitals.
4. Quantitative measurements of the paramagnetism of compounds of the d elements (*see* ***Magnetism of Transition Metal Ions***) also imply delocalization of the unpaired electrons in 'd orbitals'.

Such observations did not necessarily mean that CFT had to be discarded. After all, there is evidence that the bonding in three-dimensional solids involves considerable covalency, yet the ionic description of solids like NaCl remains firmly rooted in the thinking of most chemists. These deficiencies were becoming apparent within a few years of the 'rediscovery' of CFT by inorganic chemists in the early 1950s, when magnetochemistry, electronic spectroscopy, ESR, and NMR were arousing great interest. Some chemists took the view that simple CFT was still useful even if we had to take its basic assumptions with a grain of salt. Others insisted that

the theory needed a thorough overhaul and refurbishment, and some were inclined to abandon it altogether.

While these issues were being debated (1955–1960), MO theory was rapidly gaining ground. In the 1960s, there was much enthusiasm for semiempirical MO calculations (*see* ***Molecular Orbital Theory*** and *Extended Hückel Molecular Orbital Theory*) on complexes. These could be performed by the rudimentary computers then available, and purported to provide everything CFT could furnish, and more. Their weakness lay in the criterion used for their calibration, that is, the precision with which they reproduced spectroscopically measured d-orbital splittings. By the late 1960s, it was agreed that such methods were inappropriate for the calculation of spectroscopic quantities, although they have served inorganic chemists well in other areas.

More successful approaches tried to preserve the simplicity of the original 'five-orbital' CF model. At the same time, it was necessary (especially for the interpretation of magnetic and spectroscopic measurements) to make allowance, albeit implicitly, for the effects of orbital overlap and covalency. For d–d spectra, further details are given in Section 5; for magnetic and ESR properties, (*see* ***Magnetism of Transition Metal Ions***). Some writers use the term Ligand Field Theory (LFT) as opposed to Crystal Field Theory to describe an approach, which retains the language and spirit of the old CFT. Others use LFT to encompass all approaches, including CFT, which focus on the five orbitals of the partly filled subshell.

3.2 Angular Overlap Model (AOM)

The *Angular Overlap Model* (AOM) first appeared in a paper[48] entitled 'The Angular Overlap Model: an Attempt to Revive the Ligand Field Approaches', during the heyday of the semiempirical MO treatments when CF/LFT was in danger of obsolescence. Even the simplest MO calculation for an octahedral complex leads to 15 MOs of which 6 to 11 are occupied (qualitative discussions exist on this topic[1–18]). It is easy to reconcile the CF and MO approaches and to identify the MOs that correspond to the d orbitals of CFT. A t_{2g} set of MOs lies higher in energy than the filled and mainly ligand bonding and nonbonding MOs. Where the donor atoms are incapable of π overlap, these t_{2g} orbitals are pure, nonbonding $d_{xy,zx,yz}$. If the ligands have filled orbitals, capable of π overlap with $d_{xy,xz,yz}$, and lower in energy than the central atom d orbitals, the t_{2g} level now becomes π antibonding, but its constitution is mainly d. If the ligand has empty π orbitals, these (e.g. the π^* antibonding MOs of CO or an aromatic ligand) will lie higher in energy than the d subshell, and we obtain a predominantly-d bonding t_{2g} level corresponding to the t_{2g} level of CFT. Above this is an e_g σ-antibonding level, comprising mainly the d_{z^2} and $d_{x^2-y^2}$ orbitals; this is the MO counterpart of the CF e_g level. These situations are shown in Figure 6. The number of electrons to be allocated to these MOs is equal to the number of d electrons in a CF description; hence, we can retain much of the language and spirit of CF theory within an MO framework. Ligands that function according to Figure 6(b) are π donors, because the effect is to transfer electron density from ligand to central atom. Figure 6(c) specifies a π-acceptor ligand; the electrons in the t_{2g} level are 'd electrons', which are now delocalized over the ligands. All ligands are, of course, σ donors.

In most expositions, the AOM is developed from semiempirical MO considerations[18,49] (although a reformulation, the cellular ligand field (CLF) approach (see Section 6.3),[50–53] avoids any such derivation). The AOM retained the five-orbital concept by regarding the LF splitting as a consequence of overlap between AOs on the central atom and on the ligands. A simple perturbation treatment, assuming that the overlap is small, shows that the effect on a d orbital is proportional to the square of the overlap integral. A d orbital will have nonzero overlap with any linear combination of ligand orbitals having the same symmetry. The effect on the energy of a d orbital can be written as $n_\lambda e_\lambda$, where n_λ is a constant determined by the coordination geometry and e_λ is a parameter having units

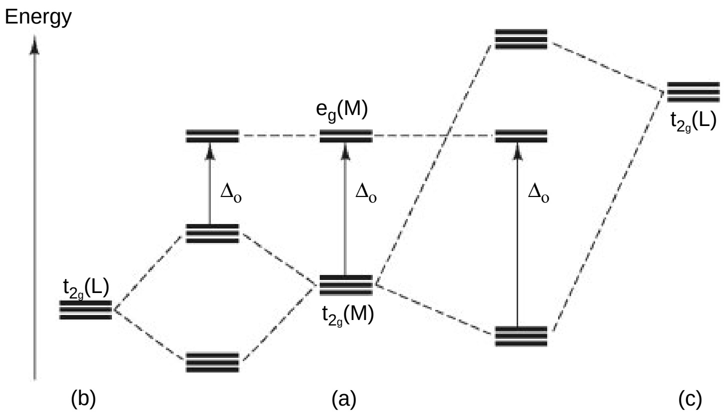

Figure 6 Effect of π-bonding on LF orbitals in an octahedral complex ML_6, showing interaction between ligand (L) and central atom (M) t_{2g} orbitals where the ligands are (a) pure σ-donors, (b) π-donors, and (c) π-acceptors

of energy; the subscript λ specifies the overlap as $\sigma, \pi, \delta, \ldots$, and so on. In an octahedral complex where each ligand has two equivalent π orbitals, the relative energies of the d orbitals are given by equations (12) and (13), and the LF splitting by equation (14).

$$E(z^2) = E(x^2 - y^2) = E(e_g) = 3e_\sigma \tag{12}$$

$$E(xy) = E(xz) = E(yz) = E(t_{2g}) = 4e_\pi \tag{13}$$

$$\Delta_o = 3e_\sigma - 4e_\pi \tag{14}$$

Now e_σ must be positive, because the e_g orbitals are unequivocally σ antibonding; their energies are higher than the free atom/ion values. e_π will be positive if the ligands are π donors, and negative if they are π acceptors. Because π overlap is usually weaker than σ overlap, we may infer that $|e_\pi| < e_\sigma$. Thus, the AOM predicts a positive Δ_o.

For tetrahedral complexes, we obtain equations (15) to (17). Note that (Δ_t/Δ_o) is (4/9), as obtained by CFT.

$$E(xy) = E(xz) = E(yz) = \left(\frac{4}{3}\right)e_\sigma + \left(\frac{8}{9}\right)e_\pi \tag{15}$$

$$E(z^2) = E(x^2 - y^2) = \left(\frac{8}{3}\right)e_\pi \tag{16}$$

$$\Delta_t = \left(\frac{4}{3}\right)e_\sigma - \left(\frac{16}{9}\right)e_\pi \tag{17}$$

The AOM helps to rationalize the spectrochemical series. The ligands towards the left-hand side (e.g. halide ions) are π donors, having filled orbitals capable of π overlap with, in the octahedral case, $d_{xy,xz,yz}$. Ligands at the right-hand side, giving large values of Δ, are π acceptors (CO, CN^-, phen, etc.). Amines, having no orbitals available for π overlap, are pure σ donors and occur in the middle of the spectrochemical series. From spectroscopic studies of noncubic complexes (which require more than one splitting parameter, Section 6), we can obtain separate e_σ and e_π values for ligands, and thus determine a two-dimensional spectrochemical series:

$$e_\sigma\text{: } I^- < Br^- < Cl^- < H_2O \approx NH_3 \approx F^- < NO_2^- < CN^- < CO$$

$$e_\pi\text{: } CO < CN^- < NO_2^- < NH_3 < H_2O < I^- < Br^- < Cl^- < F^-$$

For NH_3, e_π is assumed to be zero, so that the ligands to its left are π acceptors (negative e_π), while those to its right are π donors (positive e_π). Further aspects of the AOM will be discussed in Section 6. A more recent development, the CLF approach,[50–53] is described in Section 6.3.

4 LIGAND FIELD (LF) SPECTROSCOPY[23,26,31,54]

The colors associated with many compounds of the transition elements arise from electronic transitions, that is, the ground state and excited state have different electronic wavefunctions. Electronic spectra are mostly observed in the UV; colored species absorb in the visible region (12 000–25 000 cm^{-1}), implying relatively low-lying electronic transitions. Indeed, many d-block species have electronic transitions in the near IR. These are attributed to transitions involving the partly filled subshell; in atomic spectroscopy, transitions in which electrons are excited to higher shells or subshells usually occur in the UV. Electronic transitions within the d subshell are called *d–d Transitions* or bands. These are not always responsible for familiar colors; in purple MnO_4^- and yellow CrO_4^{2-}, the central atoms are formally d^0, and many d^{10} species are colored (e.g. yellow AgI). These colors arise from *Charge Transfer* (CT) bands, where an electron jumps from a ligand lone pair orbital into an empty d orbital on the central atom. This is a ligand-to-metal transition; a metal-to-ligand transition is from a d orbital to an empty ligand orbital, and may occur at low energy if the central atom is easily oxidized (*see Ligand-to-Metal Charge Transfer*).

4.1 d–d Transitions: Intensities and Selection Rules

The d–d bands are usually relatively low in intensity compared to CT bands; contrast the palish hues of familiar salts of Cr, Mn, Fe, Co, Ni, and Cu with the intense purple of MnO_4^-. This can be explained within the CF model. The probability of a transition is governed by selection rules (*see Group Theory*). In atomic spectra, transitions between states having the same l quantum number are forbidden; if this rule were strictly obeyed, d–d transitions should not be observable. Moreover, if there is a center of symmetry, as in an octahedral or square coplanar complex, d–d transitions are forbidden although they can be observed, albeit relatively weakly. Molecular vibration can disturb the center of symmetry, and *Vibronic Coupling* lends intensity to d–d absorption. A tetrahedral complex has no center of symmetry and the $nd_{xy,xz,yz}$ orbitals have the same symmetry as the $(n+1)p_{x,y,z}$ orbitals; these subshells can therefore mix and the selection rules forbidding d–d transitions are accordingly relaxed. CT bands, as already noted, are often fully allowed and very intense. A d–d excited state, where allowed by symmetry and/or other perturbations, may mix with a CT state and a 'forbidden' d–d transition can 'borrow' intensity from a CT state.

Another selection rule allows only transitions between states having the same spin. This is relaxed somewhat through spin–orbit (SO) coupling (*see Coupling*). In a free atom/ion, this means that the spin and orbital angular momenta (represented respectively by S and L for a state labeled ^{2S+1}L) are combined so that the state is split into $2S+1$ levels, classified according to their total angular momentum quantum number $J = L+S, L+S-1, \ldots, L-S$. For example, the ^3P (spoken as 'triplet pee') ground state of the carbon atom ($L = 1, S = 1$) is split into three states with $J = 2$, 1, and 0. The magnitude of SO coupling increases rapidly with

increasing atomic number. Thus, for the heaviest atoms, the quantum numbers L and S have largely lost their integrity and are no longer appropriate for the classification of states. The significance of SO coupling for LF spectroscopy lies mainly in its importance for the heavy transition elements, where it is less meaningful to classify states as singlets, triplets, and so on according to the superscript $2S+1$, which appears in such designations as ^{1}D and ^{3}F. The need to include SO coupling in quantitative calculations of d–d states complicates matters. The greater LF splittings for complexes of the 4d and 5d elements mean that d–d transitions appear further into the UV than for complexes of the 3d elements; they are often obscured by, and/or mixed with, CT bands. Hence, most of our discussion relates to the LF spectra of 3d complexes; here, SO splitting may appear in high-resolution spectra, and is allowed for in the most elaborate calculations.

4.2 States and Configurations[55]

LF spectroscopy is concerned with transitions between electronic states (the lower of which is nearly always the ground state) arising from the various configurations, which, in turn, arise from the splitting of the nd subshell in a chemical environment. We have already spoken of d–d states and, for both free atoms/ions and cubic environments, electron configurations. It is now necessary to distinguish carefully between ‘state’ and ‘configuration’.

The state of any system is represented by a many-electron wavefunction, which can be factorized as an antisymmetrized product of one-electron functions, that is, orbitals. A configuration (*see Electron Configuration*) is a statement of how many electrons are present in each subshell (for an atom or ion) or in each degenerate level (for a molecule or complex ion). Where a degenerate set is partly filled, a configuration does not specify the occupancy of each orbital, or the electron spins; such a precise description denotes a state. Orbitals are denoted by lower-case letters, s, p, d, f, ... for atoms and by group-theoretical symbols such as a_1, t_{2g} for molecules and polyatomic ions. States are denoted by capitals. For atoms, we use S, P, D, F, ... which correspond to the state L quantum numbers of 0, 1, 2, 3, ... and which convey degeneracies of $(2L+1)$, that is, M_L values of $L, L-1, L-2, \ldots, -L$. For molecules and polyatomic ions, we use symmetry symbols such as A_1, T_{2g}. A given configuration may give rise to more than one state. Moreover, two or more states of the same symmetry become mixed, especially if they are close together in energy. Where such *Configuration Interaction* is strong, the ground state is not associated with a unique configuration, although in most cases, one configuration dominates.

Consider the carbon atom, as a simple example. To say that ‘the ground-state configuration is $1s^22s^22p^2$’ is a rather loose way of saying that the ground state (among others) arises principally from this configuration. There are $3 \times 3 = 9$ ways of allocating two electrons to the three 2p orbitals. If the electrons have the same spin, they must have different m_l values. Representing a ‘microstate’ by the notation $\{m_l(1)m_l(2)\}$ to denote the m numbers for electrons (1) and (2), we can thus have $\{1, 0\}$, $\{1, -1\}$, and $\{0, -1\}$. These correspond, respectively, to the M_L values $(M_L = m_l(1) + m_l(2))$ of 1, 0, and -1, which arise from a ^{3}P state. If the electrons have opposite spins, there are six possible microstates $\{1, 1\}$, $\{1, 0\}$, $\{1, -1\}$, $\{0, 0\}$, $\{0, -1\}$, and $\{-1, -1\}$, having M_L values of 2, 1, 0, 0, -1, and -2, respectively. Thus, we can infer a ^{1}D state ($L = 2$; $M_L = 2, 1, 0, -1, -2$) and a ^{1}S state ($L = 0$, $M_L = 0$); the latter can be represented as a mixture of $\{1, -1\}$ and $\{0, 0\}$.

The energy of a state may be expressed as the sum of its total orbital energy and its interelectron repulsion energy. All states arising from a given configuration have the same orbital energy, and interelectron repulsion is minimized by placing the electrons in separate orbitals, with spins parallel. Hence, ^{3}P is unequivocally the ground state for the C atom; ^{1}D and ^{1}S are excited states. There are other ^{3}P states of the C atom arising, for example, from $1s^22s^22p3p$ or $1s^22s^23d^2$, but these lie very high in energy and configuration interaction, mixing these into the ground state, need not be considered for most purposes.

4.3 d–d States of Cubic d^n Systems

We now consider the electronic states that arise when a d^n ion is perturbed by a cubic field. Methods for working out the symmetry species of the states arising from a given configuration $t_{2g}^m\ e_g^n$ (or $e^m t_2^n$ for a tetrahedral complex) are given in detail in monographs;[15,19,21–32] a ‘user-friendly’ introduction for beginners in group theory is available.[56] For quantitative calculations, there are two extreme viewpoints. The weak field model considers the effect of the ligand field to be small compared to interelectron repulsion. Hence, we work out how the free-ion states are perturbed by a weak cubic field. The energies of the resulting LF states are the eigenvalues of determinants whose off-diagonal terms are multiples of LF splitting parameters. In the strong-field model, the effect of the ligand field is deemed to be much stronger than the interelectron repulsion terms that split states arising from the same d^n configuration. Here the off-diagonal terms are interelectron repulsion parameters. In either case, the diagonal terms are expressed as the sums of orbital splitting parameters and interelectron repulsion terms. The ‘truth’ generally lies somewhere between these extremes.

4.3.1 *Octahedral and Tetrahedral d^1 and d^9*

For octahedral d^1, the possible configurations are $(t_{2g})^1$ and $(e_g)^1$ (Figure 3). With $(t_{2g})^1$, the electron can be in any of d_{xy}, d_{xz}, or d_{yz}. Each of these situations corresponds to the same energy, because the three t_{2g} orbitals are degenerate and there is no interelectron repulsion. Thus, we have a threefold degenerate state $^2T_{2g}$, where the superscript $(2S+1)$ denotes

a total spin S of (1/2). This is the ground state, and the electron spends equal amounts of time in each of the t_{2g} orbitals. Likewise, the $(e_g)^1$ configuration gives rise to a twofold-degenerate state ^2E_g where the electron spends equal amounts of time in $d_{x^2-y^2}$ and d_{z^2}. This is the only d–d excited state; there is only one d–d transition, $^2T_{2g} \rightarrow {}^2E_g$. Any electronic transition energy ΔE can be expressed as equation (18), where ΔE_{orb} and ΔE_{int} are respectively the changes in orbital and interelectron repulsion energy.

$$\Delta E = \Delta E_{orb} + \Delta E_{int} \qquad (18)$$

For octahedral d^1, ΔE is equal to $\Delta E_{orb} (= \Delta_o)$ since ΔE_{int} is zero. Octahedral d^1 complexes do indeed exhibit a single, relatively weak absorption in the visible or near-UV. The historically important example of $[Ti(H_2O)_6]^{3+}$ is shown in Figure 7. The broadness of the band is a normal feature for d–d transitions where ΔE_{orb} is nonzero, for example, where an electron jumps between t_{2g} and e_g; there are (in other d^n systems) d–d transitions involving no change in orbital energy.

For tetrahedral d^1 (referring to Figure 5), we can have two configurations, $(e)^1$ and $(t_2)^1$. The former gives rise to a ^2E ground state and the latter to a $^2T_2$ excited state, so that we expect one d–d transition, $^2E \rightarrow {}^2T_2$.

Prima facie, it might be thought that for the d^9 case we will have to consider interelectron repulsion, but the situation is actually much simpler. We can view a d^9 subshell as a 'one-hole' or one-positron system; the interaction of a positron (i.e. a positive electron) with the ligand field is equal in magnitude but opposite in sign to that of an electron. Thus, the splitting parameter defined in Figure 3 is now negative; a 'one-positron' octahedral complex has in its ground state a positron in e_g. Thus, we have the d–d states $^2T_{2g}$ and ^2E_g, but the ground state is now ^2E_g and we predict a single d–d transition $^2E_g \rightarrow {}^2T_{2g}$; the transition energy is equal to $-\Delta_o$. It is difficult to verify this prediction experimentally, because

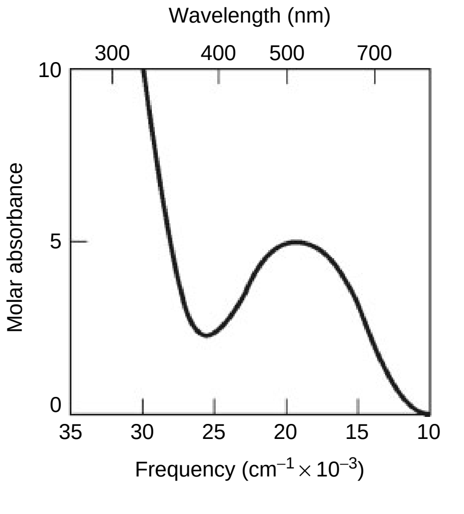

Figure 7 Electronic spectrum of $[Ti(H_2O)_6]^{3+}$ in water

(for reasons discussed in Section 7.2) regularly octahedral d^9 complexes rarely (if ever) occur and the d–d spectra of, for example, six-coordinate copper(II) systems show at least two d–d transitions.

Similarly, for tetrahedral d^9 systems, we predict a $^2T_2$ ground state and one d–d transition to a ^2E excited state; but, as in the octahedral case, 'tetrahedral' d^9 systems are not so simple. An added complication is that SO coupling can split the ground state.

In either a d^1 or d^9 free atom/ion, there can be only one d–d state ^2D (split by SO coupling into $^2D_{5/2}$ and $^2D_{3/2}$). The effect on ^2D of an octahedral or tetrahedral field is shown in Figure 8. The energy zero represents the ion in a spherical field. Where Δ is positive, we have the d–d states for octahedral d^1 or tetrahedral d^9 (to accommodate both, the g and u subscripts appropriate to the octahedral case are omitted); for negative values, we have the states for octahedral d^9 and tetrahedral d^1. For the d^1 case, Δ is defined as $E(e) - E(t_2)$, which is positive for octahedral and negative for tetrahedral symmetry. For d^9, Δ is defined for a one-positron system and is therefore negative for octahedral and positive for tetrahedral symmetry. Thus, four distinct types of cubic complex can be treated in a single energy-level diagram. In fact, four more situations have the same diagram (Sections 4.3.4 and 4.3.6). Figure 8 is of limited practical value, but it illustrates how d–d spectra of other d^n systems can be tackled.

4.3.2 *Octahedral and Tetrahedral d^2 and d^8*

Since a d^8 complex can be described as a two-positron system, the d–d energy levels obtained for d^2 will be applicable, with the necessary changes, to d^8 as well. Consider first a free d^2 atom/ion; d^2 gives rise to singlet and triplet states, but the ground state must be a triplet. If the electrons have the same spin, occupying different d orbitals, we can have the microstates {2, 1}, {2, 0}, {2, −1}, {2, −2}, {1, 0}, {1, −1}, {1, −2}, {0, −1}, {0, −2}, and {−1, −2}, with M_L values of 3, 2, 1, 0, 1, 0, −1, −1, −2, and −3, respectively. These can

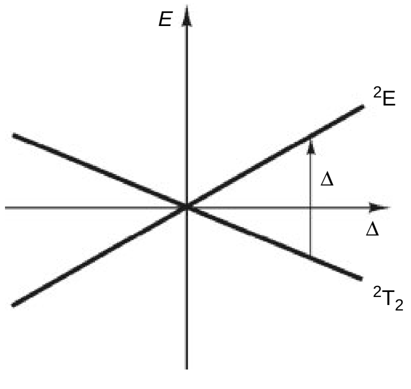

Figure 8 Energies E of d–d states for cubic d^1 and d^9 systems plotted against splitting parameter Δ

only arise from the atomic states ^{3}F and ^{3}P, of which the former (with the greater L) is the ground state. The difference in interelectron repulsion energy between ^{3}P and ^{3}F is commonly expressed in multiples of the Racah parameters B and C (*see Racah Parameter*). Here we find $E(^3\text{P} - {}^3\text{F}) = 15B$. The numerical values of B and C are obtained from atomic spectra; for example, in V^{3+} (g), the $^3\text{F} \rightarrow {}^3\text{P}$ transition is observed at 13 344 cm^{-1} so that $B = 890\ \text{cm}^{-1}$. In the d^8 case, the results are the same; the ground state is ^{3}F, with ^{3}P lying higher by $15B$.

For octahedral d^2, three configurations are possible: $(t_{2g})^2$, $(t_{2g})^1(e_g)^1$, and $(e_g)^2$, whose orbital energies (relative to the spherical field) are, respectively, $-(4/5)\Delta_o$, $(1/5)\Delta_o$, and $(6/5)\Delta_o$. The ground state will be a spin triplet arising from $(t_{2g})^2$, with the electrons in two separate d orbitals having parallel spins. There are three ways of thus allocating two electrons to three orbitals, and the equivalence of d_{xy}, d_{xz}, and d_{yz} means that each will have the same interelectron repulsion energy. Thus, the ground state is $^3T_{1g}$ (not T_{2g}, for group-theoretical reasons not discussed here). The singlet excited states $^1T_{2g}$, ^1E_g, and $^1A_{1g}$ also arise from $(t_{2g})^2$; transitions to these may appear weakly as spin-forbidden bands, if they are not obscured by nearby spin-allowed d–d bands, or by CT transitions.

For the configuration $(t_{2g})^1(e_g)^1$, there are six ways of allocating the electrons with parallel spins. However, we cannot have a sixfold orbital degeneracy. By group-theoretical methods, we obtain two threefold degenerate states, $^3T_{1g}$ and $^3T_{2g}$ (plus the corresponding singlet states $^1T_{1g}$ and $^1T_{2g}$). The two distinct $^3T_{1g}$ states require further labeling to avoid confusion. Moreover, two states of the same symmetry become mixed; this is expressed by a 2×2 determinant (equation 19).

$$\begin{vmatrix} -\left(\frac{4}{5}\right)\Delta_o + 3B - E & 6B \\ 6B & \left(\frac{1}{5}\right)\Delta_o + 12B - E \end{vmatrix} = 0 \qquad (19)$$

The diagonal terms are the calculated energies of the 'pure' (unmixed) states, and each is expressed as the sum of an orbital energy (a multiple of Δ_o) and an interelectron repulsion energy (a multiple of B), relative to the free-ion ground state ^{3}F. The determination of the orbital energy term is obvious; the calculation of the repulsion terms in both diagonal and off-diagonal elements is explained in standard monographs.[19–28] The $(t_{2g})^2$ configuration has the orbital energy $2(-2\Delta_o/5) = -4\Delta_o/5$, while $(t_{2g})^1(e_g)^1$ has $(-2\Delta_o/5 + 3\Delta_o/5) = \Delta_o/5$. The *Noncrossing Rule* requires that states of the same symmetry cannot coincide in energy, so that in the limit, where $\Delta_o \rightarrow 0$, the two $^3T_{1g}$ states must converge to different triplet free-ion states. The lower of the two, arising from $(t_{2g})^2$, is labeled $^3T_{1g}$(F) since it becomes ^{3}F in the free-ion limit, while the higher is designated $^3T_{1g}$(P). In the strong-field limit, where interelectron repulsion is negligible compared to orbital energy, the energies of $^3T_{1g}$(F) and $^3T_{1g}$(P) are equal to $-(4\Delta_o/5)$ and $\Delta_o/5$, respectively. Note that (except in the strong-field limit) the ground state cannot be described exactly in terms of the configuration $(t_{2g})^2$; mixing of the two $^3T_{1g}$ states means that each can claim parentage from both $(t_{2g})^2$ and $(t_{2g})^1(e_g)^1$, an example of configuration interaction.

The $(e_g)^2$ configuration can give rise to only one, nondegenerate triplet state, there being only one way of assigning two electrons to two separate orbitals with parallel spins. This is labeled $^3A_{2g}$ (in cubic symmetry, A, E, and T mean nondegenerate, twofold, and threefold degenerate, respectively); there are also the singlet states ^1E_g and $^1A_{1g}$. Since $^3T_{1g}$(P) becomes ^{3}P at the weak-field limit, and we have to account for the sevenfold degeneracy of the ^{3}F free-ion state, it follows that $^3A_{2g}$, together with $^3T_{2g}$ and $^3T_{1g}$(F), are derived from ^{3}F. The energy of $^3A_{2g}$ (relative to ^{3}F) is found to be $(6/5)\Delta_o$; at the weak-field limit, this is lower than $^3T_{1g}$(P), but with large values of Δ_o, $^3A_{2g}$ is the highest d–d triplet state. We can now construct an energy-level diagram for octahedral d^2, which (cf. Figure 8) can be extended to tetrahedral d^2 and to both octahedral and tetrahedral d^8. This exercise will be deferred, however, until we have dealt with d^{3,7}.

4.3.3 *Octahedral d^3 and Tetrahedral d^7*

The free-ion states arising from d^3 bear close similarities to the d^2 case. The ground state is bound to be a quartet, with three singly occupied d orbitals (this might be viewed as a two-positron problem, with two vacancies in a half-filled d subshell). The microstates for a quartet are $\{2, 1, 0\}$, $\{2, 1, -1\}$, $\{2, 1, -2\}$, $\{2, 0, -1\}$, $\{2, 0, -2\}$, $\{1, 0, -1\}$, $\{1, 0, -2\}$, $\{1, -1, -2\}$, and $\{0, -1, -2\}$, whose M_L values are respectively 3, 2, 1, 1, 0, 0, −1, −2, and −3. Analogous to the d^2 case, these are derived from the free-ion states ^{4}F and ^{4}P, the former being the ground state, separated from the latter by $15B$. It is therefore not surprising that the pattern of LF states is similar to that for d^2. We will concentrate on quartet states, since the ground state for octahedral d^3 is a quartet, with spin-allowed d–d transitions to quartet excited states.

As for d^2, three configurations can lead to a quartet ground state for octahedral d^3: $(t_{2g})^3$, $(t_{2g})^2(e_g)^1$, and $(t_{2g})^1(e_g)^2$. For $(t_{2g})^3$, $(d_{xy})^1(d_{xz})^1(d_{yz})^1$ with parallel spins describes a unique state having the same symmetry as $(d_{z^2})^1(d_{x^2-y^2})^1$; thus the ground state for octahedral d^3 is $^4A_{2g}$. The $(t_{2g})^2(e_g)^1$ configuration, analogous to $(t_{2g})^1(e_g)^1$, produces the quartet states $^4T_{1g}$ and $^4T_{2g}$, while $(t_{2g})^1(e_g)^2$ leads to $^4T_{1g}$; this latter is clearly to be distinguished as $^4T_{1g}$(P), while $^4T_{1g}$(F) is derived from $(t_{2g})^2(e_g)^1$. The situation resembles octahedral d^2, except that the relative energies are inverted, that is, we have for octahedral d^3 a ground state $^4A_{2g}$ with excited states $^4T_{2g}$, $^4T_{1g}$(F), and $^4T_{1g}$(P). Transitions to the doublet states ^2E_g and $^2A_{1g}$, derived from $(t_{2g})^3$, can be observed as weak, sharp bands in absorption (the sharpness of such transitions is discussed in Section 4.3.5); however, the emission $^2E_g, {}^2A_{1g} \rightarrow {}^4A_{2g}$ is of more importance. Under certain conditions, a Cr^{3+} ion in

an octahedral environment can absorb a photon and jump to $^4T_{2g}$, which then undergoes a radiationless transition to ^2E_g or $^2A_{1g}$; this decays back to the ground state with emission of laser light. The first laser (1960) employed crystals of ruby, that is, Cr^{3+}-doped Al_2O_3.

It may be inferred that tetrahedral d^7 has the same energy-level diagram as octahedral d^3 (omitting the g and u subscripts). Moreover, the energy levels for octahedral d^2 and tetrahedral d^8 are, with the appropriate adjustments, applicable to octahedral d^7. Hence, a single energy-level diagram can cover octahedral and tetrahedral d^2, d^3, d^7, and d^8. In Figure 9, the energies of the states of highest multiplicity (triplets for $d^{2,8}$, quartets for $d^{3,7}$) are plotted as y against the cubic splitting parameter x. A positive x is appropriate for octahedral $d^{2,7}$ or tetrahedral $d^{3,8}$ and corresponds to a positive Δ_o or Δ_t as appropriate, while the negative x axis corresponds to the cubic splitting for octahedral $d^{3,8}$ or tetrahedral $d^{2,7}$.

4.3.4 *Octahedral d^4 and Tetrahedral d^6*

In the cases discussed so far, the configuration from which the ground state is derived can be unequivocally identified. In each case, the ground state has the lowest possible orbital energy, and also the maximum number of unpaired spins that minimizes the interelectron repulsion energy. For octahedral d^4 the situation is more difficult. The configuration $(t_{2g})^4$ (which requires one t_{2g} orbital to be doubly occupied) has minimum orbital energy, but $(t_{2g})^3(e_g)^1$ allows four singly occupied d orbitals, and a total spin S of 2, compared with a maximum of $S = 1$ for states arising from $(t_{2g})^4$, giving rise to the state of minimum interelectron repulsion. Which of these will be the ground state will depend on the relative importance of orbital energy and interelectron repulsion. Assuming that the interelectron repulsion parameters are approximately the same as in the free ions (but see Section 5), the magnitude of Δ_o will be critical. The $(t_{2g})^4$ configuration gives rise

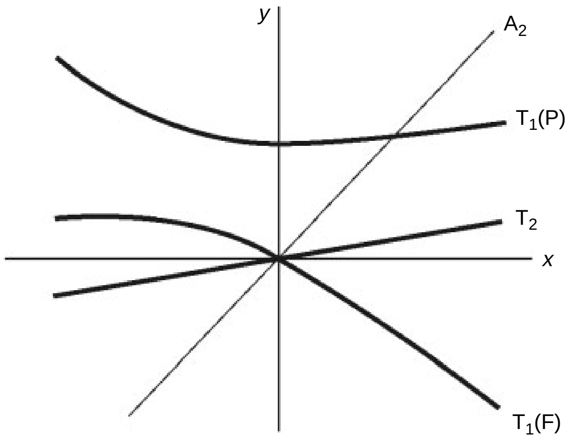

Figure 9 Energies of d–d states of highest spin (y) for cubic d^2, d^3, d^7, d^8 plotted against splitting parameter (x)

to a triplet state $^3T_{1g}$ plus singlets $^1T_{2g}$, ^1E_g, and $^1A_{1g}$ (cf. d^2; $(t_{2g})^4$ is related to $(t_{2g})^2$ in the same way as d^8 is to d^2). Its rival $(t_{2g})^3(e_g)^1$ gives rise to a quintet ^5E_g (twofold degenerate since there is only one way of allocating the three t_{2g} electrons but two ways of allocating one electron to e_g) plus triplets and singlets. The transition $^3T_{1g} \rightarrow {}^5E_g$ involves the excitation of one electron from t_{2g} to e_g but produces two additional unpaired spins. A large value of Δ_o will favor the low-spin ground state $^3T_{1g}$ while a small splitting will favor the high-spin ground state ^5E_g (*see High-spin & Low-spin Compounds*). Thus, ligands towards the right-hand side of the spectrochemical series (Section 2.3) will enforce a ground state having minimum orbital energy, while ligands lower in the series will favor a ground state having the minimum interelectron repulsion, that is, the maximum number of unpaired spins. Both types of ground state are found for octahedral d^4. The most direct evidence comes from magnetic measurements (*see* ***Magnetism of Transition Metal Ions***). Thus, $[Cr(CN)_6]^{4-}$ and $[Mn(CN)_6]^{3-}$ have magnetic moments consistent with only two unpaired electrons, indicating a $^3T_{1g}$ ground state; $[Cr(NH_3)_6]^{2+}$ and $[MnF_6]^{3-}$ apparently have four unpaired electrons, consistent with ^5E_g. Thus, complexes of Cr^{II} and Mn^{III} are classified as high-spin or low-spin. ESR is also useful for the experimental determination of the ground state.

We can plot the d–d states on an energy-level diagram, showing the changeover of the ground state at a critical value of Δ_o. There is a simpler way, however. In the high-spin case, there is only one quintet excited state $^5T_{2g}$ (derived from $(t_{2g})^2(e_g)^2$), so there can be only one spin-allowed d–d transition, $^5E_g \rightarrow {}^5T_{2g}$. The transition energy is exactly equal to Δ_o; there is no change in interelectron repulsion. High-spin d^4 can be regarded as a one-positron system, one electron short of a half-filled subshell, and is thus related to d^1 but with the relative energies of the states reversed. Hence, Figure 8 will serve for octahedral high-spin d^4, treated as for d^9. For tetrahedral high-spin d^4, that part of Figure 8 appropriate for tetrahedral d^9 may be used. For octahedral low-spin d^4, with a $^3T_{1g}$ ground state, the energy-level diagram for octahedral d^2 (Figure 9) will serve, as long as we are interested only in triplet–triplet transitions. What of low-spin tetrahedral d^4? The splitting Δ_t appears never to be large enough for orbital energy considerations to dominate over interelectron repulsion. Tetrahedral d^3, d^4, d^5, and d^6 complexes could all, in principle, have either a high-spin or a low-spin ground state, but the latter is never found in practice.

Our deliberations for d^4 complexes will have some relevance for d^6 systems. But we will first look at the d^5 situation.

4.3.5 *Octahedral and Tetrahedral d^5*

In identifying the ground state for octahedral d^5, we are again faced with a conflict between considerations of orbital energy and of interelectron repulsion energy. The latter is

minimized by placing the electrons separately in the five d orbitals with parallel spins, while the minimum orbital energy is obtained with the $(t_{2g})^5$ configuration. We look first at the high-spin case. The unique allocation $(t_{2g})^3(e_g)^2$ with all spins parallel gives rise to a sextet state $^6A_{1g}$. There being no other sextet state, there are no spin-allowed d–d transitions for high-spin d^5. The $(t_{2g})^3(e_g)^2$ configuration also gives quartet and doublet states, and weak transitions to the former are observed. Quartet states also arise from other configurations.

A typical spectrum is shown in Figure 10. The intensity of a band is measured by the molar absorbance (or extinction coefficient) ε, usually of the order of 10^3–10^6 L mol^{-1} cm^{-1} for fully allowed transitions and 1–100 for spin-allowed d–d transitions in octahedral complexes. For octahedral high-spin Mn^{II} complexes, ε is around 10^{-2} L mol^{-1} cm^{-1}, typical for spin-forbidden d–d bands in 3d complexes. Some of the bands are broad but others are sharp. Most d–d transitions are broad because of vibrational structure; the rapid changing of the central atom–ligand distances, and distortion from octahedral symmetry, mean that the LF splitting fluctuates rapidly with time, and in a solution or crystal, we observe a complex band envelope. Any change in configuration, with electron jumps between different energy levels, gives a broad band, except at low temperatures. However, a transition between states arising from the same configuration, with no change in orbital energy, may be very sharp. The first two transitions in the spectrum shown in Figure 10 at 18 900 and 23 100 cm^{-1} are, respectively, $^6A_{1g} \rightarrow {}^4T_{1g}$ and $^6A_{1g} \rightarrow {}^4T_{2g}$, both excited states arising from $(t_{2g})^4(e_g)^1$. Each is thus accompanied by a negative change in orbital energy, and of course by a larger positive change in interelectron repulsion energy with the pairing of two electrons in one t_{2g} orbital. The next two bands are to quartet states ^4E_g and $^4A_{1g}$ derived from the same configuration, $(t_{2g})^3(e_g)^2$, as the ground state. These involve only an increase in interelectron repulsion and are narrow. The energy-level diagrams for high-spin tetrahedral and octahedral d^5 are the same; d^5 is its own 'hole equivalent'.

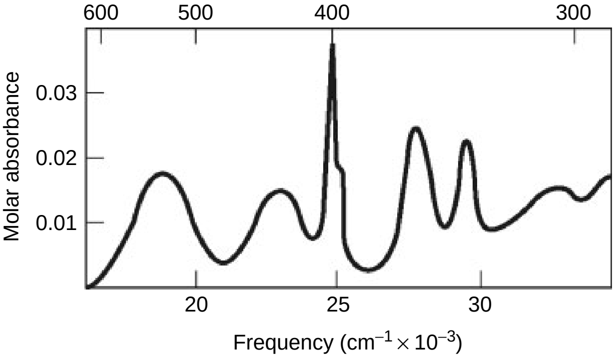

Figure 10 d–d spectrum of $[Mn(H_2O)_6]^{2+}$

For low-spin octahedral d^5, the ground state is $^2T_{2g}$, that is, $(t_{2g})^5$. One hole in t_{2g} is analogous to octahedral d^1 or tetrahedral d^9. Thus Figure 8 is applicable, with one spin-allowed d–d transition, $^2T_{2g} \rightarrow {}^2E_g$, whose energy is equal to Δ_o. There are quartet excited states, plus the unique sextet state $^6A_{1g}$. The vast majority of octahedral Mn^{II} compounds are high-spin; iron(III) complexes have larger Δ_o values and low-spin ground states are more common, for example, in $[Fe(CN)_6]^{3-}$ and $[Fe(bipy)_3]^{3+}$.

4.3.6 *Octahedral d^6*

High-spin octahedral d^6 complexes have the ground state $^5T_{2g}$, derived from $(t_{2g})^4(e_g)^2$ with four orbitals singly occupied and one t_{2g} orbital filled. As already noted, the energy-level diagram for the quintet states is covered by Figure 8 along with d^1, d^4, and d^9. Only one spin-allowed d–d transition, $^5T_{2g} \rightarrow {}^5E_g$, is possible for octahedral high-spin d^6.

The configuration $(t_{2g})^6$, with the t_{2g} orbitals filled and no unpaired electrons, minimizes the orbital energy and produces the unique state $^1A_{1g}$. This is the low-spin ground state; a very high proportion of all known octahedral complexes are low-spin d^6. The octahedral complexes of M^0 (M = Cr, Mo, and W) and M^I (M = Mn, Tc, and Re) are of little interest here, being associated with π-acceptor ligands (CO, PR_3, etc.) which produce very large LF splittings; the d–d bands are obscured by CT transitions (metal-to-ligand). This is true to a lesser degree for M^{II} (M = Fe, Ru, and Os). Many high-spin octahedral Fe^{II} complexes are known but octahedral Ru^{II} and Os^{II} complexes are invariably low-spin. Most d–d spectra of low-spin d^6 complexes have been recorded for octahedral M^{III} (M = Co, Rh, and Ir), and to a lesser extent Pt^{IV}.

The configuration $(t_{2g})^5(e_g)^1$ gives rise to two singlet states, $^1T_{1g}$ and $^1T_{2g}$; transitions to these, and little else, are commonly observed in the d–d spectra of low-spin octahedral d^6 complexes.

4.3.7 *Octahedral d^7*

Here we can have a high-spin ground state $^4T_{1g}$, arising from $(t_{2g})^5(e_g)^2$ with three unpaired electrons, or a low-spin ground state ^2E_g, arising from $(t_{2g})^6(e_g)^1$. The quartet states are related to tetrahedral d^3 as shown in Figure 9. Most octahedral Co^{II} complexes are high-spin. Low-spin octahedral d^7 is represented by a relatively small number of Co^{II}, Ni^{III}, and Cu^{IV} systems. Among the 4d and 5d series, oxidation states corresponding to d^7 are rare: the $(t_{2g})^6(e_g)^1$ configuration is unstable with respect to oxidation, with loss of the e_g electron (which in MO language is σ-antibonding). This configuration gives rise to the ground state ^2E_g, and there can be only one doublet excited state $^2T_{2g}$ resulting from excitation from t_{2g} to e_g. Thus, low-spin octahedral d^7 is analogous to octahedral d^9, as depicted in Figure 8.

5 QUANTITATIVE DETERMINATION OF LF ENERGY-LEVEL DIAGRAMS

Figures 8 and 9 are presented as qualitative plots of the energies of LF states versus the cubic splitting parameter. For any cubic complex, the energy of a symmetrically unique LF state, that is, one that does not mix with any other state of the same symmetry, can be simply expressed as the sum of an orbital energy (a multiple of the splitting parameter Δ_o) and an interelectron repulsion term, usually written in terms of the Racah parameters as $mB + nC$. Where two or more states have the same symmetry and spin, we have to set up determinants like equation (19) (SO coupling will not be dealt with here). Thus, the energy of a d–d state is a function of Δ and the Racah parameters; the state energies are plotted as functions of Δ. This requires numerical values for the Racah parameters; free-ion values are obtained from atomic spectra, but there is evidence that these are inappropriate for real crystals and complexes. This became apparent from studies of high-spin octahedral Mn^{II} systems. As noted in Section 4.3.5, the sharp $^6A_{1g} \rightarrow {}^4E_g, {}^4A_{1g}$ transitions involve only changes in interelectron repulsion; hence their energies should be the same as in the free ion. Experimentally, these transition energies are around 75–90% of the free-ion values. Detailed studies for other d^n species reveal this *Nephelauxetic Effect*; the adjective is derived from the Greek, meaning 'cloud-expanding'. This is deemed to be a manifestation of covalency; the formation of coordinate bonds with donation from ligands to the central ion lowers the charge on the cation, so that its orbitals expand outwards, reducing the repulsion among the d electrons. Ligands can be arranged in a nephelauxetic series of increasing cloud-expansion: $F^- < H_2O < NH_3 \sim Cl^- < Br^- < CN^- < I^-$. This follows the decreasing electronegativities of donor atoms, so that the nephelauxetic series reflects the extent of covalency in the central atom–ligand bond.

The discovery of the nephelauxetic effect and series in the mid-1950s did not necessarily discredit CFT. Overlap involving $(n+1)$s and $(n+1)$p could be entirely responsible for covalency and the nephelauxetic effect, so that the CF/LF orbitals remain pure nd orbitals, albeit with some adjustments to their radial wavefunctions. However, there is evidence that the nephelauxetic effect is more marked for e_g than for t_{2g} orbitals. This is consistent with the view (Section 2.3) that the e_g orbitals are σ-antibonding, while the t_{2g} orbitals may be (relatively weakly) π-bonding or π-antibonding and are often effectively nonbonding. We can distinguish between 'central-field' covalence, involving $(n+1)$s and $(n+1)$p and affecting all nd orbitals equally, and 'symmetry-restricted covalence', which affects an nd orbital to the extent of its involvement in covalent bonding.

Recognition of the nephelauxetic effect means that the free-ion values of Racah parameters are no longer appropriate in the quantitative interpretation of LF spectra and in the construction of energy-level diagrams. The simplest solution is to assume that B and C are reduced by a fixed amount (say 15%) from the free-ion values (C is often set equal to $4B$). The d–d states can then be calculated as functions of Δ and plotted accordingly; this is an Orgel diagram (*see Tanabe–Sugano Diagram*). Allowance for the nephelauxetic effect means that the d–d states do not converge exactly to the free-ion state energies when $\Delta = 0$. We seek a value for Δ that gives the best fit to the observed transition energies; the diagram enables us both to assign the bands and to determine the magnitude of the d-orbital splitting.

An alternative procedure is to leave both Δ and B (assuming $C = 4B$) as parameters to be determined by fitting the experimental transition energies. For any assumed value of the ratio Δ/B (Δ may refer to either the octahedral or tetrahedral splitting parameter), we can write the energy of a d–d state relative to the ground state as a multiple of B. Hence, we can plot E/B against Δ/B for all the d–d states. An example is given in Figure 11 (drawn for octahedral d^8 but also applicable to octahedral d^3 and tetrahedral $d^{2,7}$). The $^3A_{2g} \rightarrow {}^3T_{2g}$ transition energy is equal to Δ_o, but is in the near IR where it may escape observation. For tetrahedral d^7, the analogous $^4A_2 \rightarrow {}^4T_2$ transition is even more difficult to measure (ca. 3000 cm^{-1}). However, if the other two spin-allowed bands can be observed, we can find the appropriate value of (Δ/B) from the ratio of their transition energies. Hence, we can obtain (E/B) for the two transitions and, since the absolute values of E are known, we have an experimental value for B, and Δ will follow from the measured value of (Δ/B). This is a *Tanabe–Sugano Diagram*. The spectrochemical and nephelauxetic series have been largely established by such determinations of Δ and B. König and Kremer[57] have published very detailed LF energy-level diagrams.

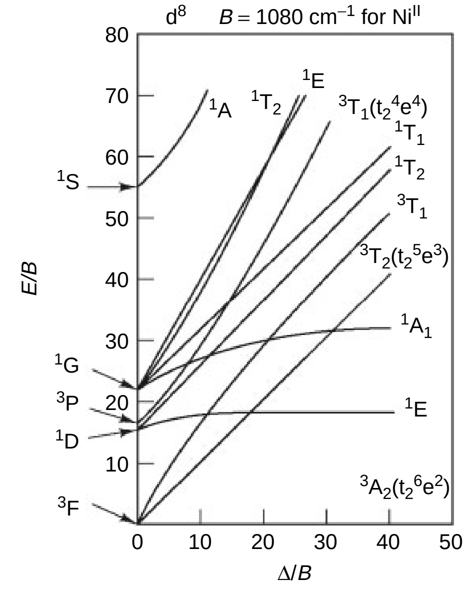

Figure 11 Tanabe–Sugano diagram for octahedral d^8

The quantitative treatment of the nephelauxetic effect – especially the treatment of differential covalence in the d subshell – has been the subject of recent developments;[58] of particular interest has been the use of density functional theory to calculate the interelectron repulsion terms with the LF model.[59,60]

At very low temperatures, high resolution is possible, and vibrational structure may be observed. SO coupling will split cubic T states as well as mixing components of different d–d states, and will mix d–d with CT states; for 3d species, SO splittings are comparable in magnitude to vibrational structure, but they are much more important among the 4d and 5d elements; there are several texts that provide more detail.[15,21,24–26]

6 LIGAND FIELD SPECTRA OF NONCUBIC COMPLEXES

These have aroused interest for two main reasons. First, they may be useful for characterization if we can identify the coordination geometry about the central atom from the d–d spectrum; this is important in situations (e.g. in bioinorganic chemistry) where standard structural methods are much more time-consuming than visible/UV spectroscopy. The second reason rests in their promise to yield information about the M–L bond if the AOM can extract values of e_σ and e_π. We will illustrate the value of such studies by looking at results for chlorocuprates(II), and at tetragonal Cr^{III} systems such as $[Cr(NH_3)_4X_2]^+$ (X = F, Cl, Br, I, etc.). The remarkable stereochemical variety of chlorocuprates(II)[61] has made them ideal subjects for both experimental and theoretical studies, while the two-dimensional spectrochemical series (Section 2.3) was largely established by studies of $Cr^{III}N_4X_2$ systems.[62]

6.1 Chlorocuprates(II)

For a noncubic complex, we need at least two parameters to describe the LF splitting. In the case of a homoleptic complex ML_n (*see Homoleptic Compound*), where all M–L distances r are equal, the simple CF description[63–65] requires two parameters, a_2 and a_4, which are proportional to r^{-3} and r^{-5}, respectively. A less regular complex requires more than two parameters. For example, the d-orbital splitting in regular square planar $CuCl_4{}^{2-}$ can be written in terms of just two parameters. For trigonal bipyramidal $CuCl_5{}^{3-}$, where the axial and equatorial Cu–Cl distances are unequal, we still need just two parameters, because a_2(eq) and a_2(ax), and a_4(eq) and a_4(ax), are related by their respective r^{-3} and r^{-5} dependence. Thus, the CF model suggests that the d-orbital splittings for all chlorocuprates(II) should be capable of analysis in terms of just two parameters. For a d^9 system (cf. Section 4.3.1), d–d transition energies can be equated to differences in orbital energies. (This is valid only if all the d orbitals have the same radial wavefunction; if we admit to some symmetry-restricted covalence, interelectron repulsion terms have to be considered.[66,67])

Some early studies[63–65] suggested that the d–d spectra of several chlorocuprates(II), including square coplanar, flattened tetrahedral, trigonal bipyramidal, and elongated octahedral geometries, could be fitted to the two parameters a_2 and a_4, scaled according to the observed internuclear distances. However, it is now agreed that this was fortuitous; much of the structural and spectroscopic data upon which these studies were based are now superseded and it is apparent that the simple CF treatment fails to explain the d–d spectra of chlorocuprates(II). The earliest application of the AOM[68] to chlorocuprates(II) appeared to be equally successful, even with neglect of π overlap; this, too, appears to have been fortuitous. The incorporation of both σ and π overlap within the AOM, plus a CF perturbation, was more successful.[69] Since the e_λ are deemed to be proportional to the squares of the appropriate overlap integrals, this proportionality constant is the only parameter needed in the analysis for all the chlorocuprates(II). However, in common with other CF/LF approaches, this model failed to account for the spectrum of square-planar $CuCl_4{}^{2-}$ (which, to be carefully distinguished from the tetragonally elongated $CuCl_6$ octahedron, was not established until 1974.[70]) Here, group theory shows that the d orbitals are split into four levels, $d_{x^2-y^2}(b_{1g})$, $d_{xy}(b_{2g})$, $d_{z^2}(a_{1g})$, and $d_{xz,yz}(e_g)$. The d–d states are labeled $^2B_{1g}$, $^2B_{2g}$, $^2A_{1g}$, and ^2E_g according to the symmetry of the singly occupied orbital that accommodates the 'hole'. All approaches agree that $d_{x^2-y^2}$ is highest in energy, and ESR measurements confirm that the ground state is $^2B_{1g}$. Likewise, all models agree on the relative energies $d_{x^2-y^2} > d_{xy} > d_{xz,yz}$, but the position of d_{z^2} is uncertain. The AOM gives the orbital energies as equations (20–23), and the d–d transition energies as equations (24–26).

$$E(x^2-y^2) = 3e_\sigma \tag{20}$$

$$E(xy) = 4e_\pi \tag{21}$$

$$E(xz, yz) = 2e_\pi \tag{22}$$

$$E(z^2) = e_\sigma \tag{23}$$

$$E(^2B_{1g} \longrightarrow {}^2B_{2g}) = 3e_\sigma - 4e_\pi \tag{24}$$

$$E(^2B_{1g} \longrightarrow {}^2E_g) = 3e_\sigma - 2e_\pi \tag{25}$$

$$E(^2B_{1g} \longrightarrow {}^2A_{1g}) = 2e_\sigma \tag{26}$$

Since Cl^- is a π donor, e_π should be positive and, on the basis of overlap integral calculations, equal to about $0.25e_\sigma$. This would place d_{z^2} close in energy to d_{xy}, and $^2A_{1g}$ close to $^2B_{2g}$. However, the spectroscopic evidence[71] indicates the energy sequence $^2B_{1g} < {}^2B_{2g} < {}^2E_g < {}^2A_{1g}$, that is, $d_{x^2-y^2} > d_{xy} > d_{xz,yz} > d_{z^2}$. The same orbital sequence had earlier been established for square $PtCl_4{}^{2-}$, using the same technique of measuring the spectra of oriented single crystals with plane-polarized radiation. The selection rules

insist that the $^2B_{1g} \rightarrow {}^2B_{2g}$ (or $d_{xy} \rightarrow d_{x^2-y^2}$) transition can have nonzero intensity only if the incident polarized beam has a nonzero component in the *xy* plane, so that this transition is readily identified.

It must be noted that in the appropriate point group (D_{4h}) nd_{z^2} and $(n+1)$s have the same symmetry, a_{1g}, and therefore can mix; in MO language, the LF a_{1g} orbital is mostly nd_{z^2}, and is σ-antibonding with respect to overlap between d_{z^2} and the ligand σ orbitals; however, there is a contribution from $(n+1)$s, and the MO is necessarily bonding with respect to its overlap. Thus, the effect of d–s mixing is to depress the energy of the LF a_{1g} orbital. This can be taken into account[72] by introducing an additional parameter e_{ds}. This, together with e_{dp}, where there is d–p mixing (e.g. T_d), helps to rationalize other anomalies in copper(II) d–d spectra. The LF splitting in the gaseous, linear $CuCl_2$ molecule has aroused much discussion. Simple CF or AOM arguments place the d_{z^2} orbital highest, so that the ground state should be $^2\Sigma_g^+$.[61,69] However, laser-induced fluorescence studies,[73] supported by elaborate theoretical calculations,[74–76] show that the ground state is $^2\Pi_g$, that is, the $d_{xz,yz}$ pair is highest in energy. This suggests a substantial depression of d_{z^2} by d-s mixing. In the analogous linear d^9 anion $[NiO_2]^{3-}$, the ground state is $^2\Sigma_g^+$, which might indicate less d–s mixing in Ni(I) compared with Cu(II), and/or less π donation to Ni(I) compared with Cu(II).[77]

It might be felt that refinements implicating s and p orbitals violate the spirit of LF theory, with its focus on just five orbitals. Moreover, the introduction of e_{ds} and so on, means that in many cases we have too many theoretical parameters to fit the spectroscopic data. In complexes of relatively high symmetry, local e_σ and e_π parameters assigned to each donor atom make additive contributions to the ligand field; but e_{ds} and e_{dp} are global, rather than local parameters except in special cases.[78] Notwithstanding these disadvantages, the d-s mixing model has undergone further refinement.[79,80]

6.2 Tetragonal Chromium(III) Complexes

Cations $[Cr(NH_3)_4X_2]^+$ have *cis* and *trans* geometrical isomers (*see* ***Coordination & Organometallic Chemistry: Principles***). The higher symmetry of the *trans* form makes its d–d spectrum easier to analyze. We assume NH_3 to be a pure σ donor (*see* ***Ammonia & N-donor Ligands***). Hence e_π (NH_3) is zero. The axial ligands are π donors ($e_\pi > 0$). The AOM orbital energies E are given in equations (27–30).

$$E(x^2 - y^2) = 2e_\sigma(\mathrm{N}) + e_\sigma(\mathrm{X}) \quad (27)$$

$$E(z^2) = e_\sigma(\mathrm{N}) + 2e_\sigma(\mathrm{X}) \quad (28)$$

$$E(xz, yz) = 2e_\pi(\mathrm{X}) \quad (29)$$

$$E(xy) = 0 \quad (30)$$

The d–d spectra yield three empirical splitting parameters so that $e_\sigma(NH_3)$, e_σ(X), and e_π(X) were obtained, and the two-dimensional spectrochemical series established.[62,81] The planar ligand py (C_5H_5N) has potentially both π donor and π-acceptor orbitals with lobes perpendicular to the molecular plane; thus e_π(py) could be positive or negative, and must be added to equations (27–30) with trigonometric factors determined by the orientations of the py rings with respect to the *xy* (CrN_4) plane. Assuming the transferability of e_σ(X) and e_π(X) from $[Cr(NH_3)_4X_2]^+$ to $[Cr(py)_4X_2]^+$, it was possible to determine e_σ(py) and e_π(py), together with the angle of orientation of the py plane.[81] The value for e_π(py) turned out to be negative, implying that py is a π acceptor. This finding was challenged,[82] partly on the grounds that the transferability of AOM parameters was questionable and partly because the implied acceptor function of py towards Cr^{III} seemed incompatible with the positive e_π found[83] for py bonded to Ni^{II} and Co^{II}. Further work[53,84,85] has clarified matters, although the transferability of AOM parameters remains controversial. Some authors ascribe a quantitative significance to the relative magnitudes of AOM parameters as measures of σ donor and π donor or -acceptor function. Others reject this view, noting (among other things) that in Cr^{III} systems, $e_\sigma(F^-)$ is comparable with $e_\sigma(NH_3)$ although ammonia is surely a better σ donor than fluoride. It must be understood that the effect of a ligand on d orbital energies is not necessarily related to the extent of electron donation or acceptance. It has been noted[85] that cyanide produces large values of Δ_o, suggesting a negative e_π, even in complexes where the oxidation number of the metal is +3 or greater and CN^- is unlikely to be a net π acceptor. Ligands such as cyanide and pyridine can function in principle both as π donors and π acceptors; e_π is therefore a composite parameter, the algebraic sum of a positive and a negative term. It is possible that a small amount of π acceptance might have energetic consequences which outweigh the effects of π donation, leading to a negative e_π even where there is net π donation. Thus, even the sign of e_π is not necessarily reliable as a qualitative indicator of a ligand's π function. However, useful comparisons can be made from data for a range of related systems.

6.3 The Cellular LF (CLF) Model[50–53]

Gerloch and Woolley[50,51] reformulated the AOM in a way that resolves some of the difficulties encountered with, for example, square planar $CuCl_4{}^{2-}$, but rejects parameter transferability. The LF parameters are determined from both optical and magnetic data, with SO coupling taken fully into account. The 'five-orbital' model, which lies at the heart of LF theory is retained; the d orbitals, it is argued, are not significantly involved in covalency and remain 'pure', albeit with expanded radial functions as a consequence of central-field covalence.

Although certainly inspired by the AOM, the CLF approach parts company from its parent in some important respects. The d-orbital splitting is deemed to arise from 'spatially local' interactions between the d orbitals and 'bond orbitals'; the bonding involves mainly the central atom $(n+1)$s and $(n+1)$p orbitals. However, some of the notation of AOM is retained, and, for the simplest situations, the results are the same. The CLF approach explains such anomalies as the position of d_{z^2} in square $CuCl_4^{2-}$ without the need to introduce d–s mixing. Thus, the absence of axial ligands in a square-planar complex creates 'voids' whose effect can be shown to depress the energy of the d_{z^2} orbital. These developments have brought LFT round almost in a full circle in the last 40 years. However, other formulations of the AOM continue to be used, and the concept of voids has been harshly criticized.[78] Computer programs for both CLF and conventional AOM analyses of spectroscopic and/or magnetic data have been described.[86]

7 OTHER APPLICATIONS OF LIGAND FIELD THEORY

7.1 Crystal Field/Ligand Field Stabilization Energy

This useful concept has been the butt of much criticism. The basic idea is that the total orbital energy of the d^n configuration in the ground state of a complex is always less than or equal to the orbital energy in the spherical field. Thus, from Figure 3, the orbital energy associated with the configuration $(t_{2g})^m(e_g)^n$ for an octahedral complex is equal to $(3n-2m)\Delta_o/5$. The crystal (or ligand) field stabilization energy (CFSE or LFSE, *see Crystal Field Stabilization Energy*) is the lowering in orbital energy of the d^n configuration in a specified coordination geometry relative to that in an equivalent spherical field: for octahedral geometry, this is equal to $(2m-3n)\Delta_o/5$. For the tetrahedral configuration $(e)^n(t_2)^m$, the CFSE is equal to $(3n-2m)\Delta_t/5$. In both cases, the CFSE is zero for d^0, d^{10}, and high-spin d^5. For high-spin systems, remembering that the low-spin option is never exercised in the tetrahedral case, we obtain a maximum CFSE of $(6/5)\Delta$ for octahedral d^3/d^8, and for tetrahedral d^2/d^7. Higher CFSEs are obtained for low-spin octahedral d^n $(n=4–7)$, with a maximum at d^6. These maxima are alleged to be related to the prevalence of these configurations, which are marked by both thermodynamic stability and kinetic inertness. The following observations are noteworthy.

1. Octahedral complexes of Cr^{III} (d^3), and of the low-spin d^6 species Co^{III}, Rh^{III}, Ir^{III}, and Pt^{IV}, are numerous and well studied. They are kinetically inert, that is, they undergo ligand-substitution reactions relatively slowly, and the bulk of kinetic and mechanistic studies on transition element complexes have been performed on them; this implies high activation barriers. Most substitution reactions of octahedral complexes appear to have dissociative mechanisms, with five-coordinate intermediates; both CF and AOM calculations lead to large losses of CFSE for d^3 and low-spin d^6 systems in going from octahedral ML_6 to ML_5 (*see Coordinatively Inert & Labile Complexes*).
2. Tetrahedral complexes are particularly common for d^7, which is well represented by cobalt(II). Although tetrahedral d^2 is less common, this configuration seems to stabilize otherwise unusual oxidation states (e.g. isoelectronic CrO_4^{4-}, MnO_4^{3-}, and FeO_4^{2-}).
3. The 'ionic' species MX_2 (X = halogen) and MO (where M is a 3d element other than Zn) have octahedrally coordinated M^{II}. If their lattice energies (as positive ΔH quantities) are plotted against the atomic number of M, there are maxima at M = V and Ni, corresponding to d^3 and d^8. Likewise, maxima are observed in a plot of the hydration enthalpy of M^{2+} against atomic number at V^{2+} and Ni^{2+}. This is attributed to the extra CFSE of $[M(H_2O)_6]^{2+}$ where M^{2+} is d^3 or d^8.

Burdett[87] has examined the CFSE concept in terms of the AOM. Essentially similar conclusions can be reached concerning the relative stabilities of configurations. The case of Ni^{II} (d^8) is particularly interesting. This has maximum CFSE for octahedral coordination, but other geometries are competitive; for example, Cr^{III} is rarely found in any coordination other than octahedral, but four- and five-coordinate Ni^{II} complexes are abundant, and octahedral Ni^{II} is not conspicuously inert. The removal of two ligands to convert octahedral to square planar will stabilize d_{z^2} (see also Section 7.2) and it can be seen that the change from $(d_{xy})^2(d_{xz})^2(d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^1$ to $(d_{xy})^2(d_{xz})^2(d_{yz})^2(d_{z^2})^2$ will lower the orbital energy and enhance CFSE. Octahedral to square equilibria of the type

$$Ni^{II}(L-L)_2L'_2 \rightleftharpoons Ni(L-L)_2 + 2L'$$

are common where (L–L) is a bidentate ligand and $Ni^{II}(L–L)_2$ is square planar. Such equilibria and distortions will be mentioned again in Section 7.2.

Finally in this section, we note the remarkable prevalence of tetrahedral four-coordination in zinc(II) chemistry (*see* ***Zinc: Inorganic & Coordination Chemistry***), to an extent comparable with cobalt(II), although d^{10} enjoys no advantage from CFSE. Tetrahedrally bonded zinc(II) is found in many metalloenzymes (*see* ***Zinc Enzymes***) and can often be replaced by cobalt without loss of enzymatic activity. This can be attributed to d–p mixing.[88] In tetrahedral symmetry (T_d), the $nd_{xy,xz,yz}$ and $(n+1)p_{x,y,z}$ orbitals each constitute a threefold-degenerate t_2 set and become mixed. The LF t_2 orbitals are thus lowered in energy, and the d^{10} configuration (where t_2 is filled) is consequently stabilized.

7.2 The Jahn–Teller (J–T) Effect

The *Jahn–Teller Effect* is something of a totem or icon among inorganic chemists. The original paper[89] showed how interactions between vibrational and electronic states caused a nonlinear molecule or complex ion in an orbitally degenerate state (e.g. E_g, T_{1g}) to be unstable with respect to a distortion that relieves the degeneracy (the J–T theorem). The ground state of any system will be orbitally degenerate if any degenerate set of orbitals is unevenly occupied, that is, if the degenerate orbitals are other than all empty, filled or half-filled. The J–T effect is the observation of such distortions where they are predicted by the theorem. Thus, regularly octahedral complexes ML_6 where M is d^9 or high-spin d^4 are rarely, if ever, found: here, an E_g ground state is predicted but the observed structures of six-coordinate Cr^{II} and Cu^{II} species can always be described as distorted octahedra with nondegenerate ground states. Distortions that relieve a threefold degeneracy, for example, for octahedral d^2, are less pronounced.

Most of the structural features that have been blamed on the J–T effect are to be found in Cu^{II} chemistry.[90] In six-coordinate Cu^{II} systems, the structure is usually a tetragonally elongated octahedron. Two trans axial ligands are at much longer (ca. 20%) distances from the Cu atom than expected for an octahedron, while the four equatorial ligands are at slightly shorter distances than expected. This is shown in Figure 12, where we compare the bond lengths of $[Ni(NH_3)_4(NO_2)_2]$ and $[Cu(NH_3)_4(NO_2)_2]$.

Notwithstanding the vibronic origins of the J–T theorem, attempts have been made to find simple explanations based on orbital energy considerations for those structural features described as J–T distortions. A simple CF analysis considers the effect on the d orbitals of an octahedral d^9 complex of withdrawing two axial ligands away from the central atom, while allowing (on account of the consequent relief of interligand repulsion) the four equatorial ligands to move a little closer to the center. The axis of elongation is conventionally labeled z. The axial elongation will stabilize d_{z^2}, which experiences a weaker field, and to a lesser extent $d_{xz,yz}$. The equatorial contraction will destabilize $d_{x^2-y^2}$ and to a lesser extent d_{xy}. The further d-orbital splitting, as octahedral ML_6 is distorted towards square planar ML_4, is shown in Figure 13. There will be a lowering in orbital

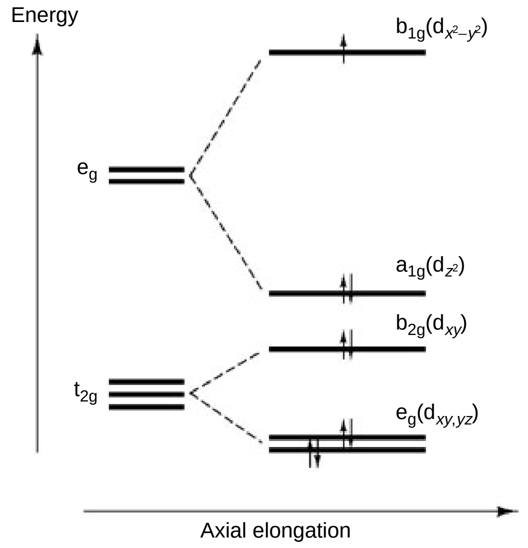

Figure 13 Effect on d-orbital energies for an octahedral d^9 system of an axial elongation

energy, that is, a gain in CFSE, and this provides the driving force for the J–T distortion. In Section 7.1, we looked at a similar distortion in the case of octahedral Ni^{II}; although this does not have an orbitally degenerate ground state, we can interpret the tendency for the removal of two opposite ligands by arguments similar to those advanced for the so-called J–T distortion of octahedral Cu^{II}! Burdett[91–94] has applied the AOM to the discussion of these points.

The point is often made that the original proof of the J–T theorem provides no guidance as the nature of the predicted distortion, except that it must remove the orbital degeneracy. In the case of octahedral Cu^{II}, we can envisage many distortions that would satisfy the theorem. For example, an equatorial compression, leading to two short and four long bonds ($2 + 4$ coordination, as opposed to $4 + 2$ already described) would relieve the degeneracy, giving an $^2A_{1g}$ ground state with the odd electron in d_{z^2}. However, such a distortion is rarely observed except in an environment that imposes a flattened configuration. The frequently cited example of K_2CuF_4 actually contains axially elongated CuF_6 octahedra,[95] although extended X-ray absorption fine structure (EXAFS) studies show that in $KAlCuF_6$, the coordination about Cu(II) is definitely compressed octahedral.[96] Several cases of compressed octahedra inferred from X-ray measurements have been shown by EXAFS to contain the usual elongation.[97] There is often a dynamic equilibrium among three conformers, differing in the orientation of the long axis. Where these are all of equal (or nearly equal) energy, as in $[Cu(H_2O)_6][SiF_6]$, a room temperature X-ray analysis leads to a regularly octahedral configuration, with averaged bond lengths, and the ESR signal is isotropic. However, an axial elongation is apparent from EXAFS measurements.[98] In some cases,

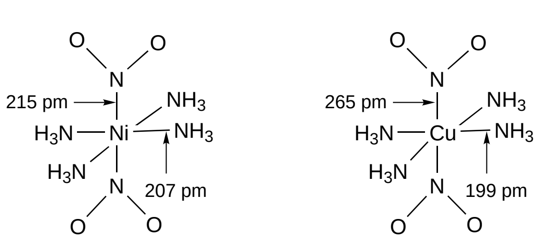

Figure 12 Bond lengths in $[Cu(NH_3)_4(NO_2)_2]$ and $[Ni(NH_3)_4(NO_2)_2]$, an illustration of the Jahn–Teller effect

two of the three conformers are much lower in energy than the third; the X-ray analysis then gives one short axis and two longer axes, intermediate between short and long.[97] As an example of this behavior, $(NH_4)_2[Cu(H_2O)_6](SO_4)_2$ appears to be tetragonally compressed at high temperatures, but low temperature X-ray and neutron diffraction studies show an elongation with a rhombic distortion. On deuteration, the directions of the long and intermediate axes are interchanged.[99] The dynamics of the Jahn–Teller effect has also been thoroughly studied in copper(II) complexes containing two tridentate N-donor ligands.[100] The preference for axial elongation can be explained if we recall (Section 6.1) that in D_{4h} symmetry (which holds for both types of tetragonal distortion, as well as square planar), $3d_{z^2}$ mixes with 4s, and the LF d_{z^2} orbital is further stabilized. This enhances the CFSE more in the case of an axial elongation (where d_{z^2} is doubly occupied) than for an equatorial compression (where d_{z^2} is singly occupied). Such mixing will also assist the octahedral–square transformation for Ni^{II}.[100,101]

Glossary

Activator: luminescent center
AX: B means that the luminescent-ion B is substituted for the A cation of the host lattice AX
Excitation spectrum: variation of the luminescence intensity at a given wavelength as a function of the wavelength of the excitation radiation
Phosphor: luminescent material, usually in powder form
VUV (vacuum ultraviolet): ultraviolet radiation with wavelength below 190 nm

1 INTRODUCTION

Luminescence is the emission of light from a nonthermal excitation. The use of the term has been extended to the emission of UV or IR radiation. A luminescence is obtained under a variety of excitation sources, for example:

- electromagnetic radiation: Vacuum ultraviolet (VUV), UV (photoluminescence), X rays, γ rays
- particles: electron beam (cathodoluminescence), neutrons, and so on
- electric field (electroluminescence).

The luminescence yield depends on the probabilities of excitation and radiative decay of luminescent centers. Photon emission competes with phonon emission, the latter resulting in temperature rise.

In most luminescent materials, emission is the result of an electronic transition within an ion. The luminescent ion, called the activator, is generally substituted for ions with comparable size in a compound termed host lattice, transparent to the emitted radiation. The emitting level must lie below the conduction band in order to avoid ionization. The luminescence characteristics are strongly dependent on the nature of the host. For instance, depending on the covalency and crystal field, the position of the emission band of Eu^{2+} in oxide lattices can vary from the UV (maximum at 367 nm in SrB_4O_7) to the red (733 nm in CaO). The luminescence spectra of most efficient materials have been collected in Ref. 1.

Luminescence can also arise from a trapped exciton or from a transition between two centers (donor–acceptor transitions).

2 LUMINESCENCE PROCESSES

2.1 Electronic Transitions within Ions

Transitions occur mainly by an electric dipole mechanism. Such transitions are allowed if the initial and final states are made up of orbitals of opposite parity ($\Delta l = 1, 3, \ldots$; l: orbital angular momentum quantum number) and if the spin remains unchanged ($\Delta S = 0$) (Laporte rules, *see* ***Ligand Field Theory & Spectra***). However parity-forbidden transitions can occur as a result of mixing with states of opposite parity. Mixing of states by the crystal field requires that the cationic site lacks an inversion center. If the site is centrosymmetric, transitions can nevertheless be observed owing to vibronic coupling. Their probability is low and increases with temperature.

In absorption spectra, the probability of a transition is expressed by its oscillator strength, f. While f is close to unity for allowed transitions, it is of the order of 10^{-5}–10^{-4} and 10^{-6}–10^{-5} respectively for spin-allowed transitions within the $3d^N$ and $4f^N$ configurations. Efficient conversion of a UV radiation to light (as needed in fluorescent lamps) requires strong absorption properties at the wavelength of incident photons. Figure 1 shows a comparison of the luminescence intensity for 4f → 5d ($\Delta l = 1$) and 4f → 4f ($\Delta l = 0$) excitations in the case of a terbium compound.

When isolated ions in a lattice have been promoted to the excited state, the population of emitting ions decreases exponentially:

$$I(\mathrm{t}) = I_0 \exp(-Wt) \quad (1)$$

where I_0 is the initial luminescence intensity and W the sum of radiative and nonradiative rates expressed in s^{-1}: $W = W_r + W_{nr}$. The radiative rate is given by:

$$W_r = \frac{64\pi^4 \chi e^2}{3hg_i\lambda^3}\mathrm{S} \quad (2)$$

where g_i is the degeneracy of the initial state, λ the peak emission wavelength, and S the line strength: $S = |\langle\psi_a|P|\psi_b\rangle|^2$ where P is the electric dipole operator; χ is the local field correction:

$$\chi = \frac{n(n^2+2)^2}{9} \quad (3)$$

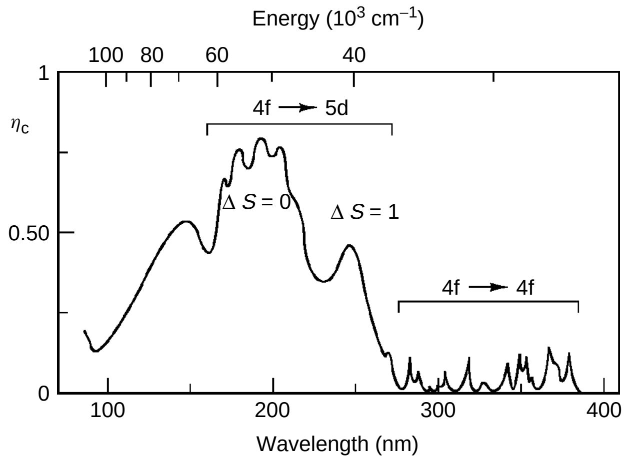

Figure 1 Variation of the conversion yield, η_c (ratio of the number of photons emitted to the number of incident photons), as a function of the excitation wavelength for $Tb_{0.70}La_{0.30}MgB_5O_{10}$ [2]

where n is the refractive index. For allowed transitions such as the 5d → 4f transitions of Eu^{2+} or Ce^{3+} S is little influenced by the host.[3,4] Thus the radiative rate depends essentially on the emission wavelength and refractive index.

$\tau_r = 1/W_r$ is the radiative lifetime. τ_r varies from 10^{-8} to 10^{-7} s for allowed transitions to 10^{-4}–10^{-2} s for forbidden transitions.

Magnetic dipole transitions play a role in the luminescence of some lanthanide ions, specially Eu^{3+}, when the local symmetry deviates little from inversion symmetry. They are parity-allowed between states of the $3d^N$ or $4f^N$ configurations but have a low probability. They are subject to selection rules: $\Delta L = \Delta S = 0$ and $\Delta J = 0, \pm 1$ (0 ↔ 0 forbidden).

2.2 Shape of Emission Bands – The Single-configurational-coordinate Diagram Model

Figure 2 shows configuration curves for the ground state and an excited state. They represent the energy dependence on the cation-anion distance: $E = 1/2\,kr^2$, where r is the cation–anion distance and k the force constant, and the equilibrium distance of the ground state is taken as the origin. Equidistant lines inside the parabolas represent vibrational energy levels whose population corresponds to a Bolztmann distribution. The amplitude of the vibrational wavefunction is maximum for $r = 0$ for the first vibrational level and at the end of the segments (at the turning points), on the parabola, for higher levels. Electronic transitions are represented by vertical lines because they occur in a very short time compared to that of atomic displacements.

If the transition involves only inner orbitals, the equilibrium distance is not modified (Figure 2a); the parabola of the excited state has the same shape than that of the ground state. Since the two parabolas are parallel, all transitions have nearly the same energy. The corresponding spectrum consists of a narrow

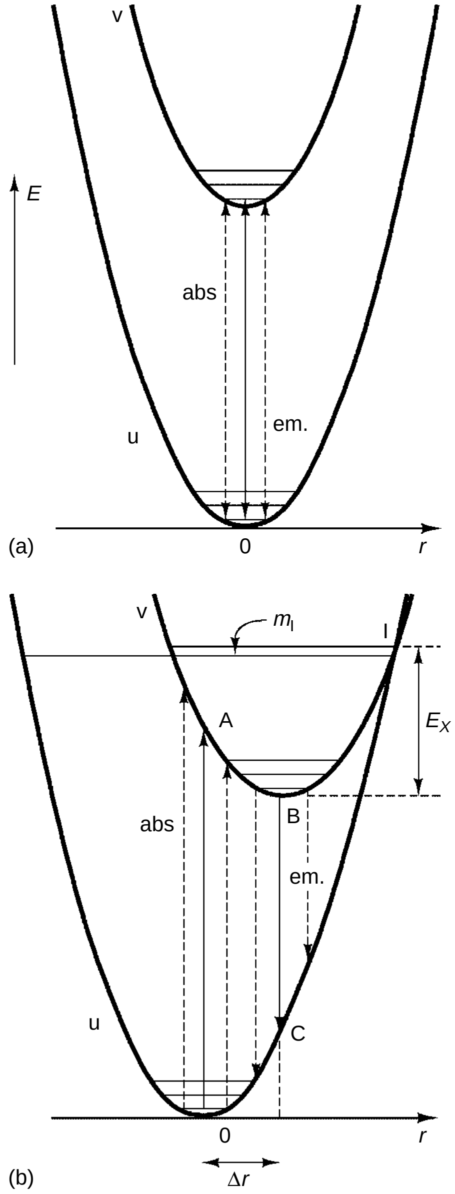

Figure 2 Configurational-coordinate diagrams for (a) negligible and (b) strong offset Δr

line at the same position in absorption and emission. Because the 4f levels are internal, the bonding is not significantly modified when electronic transitions occur between these levels. 4f–4f transitions give rise to sharp lines in absorption and emission spectra.

If the transition involves an external orbital, the equilibrium distance is changed (Figure 2b). Transitions from a vibrational level of the ground state end on different vibrational levels of the excited state. The absorption spectrum consists of a band which broadens with increasing temperature as a result of the population of higher vibrational levels of the initial state. After excitation the ion returns to the ground state by the following processes:

1. relaxation to the bottom of the excited-state parabola (transitions A → B, Figure 2b) by emitting phonons (i.e. by giving up heat to the lattice), in a time of the order of 10^{-13} s;
2. radiative emission (transitions B → C);
3. relaxation to the minimum of the ground-state parabola with phonon emission (transitions C → 0).

The emission band lies at lower energy than the absorption band. The energy difference between the maxima is called the Stokes shift. The energetic distribution of transitions in absorption or emission has approximately a Gaussian shape. Because of the weakening of the bonding, the excited-state parabola is wider than the ground state one. Consequently the emission band is broader than the corresponding absorption band. The width increases with increasing offset Δr and phonon energies.

Examples of band emissions are the 3d → 3d transitions of transition metal ions such as Mn^{2+}, the 5d → 4f transitions of lanthanide ions such as Ce^{3+} and Eu^{2+} and the np → ns transitions of ions with s^2 configuration such as Pb^{2+}, Sb^{3+}, and Bi^{3+}.

2.3 Luminescence Quantum Efficiency – Nonradiative Transitions

The luminescence quantum yield is the result of the competition between radiative and nonradiative transitions:

$$\eta_r = \frac{W_r}{W_r + W_{nr}} \tag{4}$$

Nonradiative transitions between the 4f levels of lanthanide ions are caused by multiphonon processes. In the case of band emissions, the quantum efficiency is commonly interpreted by the Mott's model. It should be noted that Struck and Fonger have shown that in fact an unified model can be used for these two types of emission.[5]

2.3.1 Narrow Line Emission – Multiphonon Processes

Nonradiative relaxation between the 4f states of lanthanide ions can occur by the simultaneous emission of several phonons.[6,7] The multiphonon emission rate decreases exponentially with the energy gap ΔE to the next-lower level:

$$W_{nr} = C\exp(-\alpha\Delta E) \tag{5}$$

C and α are constants characteristic of the host and, with rare exceptions, independent of the nature of the lanthanide ion or electronic state involved. The validity of the exponential dependence on the energy gap has been well experimentally established.[8] A modified exponential energy gap has been derived by van Dijk and Schuurmans:[9]

$$W_{nr} = \beta_{el}\exp[-\alpha(\Delta E - 2\hbar\omega)] \tag{6}$$

Unlike C, β_{el} varies little with the host lattice.

The nonradiative transition rate increases with rising temperature. The effect of T increases with the number of phonons involved in the process:

$$W_{nr}(T) = W(0)(n+1)^p \tag{7}$$

where $W(T)$ is the transition rate at temperature T, p is the number of phonons of equal energy emitted, $p = \Delta E/\hbar\omega$, and n the average occupation number of vibrational levels,

$$n = \left[\exp\left(\frac{\hbar\omega}{kT}\right) - 1\right]^{-1} \tag{8}$$

Since the transition rate decreases exponentially with the number of phonons required to bridge the energy gap, the highest-energy phonons make the largest contribution to the process. Vibrational frequencies increase with increasing bond strength and decreasing atomic mass, following the trend

oxides > fluorides > sulfides > chlorides > bromides

Figure 3 shows the nonradiative rate dependence on the energy gap to next-lower level for some halide and oxide host lattices. The nonradiative rate amounts to $10^4\,s^{-1}$ (a value of the order of the radiative rate of spin-allowed 4f → 4f

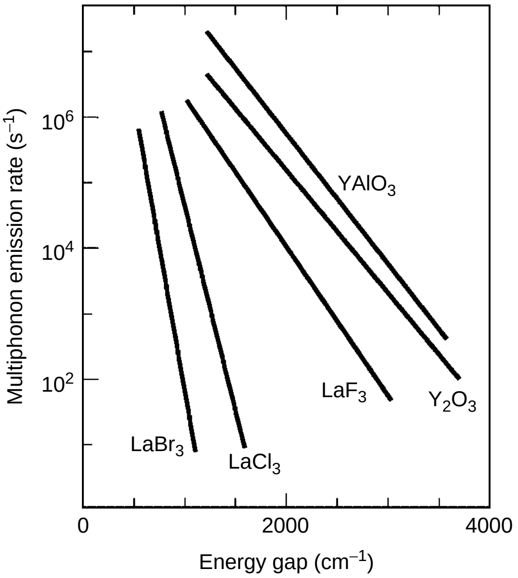

Figure 3 Multiphonon emission rates from excited states of trivalent rare earths as a function of energy gap to the next lower level. (Reproduced by permission of Ref. 5)

transitions) for an energy gap of $1000\,cm^{-1}$ in chlorides and $2500-3000\,cm^{-1}$ in oxides such as Y_2O_3 or $YAlO_3$.[8]

2.3.2 Quantum Efficiency of Band Emissions

In the Mott's model, nonradiative transitions are pictured as taking place at the intersection of the configuration coordinate curves, I (Figure 2b). The stability of the emission depends on the energy difference, E_X, between the minimum of the excited-state parabola and the intersection. When with rising temperature the m_I vibrational level becomes populated, the luminescence center can return to the ground state by giving up phonons to the lattice. The rate is described by Mott's activation-energy formula:

$$W_{nr} = A_M \exp\left(\frac{-E_X}{kT}\right) \tag{9}$$

where A_M is a rate constant of the order of $10^{13}\,s^{-1}$.

Hence the thermal stability increases with increasing energy of the excited state and decreasing value of the offset, Δr.

The effect of the excited-state energy can be illustrated by the charge transfer (CT) luminescence of tetrahedral groups $MO_4{}^{2-}$ where M is a transition metal: Cr, Mo, W. These groups exhibit an absorption band corresponding to a transition from a predominantly anionic molecular orbital to a predominantly cationic molecular orbital.[10] Its position lowers in energy with increasing oxidizing character of the cation: W > Mo > Cr. The luminescence of chromates has been observed only at very low temperature and for all molybdates quenching starts below room temperature. In contrast, the emission of various tungstates, $MgWO_4$, $CaWO_4$, $CdWO_4$, exhibits high efficiency at 300 K.[11]

Quenching curves actually often deviate from the shape expected from a single activation energy. The reason is that the probability of nonradiative transitions from vibrational levels below the intersection I is not negligible. Struck and Fonger proposed a method of calculation of nonradiative rates.[5] For the ground state u and excited state v, the vibrational wavefunctions and phonon energies are called u_n, $\hbar\omega_u$ and v_m, $\hbar\omega_v$ respectively. The rate of a transition between the vibrational levels m and n is proportional to the product of the population of the initial level according to a Boltzmann distribution and the square overlap integral $\langle u_n | v_m \rangle^2$. The multiple activation energies $m\hbar\omega_v$ to the initial vibrational states produce an increase in the nonradiative rate poorly described, in general, by a single activation energy. This model shows that in addition to the energy of the excited state and the offset Δr, phonon energies are an important parameter governing the probability of nonradiative transitions. For a hypothetical red phosphor exhibiting an excitation band in the UV at about 310 nm, the temperature at which the intensity is reduced to half of its value at low temperature falls from 560 K for $\hbar\omega = 400\,cm^{-1}$ to 325 K for $\hbar\omega = 600\,cm^{-1}$.[12] In the latter case, at low temperature the quantum efficiency remains far below unity.

Configurational-coordinate diagrams can be established from the shape of absorption and emission bands. It must be stressed that the validity of the model is limited by the assumption of a single vibrational mode.

2.4 Energy Transfer

An ion in an excited state can transfer part or whole of its energy to a neighbor ion (Figure 4) by a radiative or nonradiative process. The acceptor ion can be in the ground state or in an excited state *(upconversion)*. Energy transfer is responsible for the drop in luminescence efficiency usually observed at high activator concentration (*concentration quenching*) and is used for increasing the probability of excitation of luminescent ions (*sensitization*).

2.4.1 Energy Transfer Mechanisms

Radiative transfer plays a role essentially when the absorption band of the acceptor ion is allowed. A photon emitted by an ion is absorbed by an other ion before escaping from the material. This requires overlap of the emission spectrum of the donor with the absorption spectrum of the acceptor. Radiative transfer between identical ions causes a modification of the spectral distribution. This is the case for the Ce^{3+} emission when the Stokes shift is small. The cerium emission originates from the lowest 5d state and consists of two bands because the ground state $4f^1$ is split by spin-orbit coupling into the states $^2F_{5/2}$ and $^2F_{7/2}$ (Figure 5), the shorter-wavelength component 5d → $4f(^2F_{5/2})$ having the

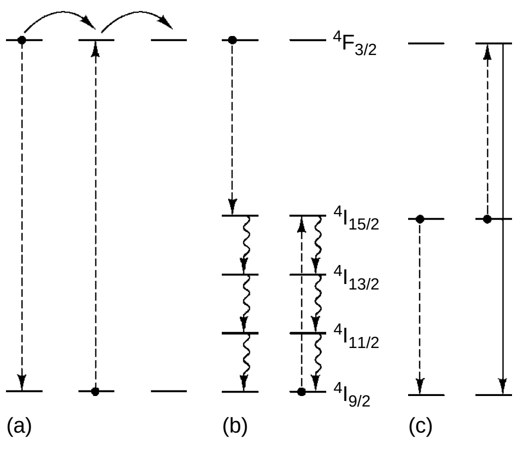

Figure 4 Schematic representation of energy transfers: (a) energy migration; (b) cross-relaxation; (c) upconversion. Vertical arrows in broken lines correspond to energy transfer and in solid lines to radiative transition. The energy diagram that illustrates the cross-relaxation mechanism is the Nd^{3+} one

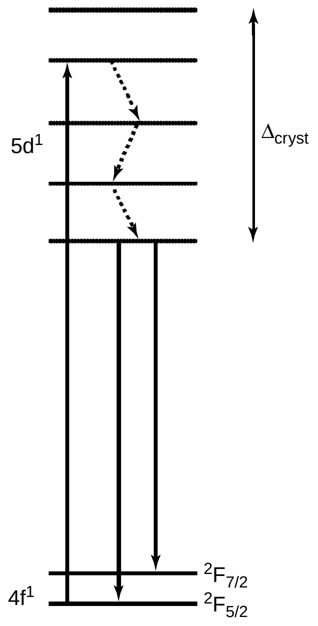

Figure 5 Luminescent processes of Ce^{3+}

strongest intensity. Owing to the overlap with the lower-energy $4f(^2F_{5/2}) \rightarrow 5d$ absorption band, with increasing Ce concentration the relative intensity of the shorter-wavelength emission band decreases with respect to that of the longer-wavelength component.

Nonradiative energy transfer is due to electric or magnetic multipolar interactions or to exchange interactions.[10,13–15]

For electric multipolar interactions, the transfer rate W_{DA} is proportional to the probability of the donor and acceptor transitions, to the overlap between the emission and absorption bands of the donor and acceptor, and to an inverse power of the donor–acceptor separation, R^{-s} with $s = 6, 8, 10$ for dipole–dipole, dipole-quadrupole, or quadrupole–quadrupole interaction. For electric dipole–dipole interaction, the transfer rate is proportional to

$$\frac{Q_A}{R^6 \tau_r} \int \frac{F_D(E) F_A(E)}{E^4} \tag{10}$$

where Q_A is the area under the absorption band of the acceptor: $Q_A = \int \sigma(E)\, dE$, σ absorption coefficient; τ_r is the luminescence lifetime of the donor and $F_D(E)$ and $F_A(E)$ are normalized functions such as $\int F(E)\, dE = 1$.[16] If the activator is dilute in the lattice, transfer occurs mainly by dipole–dipole interaction.[6]

For exchange interaction, the transfer rate decreases exponentially with the donor–acceptor distance. It depends on wavefunction overlap and is not influenced by the probability of transitions.[16]

The critical distance is the distance at which the probability of energy transfer is equal to the probability of intrinsic decay rate $W = 1/\tau_D$, where τ_D is the excited-state lifetime of the donor. The critical distance may reach 30 Å if the optical transitions of the donor and acceptor ions are electric dipole allowed transitions; it is of the order of 4–6 Å for overlap between an allowed emission band and the $4f \rightarrow 4f$ absorption lines of lanthanide ions (oscillator strength $f \approx 10^{-6}$).[12]

When acceptor ions are present, the decay of donor ions does not exhibit an exponential behavior. In the absence of energy transfer between donor ions and assuming a random distribution of acceptor ions, for multipolar interactions the decay is given by

$$I = I_0 \exp\left(\frac{-t}{\tau_D} - \alpha \left(\frac{t}{\tau_D}\right)^{3/s}\right) \tag{11}$$

where α is a parameter which depends on the acceptor concentration and critical distance.[17] The presence of acceptor ions results in a faster initial decay. With time the luminescence originates increasingly from excited ions which are far from acceptor ions and relax at a rate governed by the intrinsic decay rate.

If energy transfer between donor ions is possible, excitation may migrate until it comes into the vicinity of an acceptor ion. When the rate of energy diffusion is slow and the acceptor concentration is low, the donor decay is governed by intrinsic relaxation and by diffusion-limited relaxation to acceptors. The decay at long times after the excitation pulse is exponential with a decay time given by $1/\tau = 1/\tau_D + 1/\tau_{dif}$ where $1/\tau_{dif}$ is the decay rate due to diffusion. When the probability of energy transfer between donor ions is large, energy diffusion can be very rapid. The rate limiting step in the energy transfer process is the donor–acceptor transfer rate. Because the diffusion occurs on a much shorter timescale, the emission of donor ions exhibits an exponential decay.

2.4.2 Concentration Quenching

Interactions between luminescent ions cause nonradiative losses by two mechanisms: *energy migration* and *cross-relaxation*.

1. By a sequence of energy transfers between identical ions, the excitation can migrate in the lattice (Figure 4a). When there is no intermediate level between the emitting and ground states, concentration quenching is the consequence of *energy migration* to defects or impurities where the excitation is lost nonradiatively. Because of the broadening of emission and absorption bands, losses due to concentration quenching increase with rising temperature.

   For strong spectral overlap and high oscillator strengths, energy transfer can occur between distant ions. For Bi^{3+} in $LaMgB_5O_{10}$ (6s–6p transitions) the critical distance has been estimated to be 25 Å and concentration quenching starts at low Bi^{3+} concentrations, that is, above about

2%.[18] The arrangement of ions in the lattice in this case does not influence the migration. For ions like Eu^{3+} or Tb^{3+}, owing to the small oscillator strengths of the 4f–4f transitions involved in the transfer ($^7F_0$,$^7F_1$–$^5D_0$ for Eu^{3+} and $^7F_6$–$^5D_4$ for Tb^{3+}, Figure 9), transfer occurs mainly between nearest neighbors. The shape of the decay curves shows that the migration has the dimensionality of the assembly of coordination polyhedra with common corners.[12] In $EuMgB_5O_{10}$, the rare earth ions form a monodimensional assembly. The probability of energy transfer between the Eu^{3+} ions at 300 K has been estimated to be $10^7\,s^{-1}$ within the chains and $10\,s^{-1}$ between the chains.[19] A small amount of rare earth ions R^{3+} like Y^{3+}, La^{3+}, or Gd^{3+} in the chains is sufficient to inhibit energy migration to impurities. In solid solutions such as $Li_6\ Eu_xR_{1-x}(BO_3)_3$ or $MgEu_xR_{1-x}B_5O_{10}$, quenching appears only for x values close to unity.

2. *Cross-relaxation* is the main cause of concentration quenching for the lanthanide ions having a great number of 4f levels like Pr^{3+}, Nd^{3+}, Ho^{3+}, Er^{3+}, or Tm^{3+} (Figure 9). Some emission lines originating from an excited level are close in energy to absorption lines, hence part of the energy of the excited ion can be transferred to a neighbor ion. This is illustrated in Figure 4(b) by neodymium. When two Nd^{3+} ions occupy neighbor sites, an ion in the excited state $^4F_{3/2}$ can decay nonradiatively to the intermediate state $^4I_{15/2}$ by giving the corresponding energy to the second ion which is excited to the level $^4I_{15/2}$. Both ions then decay nonradiatively. The transfer is often phonon-assisted, that is, phonon absorption or emission compensates for small differences in energy between emission and absorption lines. The probability for energy transfer decreases with decreasing crystal field splitting of 4f levels. The effect of cross-relaxation is very pronounced. For instance about 50% of the ions excited in the levels $^3H_4$, $^1G_4$, or $^1I_6$ of Tm^{3+} in Y_2O_3 are depopulated nonradiatively for a concentration of 1%.[21]

2.4.3 *Sensitization*

Energy transfer is used for increasing luminescence efficiency. In photoluminescence, a high conversion yield requires a strong absorption of the excitation radiation. When the absorption properties of the activator at the excitation wavelength are insufficient, the luminescence yield can be improved by adding an ion, called sensitizer, which absorbs the excitation radiation more efficiently and transfers the energy to the activator. For instance, in green-emitting phosphors for low-pressure mercury-vapor lamps ($\lambda_{exc.} = 254$ nm), Tb^{3+} is excited through the intense 4f → 5d absorption bands of Ce^{3+} and in YVO_4:Eu, the red phosphor for high-pressure mercury-vapor lamps ($\lambda_{exc.} = 365$ nm), Eu^{3+} is excited via the CT transition of $VO_4{}^{3-}$ groups.[12]

2.4.4 *Upconversion*

If an ion possesses two excited states with approximately same energy separation, energy transfer can occur between two ions in the first excited state (Figure 4c). One ion returns nonradiatively to the ground state while the second is promoted to the second excited state, then decays with emission of a photon whose energy is about twice that of incident photons. There are other upconversion processes: two-step absorption, cooperative sensitization, cooperative luminescence.[22] Upconversion by energy transfer is the most efficient process.

2.5 Influence of the Host Lattice on the Position of the Emitting Level

The energy of the emitting level depends on the *nephelauxetic effect* and the *crystal field* at the luminescent-ion site.

The nephelauxetic effect is a reduction of the electrostatic interaction of the luminescent-ion electrons when the covalency of the bonds increases, resulting in a lowering of the position of the energy levels. This effect therefore increases with decreasing ligand electronegativity:

$$F < O < Cl < Br < S$$

The crystal field splitting increases with increasing charge and decreasing size of ligands:

$$O > S > F > Cl > Br > I$$

For the same ligand, the nephelauxetic effect and the crystal field depend on the following factors:

1. The ionic radius of the substituted cation M: the higher the size of M, the smaller the overlap of cationic and anionic orbitals and therefore the lower the nephelauxetic effect and the ligand field.
2. The coordination. Transition element ions are in general tetrahedrally or octahedrally coordinated. The ligand field is about twice lower for the fourfold coordination than for the sixfold one (*see* ***Ligand Field Theory & Spectra***). The coordination number of lanthanide ions varies from 6 to 12. The nephelauxetic effect and crystal field decrease with increasing coordination number.
3. The nature and number of other cations (M′) in the lattice: if the ligands form strongly covalent bonds with other atoms in the lattice, the bonds with the luminescent ion weaken, resulting in a decrease in nephelauxetic effect and ligand field interaction (inductive effect).[23] The higher the number of bonds formed by the ligand with M′ atoms, the stronger this effect. If the ligand–M′ bonds have a marked ionic character, the charge of the M cations reduces the field generated by the ligands.

Table 1 influence of the host lattice on the nature of the luminescence of Eu^{2+} in alkaline earth fluorides. A 4f → 4f emission is observed when the first $4f^65d$ states are above the first excited level of the $4f^7$ configuration at 27 800 cm^{-1}

Host	Coordination number	Lowest limit of the 4f → 5d absorption band (cm^{-1})	Nature of radiative transitions
CaF_2	8	24 200	
SrF_2	8	25 000	
BaF_2	8	25 500	5d → 4f
$BaMgF_4$	8	26 500	
$CaBeF_4$	8	26 600	
α-$SrBeF_4$	9	28 000	5d → 4f
$BaBeF_4$	10	29 000	and
$BaLiF_3$	12	29 500	4f → 4f
BaY_2F_8	12	30 000	
$SrSiF_6$	12	31 000	4f → 4f
$BaSiF_6$	12	32 000	

The influence of these three factors is illustrated in Table 1 by the energy of the first 4f → 5d transitions in the excitation spectra of Eu^{2+}-doped alkaline earth fluorides. A smaller nephelauxetic effect and lower ligand field with increasing coordination number shift the lower 5d level to high energies. The splitting is particularly reduced for BaY_2F_8, $SrSiF_6$, and $BaSiF_6$ owing to the presence in the lattice of atoms with high oxidation state. This results in a change of the nature of the Eu^{2+} emission. In most host lattices, the nephelauxetic effect and crystal field splitting lowers the bottom of the 5d band well below the first excited level of the $4f^7$ configuration $^6P_{7/2}$, located at about 27 800 cm^{-1}, and similarly to Ce^{3+} (Figure 5), Eu^{2+} exhibits a 5d → 4f emission. This is not the case for BaY_2F_8 and the fluorosilicates. Excitation into a 5d state is followed by nonradiative deexcitation to the $^6P_{7/2}$ state

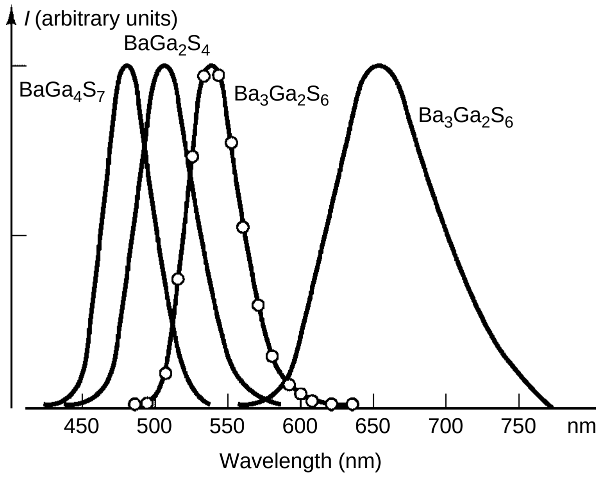

Figure 6 Spectral distribution of the Eu^{2+} emission in barium thiogallates.[24] The points on the $Ba_3Ga_2S_6$:Eu band correspond to the calculation of the shape from the single-configurational-coordinate model. (Reproduced by permission of Ref. 4)

which gives rise to a UV line emission. For fluoroberyllates and $BaLiF_3$, because of the proximity of the lowest 5d states with $^6P_{7/2}$, both the 5d → 4f band and the 4f → 4f lines are present in the emission spectra at 300 K.

The effect of the number of covalent bonds formed by the ligand (point (3) above) is illustrated in Figure 6 by the shift of the emission band of Eu^{2+} in barium thiogallates. When phases with various MO/M'_xO_y or MS/M'_xS_y ratios exist (M = alkaline earth, M′ = B, Al, Ga, Si, etc.), the first 5d level of Eu^{2+} substituted for M tends to lower with increasing value of the ratio. This results in the case of barium thiogallates in a shift of the emission maximum from 480 nm, in the blue, for the Ga_2S_3-richest phase, to 655 nm, in the red, for the BaS-richest one.

3 MAIN FAMILIES OF LUMINESCENT IONS

Table 2 lists the main families of luminescent ions with representative lifetimes.

3.1 Transition Metal Ions

3.1.1 Ions with a Partly Filled nd Subshell

The number of states for the nd^N ($n = 3, 4, 5$) electronic configurations of transition metal ions is equal to the number of combinations $C_{10}{}^N$. Interelectronic repulsions partially remove the degeneracy, leading to the spectroscopic terms ^{2S+1}L with $(2S+1)(2L+1)$ degeneracy. In a lattice, the degeneracy of the ^{2S+1}L terms is partially removed by interaction with the crystal field. Figure 7 shows the effect of an octahedral field for the $3d^3$ and $3d^5$ configurations. For the d^3 ions, spin-allowed transitions can occur from the ground state, $^4A_{2g}$, to three excited states, $^4T_{2g}$, $^4T_{1g}(^4F)$, $^4T_{1g}(^4P)$. Chromium compounds are strongly colored as a result of absorption of light by the two lower-energy spin-allowed transitions. For d^5 ions like Mn^{2+}, all transitions are spin-forbidden since the subshell is half-filled, and light absorption is often too small to give rise to a discernible color.

A high probability of radiative deexcitation requires a large gap between a level and the next-lowest level (2.3). Excitation of transition element ions in a high-energy state is followed by nonradiative transitions between the different states down to the lowest excited state from which emission can occur if the energy separation with the ground state is high enough. This condition is fulfilled for Ti^{3+} (d^1), Cr^{3+}, Mn^{4+} (d^3), and Mn^{2+}, Fe^{3+} (d^5), which emit in the visible range.[15] Also Ni^{2+} can give an emission at 300 K, located in the IR.[25] At low temperature, V^{2+} (d^3) and Co^{2+} (d^7) show an infrared emission when incorporated in lattices with low phonon energies like halides and chalcogenides. For most ions,

Table 2 Main families of luminescent ions, nature of transitions, and order of magnitude of radiative lifetimes (values at 300 K, except for the charge transfer (CT) emission of Ce^{4+} and Yb^{3+} whose emission is affected by thermal quenching at room temperature)

Nature of ions	Transition	Δ l	τ (s)
Ti^{3+}, V^{2+}, Cr^{3+}, Mn^{2+}, Mn^{4+}, Fe^{3+}, Co^{2+}, Ni^{2+}	3d → 3d	0	10^{-5}–10^{-4} ($\Delta S = 0$) 10^{-3}–10^{-1} ($\Delta S = 1$)

Oxyanions of a lanthanide: Ln = Ce^{4+}, Yb^{3+}	O → Ln CT	(CeΔS = 1) (YbΔS = 0)	Ln = Ce 3–6.10^{-5} Ln = Yb 1–2.10^{-7}
Oxyanions of U^{6+}	O → U CT		

the first excited state corresponds to an electronic transition between orbitals of different symmetry, for instance, from a t_{2g} to e_g orbital in octahedral coordination. This causes a change in the equilibrium interatomic distances and the spectrum consists of a band (or at low temperature of a zero-phonon line corresponding to transitions between the m = 0 and n = 0 levels, accompanied by a broad vibronic band). The first excited states of d^3 ions in a strong crystal field, ^2E_g and $^2T_{1g}$ (Figure 7), like the ground state, arise from the t_{2g3} configuration. The change in equilibrium distance in this case is very small. Mn^{4+} ions exhibit a line emission in the deep red around 650 nm.[1] Depending on the strength of the crystal field, Cr^{3+} gives a band emission originating from $^4T_{2g}$ or a line emission from ^2E_g. The $^2E_g \rightarrow {}^4A_{2g}$ emission line of Cr^{3+} in the red is responsible for the laser emission of ruby (694 nm).[26] The luminescence band of crystals of Al_2O_3:Ti^{3+}, $BeAl_2O_4$:Cr^{3+}, $LiSrAlF_6$:Cr^{3+}, and V^{2+}, Co^{2+} or Ni^{2+}-doped fluorides such as MgF_2 permits tunable laser operation.[27]

For a d^5 ion, the energy of the luminescence transition, $^4T_1 \rightarrow {}^6A_1$, decreases with increasing crystal field (Figure 7). In oxide lattices, the emission of Mn^{2+} lies in the green for tetrahedral coordination (e.g. Zn_2SiO_4:Mn^{2+}, a phosphor for lamp, plasma display panel (PDP) or cathode ray tube (CRT) display, or $MgAl_2O_4$:Mn^{2+}) and in the red for octahedral coordination ($LaMgB_5O_{10}$:Mn^{2+} or $Cd_2B_2O_5$:Mn^{2+}).[1] Because of the low oscillator strengths of the f–f absorption bands, the luminescence is weak for excitation into these transitions. Mn^{2+} can be excited efficiently in the UV range by energy transfer from sensitizing ions such as Sb^{3+}, Bi^{3+}, Ce^{3+}, or Eu^{2+}, which have allowed transitions. In Zn_2SiO_4, Mn^{2+} possesses an intense absorption band below 300 nm allowing efficient direct excitation.[1] This band has been ascribed to a CT in which Mn^{2+} is involved. The luminescence transition being parity- and spin-forbidden, at low concentration the manganese emission exhibits long decay times, of the order of 10 ms in oxide hosts for tetrahedral coordination. In some host lattices such as Zn_2SiO_4, the decay becomes faster with increasing Mn concentration owing to the contribution of Mn^{2+} pairs to the luminescence. In pairs the oscillator strengths are increased by exchange interactions.[28] The decay time is one order of magnitude shorter than for isolated ions: 1.7 ms instead of 15 ms in Zn_2SiO_4 at 300 K.[29]

3.1.2 *d^{10} Ions*

The luminescence of the monovalent ions Cu^+ and Ag^+ is usually ascribed to $3d^94s \rightarrow 3d^{10}$ and $4d^95s \rightarrow 4d^{10}$ transitions, respectively.[15,30] In octahedral coordination the excited configuration d^9s is split into the levels ^3E_g, ^1E_g, $^3T_{2g}$, and $^1T_{2g}$. The emission originates from the lower state ^3E_g. The luminescence of isolated Cu^+ and Ag^+ ions lies in the UV in fluorides and in the blue or blue-green regions in alkaline earth sulfides.[31,32]

3.1.3 *Complexes of d^0 Ions – Charge Transfer Luminescence*

Oxides containing a nd^0 ion (n = 3, 4, 5) (titanates, vanadates, molybdates...) show an intense absorption band in the UV due to a CT transition, whose energy varies linearly with the corresponding ionization potential.[33] The first excited states are triplets ($S = 1$: the spin of the electron transferred

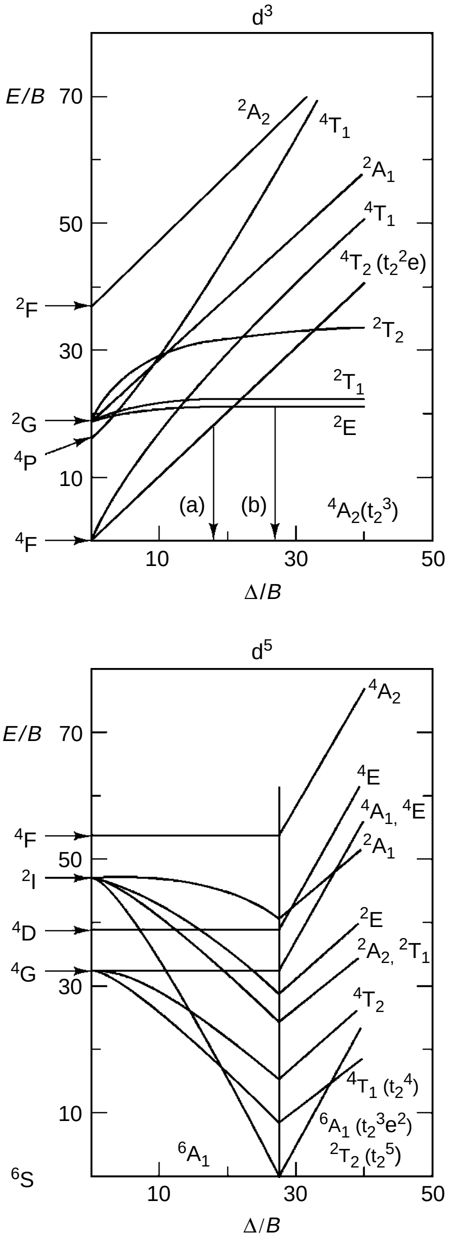

Figure 7 Crystal field splitting of the lower spectroscopic terms of d^3 and d^5 ions for octahedral coordination (Tanabe-Sugano diagrams): Δ, ligand field parameter; B, Racah parameter (for Cr^{3+} substituted for Al^{3+} in Al_2O_3, $\Delta = 17\,800\,cm^{-1}$ and $B = 665\,cm^{-1}$). Vertical arrows in the d^3 ion diagram represent radiative transitions: (a) band emission exhibited by V^{2+} and Cr^{3+} for low crystal field; (b) line emission shown by Cr^{3+} for high crystal field and by Mn^{4+}

onto a predominantly cationic molecular orbital is parallel to that of the unpaired electron on ligand MOs).[10] Transitions from the ground state $^1A_1$ to these levels are therefore spin-forbidden. The intense absorption bands correspond to transitions to higher-energy singlet states ($\Delta S = 0$). They lie at lower energy for octahedral groups than for the tetrahedral ones.[10]

Because of the strong variation of the equilibrium distance Δr, a radiative decay requires a high position of the emitting level (2.3.2). A high efficiency cannot be expected if the absorption bands extend to the visible. The emission of titanate, zirconate, vanadate, niobate, tantalate, tungstate groups can show high thermal stability. Emission occurs from the lower excited states ($\Delta S = 1$). Because of the large offset Δr, the Stokes shift is very high, 12 000 to 20 000 cm^{-1}, and the emission bands very broad, typically 4000–5000 cm^{-1}. The thermal stability and the Stokes shift depend strongly on composition and structure.[10] The presence in the lattice of cations forming relatively strong bonds like Mg^{2+}, Zn^{2+}, Ca^{2+}, and Y^{3+} is favorable, since they hinder displacements caused by the CT.[11] The Stokes shift is in general lower for octahedral than for tetrahedral coordination. Because of the absence of overlap between absorption and emission, often no concentration quenching occurs. An example is $CaWO_4$ which was used for many years in radiology.[34]

The selection rule $\Delta S = 1$ is partially relaxed by the spin-orbit coupling. The latter increases with the principal quantum number n. The lifetime is of the order of 10^{-3} s for tetrahedral vanadate groups and lowers to 15×10^{-6} s and 5×10^{-6} s (at 77 K) for $YNbO_4$ and $YTaO_4$, respectively.

3.2 Lanthanide ions

3.2.1 Nature of Transitions

Three types of transitions are responsible for the luminescence of lanthanide ions:

1. 4f–4f transitions. Trivalent lanthanide ions from Pr^{3+} ($4f^2$) to Yb^{3+} ($4f^{13}$) show a luminescence corresponding to transitions between levels of the $4f^N$ configurations. The number of states, $C_{14}{}^N$, can be very high. Interelectronic repulsions partially remove the degeneracy, leading to the spectroscopic terms ^{2S+1}L. Because of the shielding effect of the 5s and 5p electrons, the crystal field interaction with the 4f electrons is weak. The influence of spin-orbit coupling on the position of levels is much more pronounced (Figure 8). The splitting of the ^{2S+1}L levels into $^{2S+1}L_J$ levels ($(L-S) \leq J \leq (L+S)$) ranges from 2×10^3 to 5×10^3 cm^{-1} for the first elements of the series to more than 10^4 cm^{-1} for the last ones. Maximum values of the crystal field splitting of the $^{2S+1}L_J$ levels in oxides are of the order of 10^3 cm^{-1}. Spin-orbit coupling mixes states with the same J value. The wavefunctions are linear combinations of Russell–Saunders wavefunctions; S and L in the symbol $^{2S+1}L_J$ refer to orbitals providing the most important contribution. For a large admixture of states having different S values, the requirement $\Delta S = 0$ is relaxed. This is not, however, the case for the Eu^{3+} and Tb^{3+} transitions in the visible region, whose probability is reduced by a factor of about 10 (unlike other lanthanide

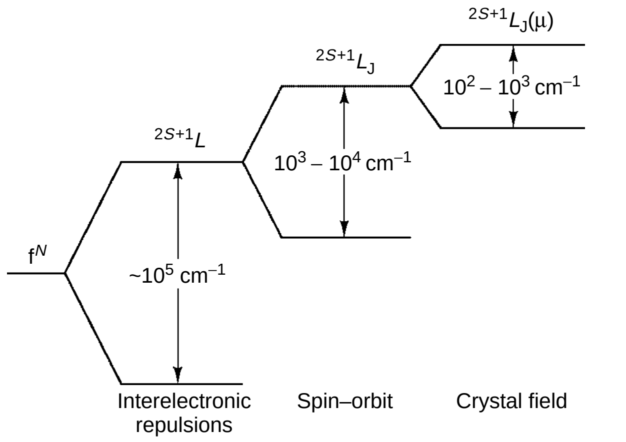

Figure 8 Splitting of rare earth energy levels owing to the interelectronic, spin-orbit, and crystal field interactions

ions having f–f transitions in this wavelength range, Eu^{3+} and Tb^{3+} are nearly colorless).

Figure 9 shows the energy level diagrams of trivalent lanthanide ions in LaF_3. Since the crystal field is a minor perturbation, the sequence of most $^{2S+1}L_J$ levels does not depend on the host.

2. 4f–5d transitions. The first excited configuration of rare earth ions is $4f^{N-1}5d$. The 4f → 5d absorption bands are very intense ($\Delta l = 1$). Figure 10 shows the energy difference between the lowest levels of the $4f^N$ and $4f^{N-1}5d$ configurations for the trivalent ions incorporated in CaF_2. The plot consists of two zig-zag curves having their maximum at $N = 7$ and 14 with slightly higher energy for $N + 7$ than for N. The variation reflects the influence of the spin-pairing energy. Only Ce^{3+} ($4f^1$), Pr^{3+} ($4f^2$), and Tb^{3+} ($4f^8$) exhibit absorption bands above 200 nm.[35] For the other cations, the 4f → 5d transitions

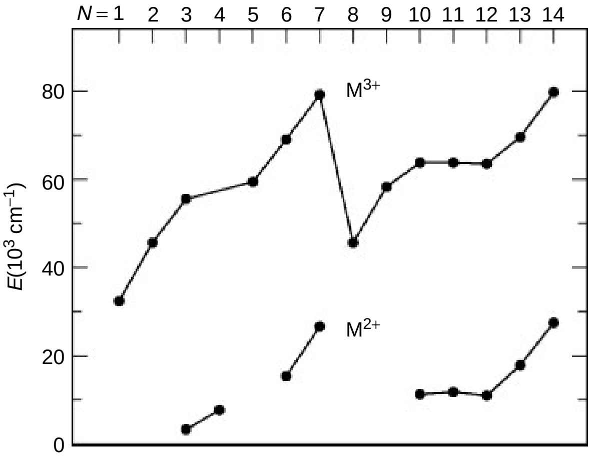

Figure 10 Energy difference between the lowest levels of the $4f^N$ and $4f^{N-1}5d$ configurations for divalent and trivalent lanthanide ions in fluorite. (Reproduced by permission of Ref. 37)

are located in the VUV and hence can be observed essentially in fluorides.[35,36]

The energy of 4f → 5d transitions is much lower for divalent ions (Figure 10). For the most stable ions, Eu^{2+} ($4f^7$) and Yb^{2+} ($4f^{14}$), the corresponding absorption bands in oxide or fluoride hosts most often lie in the UV range.

3. CT transitions: electron transfer can occur from the highest filled ligand MOs to the partly filled 4f shell. As a consequence of the gain in spin-pairing energy, ions with a nearly half-filled or filled 4f shell have the higher oxidizing character. In the case of trivalent ions, the energy of the CT transition increases according to the sequence.

$$Eu^{3+}(4f^6) < Yb^{3+}(4f^{13}) < Sm^{3+}(4f^5) < Tm^{3+}(4f^{12})$$

The position of the CT band shifts to longer wavelengths with decreasing electronegativity of the ligand. Typical values of the energy of the absorption band maximum of Eu^{3+} are: 30 000–34 000 cm^{-1} in oxysulfides and oxybromides, 33 000–35 000 cm^{-1} in oxychlorides, 37 000–45 000 cm^{-1} in oxides, and around 65 000 cm^{-1} in fluorides.[38]

3.2.2 4f → 4f Emission

Relaxation from a high-energy level of the $4f^N$ configuration occurs by multiphonon transitions between closely spaced levels down to a level whose energy gap to the next-lower level is wide enough to allow radiative decay (Section 2.3).

The radiative rate is increased by covalency, which causes admixing of states of opposite parity. The excited-state lifetime becomes shorter with decreasing ligand electronegativity, as shown below for the $^4F_{3/2}$ emission of neodymium:

Host	LaF_3	Y_2O_3	$LaCl_3$	γ-La_2S_3
τ (µs)	700	260	220	60

The wavelength range of luminescence transitions within the $4f^N$ configurations extends from the infrared to the ultraviolet.

UV and Visible Emisssions. A large energy gap exists for ions in the middle of the series of trivalent lanthanide ions (Figure 9). In oxides, the probability for radiative decay is nearly unity for Eu^{3+} ($^5D_0$) (red emission), Gd^{3+} ($^6P_{7/2}$) (UV) and Tb^{3+} ($^5D_4$) (green). It is also very high for Pr^{3+} ($^1D_2$) (red), Sm^{3+} ($^4G_{5/2}$) (orange), Dy^{3+} ($^4F_{9/2}$) (whitish or yellow), and Tm^{3+} ($^1I_6$) (UV) and ($^1D_2$, $^1G_4$) (predominantly blue). Water molecules are particularly detrimental for luminescence owing to the high vibrational frequencies (3500 cm^{-1}). However, because of the large energy gap, Gd^{3+} and to a lesser extent Tb^{3+} show high efficiency, even in aqueous solution or in hydrates:[38]

Ion:	Gd^{3+} ($^6P_{7/2}$)	Tb^{3+} ($^5D_4$)	Eu^{3+} ($^5D_0$)	Sm^{3+} ($^4G_{5/2}$)	Dy^{3+} ($^4F_{9/2}$)
Energy gap (cm^{-1}):	32 000	14 500	12 000	7000	7000
Efficiency (%):	100	70	10	≈1	≈1

Concentration quenching of the Eu^{3+} $^5D_0$ and Tb^{3+} $^5D_4$ emissions occur by energy migration to defects. This process starts at relatively high activator concentrations, for instance, for $x = 0.07$ and 0.15 respectively in the solid solutions $Y_{2(1-x)}Eu_{2x}O_3$ and $Y_{1-x}Eu_xBO_3$.[39] Because of the possibility of high dopant concentration, high luminescence efficiencies can be achieved under UV, VUV, or electron beam excitation. Short-wavelength UV radiation can be wholly absorbed by the CT band of Eu^{3+}. The CT induces a large offset Δr (Figure 2b). Hence a high position of the CT state is necessary for avoiding nonradiative transitions to the fundamental multiplet ^7F_J ($J = 0$–6). The position of the CT absorption band tends to lower with increasing coordination of the Eu^{3+} ion and for a same coordination number with increasing radius of the substituted cation.[40] The CT band lies at markedly longer wavelength in lanthanum compounds than in gadolinium or yttrium compounds. The energy of the transition depends also on the nature of the bonds formed by the ligand with other elements of the matrix. In oxides, the highest energies are observed when the oxygen atoms surrounding europium belong to covalent groups such as $(BO_4)^{5-}$ or $(PO_4)^{3-}$. The quantum efficiency of the luminescence of Eu^{3+} is near unity for excitation in the CT band of YBO_3: Eu and YPO_4: Eu, located in these lattices at very short wavelength (maximum

at 220 nm). At longer wavelengths, Eu^{3+} can be efficiently excited by energy transfer from oxidizing groups such as the titanate, vanadate, tungstate groups, possessing CT bands. Tb^{3+} can be efficiently excited into its parity-allowed 4f → 5d transitions below 250 nm (Figure 1) or by energy transfer from Ce^{3+}, as in the case of the lamp phosphors $CeMgAl_{11}O_{19}$:Tb, $LaPO_4$:Ce,Tb, and $GdMgB_5O_{10}$:Ce,Tb.[1,12]

The spectral distribution of the Eu^{3+} emission is very sensitive to the site symmetry. An example of interest for lighting or display application is that of the influence of a center of symmetry. Figure 11 shows the emission spectra of this ion in two oxides with crystal structures related to NaCl:$NaInO_2$, and $NaGdO_2$. The $^5D_0 \rightarrow {}^7F_1$ transitions around 590 nm have magnetic dipole character; the $^5D_0 \rightarrow {}^7F_2$ transitions in the 610–630 nm range have electric dipole character and are allowed only if the site lacks a center of symmetry. Minor differences in the structural characteristics induce large differences in emission spectra. The site of the trivalent ion in $NaInO_2$, of α-$NaFeO_2$ structure type, is centrosymmetric; the spectrum consists essentially of the $^5D_0 \rightarrow {}^7F_1$ transitions in the orange region of the visible spectrum; weak broad lines in the range of the $^5D_0 \rightarrow {}^7F_2$ transitions are due to vibronic transitions. The site of the rare earth ion in $NaGdO_2$, of α-$LiFeO_2$ structure type, lacks an inversion center. Since the radiative rate of electric dipole transitions is much higher than that of magnetic dipole transitions, the $^5D_0 \rightarrow {}^7F_2$ emission is predominant. Such is the case for the red-emitting phosphors YVO_4: Eu, Y_2O_3: Eu, and Y_2O_2S:Eu.[1]

The luminescence of other luminescent ions emitting in the visible, Pr^3, Sm^{3+}, Dy^{3+}, Tm^{3+} is most often affected by cross-relaxation processes at low activator concentration (2.4.2).

Two visible photons per UV photon can be obtained by a cascade process with Pr^{3+}. In lattices generating a low crystal field, the lowest 5d states lie above the highest level of the configuration $4f^2$, $^1S_0$ (Figure 9), which decays radiatively by the transition $^1S_0 \rightarrow {}^1I_6$, followed by a nonradiative transition

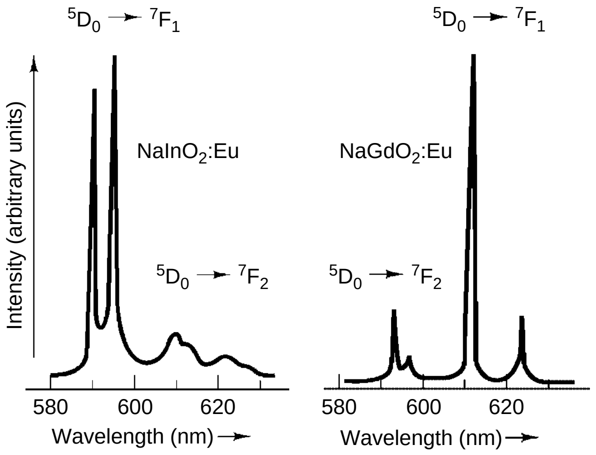

Figure 11 Emission spectrum of Eu^{3+} substituted for the trivalent ion in $NaInO_2$ and $NaGdO_2$. (Reproduced by permission of Ref. 41)

to $^3P_0$ from which a second photon is emitted when the phonon energies are sufficiently low.[42] Two photons per UV photon absorbed can also be obtained in Eu-doped Gd fluorides. Excitation of Gd^{3+} into the ^6G_J levels around 50 000 cm^{-1} is followed by two successive energy transfers to Eu^{3+} ions which are promoted to the $^5D_0$ state.[43]

Ions such as Ho^{3+} or Er^{3+} can decay radiatively from levels in the visible range in halide or sulfide hosts. This is the case, for instance, for the green-emitting level $^4S_{3/2}$ of Er^{3+} in fluorides.[44,45] With Ho^{3+}, Er^{3+}, and Tm^{3+} IR radiation can be converted to visible by upconversion (2.4.4). Only a small amount of doping ions can be introduced without concentration quenching. The absorption in the IR around 0.98 nm is increased by codoping with ytterbium which can be incorporated in large quantity since its excited state, $^2F_{5/2}$, is not affected by cross-relaxation processes. The proximity of the position of the $Yb^{3+}\,{}^2F_{5/2}$, and $Er^{3+}\,{}^4I_{11/2}$ levels allows energy transfer.[22,45]

IR emission. The $^4F_{3/2}$ level of Nd^{3+} (Figure 4) is separated from the lower-lying level by 5000 cm^{-1}, a gap generally large enough for inhibiting nonradiative processes, except in borate glasses where vibrational frequencies exceed 1300 cm^{-1}. The most intense transition from this level is $^4F_{3/2} \rightarrow {}^4I_{11/2}$ at about 1.06 µm. Laser radiation can be obtained by pumping into the numerous absorption transitions in the visible. In most lattices with increasing Nd concentration, the luminescence is strongly affected by cross-relaxation processes (Figure 4) and disappears nearly completely at high concentrations. The overlap between emission and absorption lines decreases with decreasing crystal field splitting of the *J* levels. For a few neodymium compounds, as shown by the comparison of the lifetimes of the emitting state $^4F_{3/2}$ (Table 3), the quantum efficiency is only reduced by a factor of about 2.5 in the nondilute material. For such lattices the crystal field is particularly low, as indicated by the splitting of the ground state, $\Delta E(^4I_{9/2})$ (Table 3). A criterion for low quenching is that ΔE must be lower than 470 cm^{-1}.[46] This is observed in phosphates or borates rich in covalent groups. In addition, the neodymium coordination polyhedra must have no common apices. Owing to the high

Table 3 Minimum Nd–Nd distance, splitting of the ground state $^4I_{9/2}$, and ratio of the luminescence lifetimes for $x = 1$ (τ) and $x = 0.01$ (τ_0) for (a) Low or (b) High concentration quenching neodymium materials ($1/\tau = 1/\tau_0 + W_{nr}$ where W_{nr} is the rate of nonradiative decay due to concentration quenching)[46]

	Composition	Nd–Nd distance (Å)	$\Delta E(^4I_{9/2})$ (cm^{-1})	τ/τ_0
(a)	$LiLa_{1-x}Nd_xP_4O_{12}$	5.94	375	0.42
	$La_{1-x}Nd_xAl_3B_4O_{12}$	5.91	410	0.40
	$La_{1-x}Nd_xP_5O_{14}$	5.19	320	0.36
(b)	$NaLa_{1-x}Nd_xO_2$	3.59	619	<0.03
	$Y_{3(1-x)}Nd_{3x}Al_5O_{12}$	–	857	–

neodymium concentration, with crystals of phosphates like NdP_5O_{14}, laser emission can be achieved for a low pumping threshold.[47]

The large gap between the levels $^4F_{5/2}$ and $^4F_{7/2}$ of Yb^{3+} (10 000 cm^{-1}) prevents nonradiative decay. Because of the absence of intermediate levels the concentration of Yb^{3+} can be very high. Hence powerful compact lasers can be obtained with diode-pumped Yb^{3+}-doped materials.[48,49]

Laser emissions over the 1–5 µm wavelength range are obtained with Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}.[50,51]

3.2.3 5d → 4f Emission

After excitation into one of the 5d states the lanthanide ion relaxes by nonradiative transitions to the lowest-energy one from which emission can occur if there is a large energy gap with the ground or excited 4f levels. This condition is fulfilled by Ce^{3+} ($4f^1$), Yb^{2+} ($4f^{14}$) and generally Eu^{2+} ($4f^7$) (Section 2.5). Also Pr^{3+} ($4f^2$) exhibits a 5d → 4f emission, located mainly in the UV, when the nephelauxetic effect and crystal field splitting lower the first 5d state below the $^1S_0$ ($4f^2$) level at 47 000 cm^{-1}.[52] 5d → 4f emissions in the VUV are observed for Nd^{3+}, Er^{3+} and Tm^{3+} in fluorides.[36,53]

A second requirement for luminescence is that the lowest 5d state is located under the conduction band. Ce^{3+}, Eu^{2+}, Yb^{2+} can easily take the upper oxidation state. The 4f ground state of Ce^{3+} lies well above the valence band, 20 000 cm^{-1} in $Y_3Al_5O_{12}$.[54] In this lattice, Ce^{3+} exhibits an intense emission for excitation in the first 5d level. Excitation in the higher 5d levels is much less efficient because these levels can be depopulated by electron transfer to the conduction band (photoionization process). The absence of luminescence in La_2O_3, Y_2O_3, and Lu_2O_3 is ascribed to the fact that all 5d levels, as shown by photoconductivity measurements, lie in the conduction band.[55] In oxide lattices, Ce^{3+} exhibits high efficiency for band gaps exceeding 50 000 cm^{-1} ($\lambda = 200$ nm). Likewise the luminescence of Eu^{2+} has been observed in borates, aluminates, silicates, phosphates, and not in gallates and germanates, which have smaller band gap. In the fluorides CaF_2 and SrF_2, Eu^{2+} exhibits a 5d → 4f blue emission. This is not the case in BaF_2. All the 5d states being in the conduction band, irradiation in the 4f → 5d absorption bands causes ionization with the formation of an exciton-like state: the electron is held on neighbor barium ions in the Coulomb field of the Eu^{3+} ion.[56] At low temperature, the electron-Eu^{3+} recombination yields a yellow emission.

Because of their interest for applications, the luminescence of Ce^{3+} and Eu^{2+} has been investigated in a great number of compounds.

1. Ce^{3+}: The energy of the emitting 5d level lowers with increasing nephelauxetic effect and crystal field splitting Δ_{cryst} (Figure 5). The positions of the shorter-energy 4f → 5d absorption band and the emission band published for Ce^{3+} in inorganic compounds have been collected in Ref. 57. The Stokes shift of the Ce^{3+} emission is usually moderate, of the order of 2000–4000 cm^{-1}. In fluorides, the Ce^{3+} emission is generally located in the UV around 300 nm. In most oxides, the emission peaks in the UV, between 300 and 400 nm. The shorter wavelengths are observed for B-rich borates ($LaMgB_5O_{10}$, GdB_3O_6) and P-rich phosphates (LaP_3O_9, $LiLaP_4O_{12}$). In these lattices, the ionicity of the Ce–O bond is enhanced and the crystal field reduced by the covalent bonds formed by the ligands with B or P. In the garnets such as $Y_3Al_5O_{12}$:Ce^{3+}, the lower 5d state lies exceptionally in the visible, leading to a yellow emission. In sulfides, the nephelauxetic effect shifts the emission to the visible. In most hosts, concentration quenching starts for a cerium content of a few percents. However, in a few host lattices, owing to a strong Stokes shift (ΔE_{St}) nearly no concentration quenching occurs up to complete substitution of Ce for the host cation. This is the case in $LaMgAl_{11}O_{19}$ ($\Delta E_{St} = 7000\ cm^{-1}$) and LaF_3 ($\Delta E_{St} = 5000\ cm^{-1}$).
   The radiative lifetime varies between 15 and 60 ns. For comparable refractive indices, the lifetime increases with increasing wavelength of the peak emission (Section 2.1): $\tau = 18$ ns for $YAlO_3$:Ce with $\lambda_{em.} = 362$ nm, $\tau = 62$ ns for $Y_3Al_5O_{12}$:Ce with $\lambda_{em.} = 550$ nm.[4] For emission in the same wavelength range, τ varies according to: sulfides < oxides < fluorides.
2. Eu^{2+}: The emission of Eu^{2+} is shifted to the red compared with that of Ce^{3+}. For the same host lattice, the position of the emitting level is lowered by about 3000 cm^{-1}.[58] In oxide lattices, the position of the emission band shows considerable variations. For instance, in the Sr-rich borate $Sr_3(BO_3)_2$ the band peaks in the orange (585 nm) while in SrB_4O_7 because of the weak nephelauxetic effect and low crystal field the emission lies in the UV (367 nm).[59] Eu^{2+} is usually substituted for an alkaline earth ion M. The larger the size of M, the smaller the ligand field splitting of the 5d states and hence the higher the position of the emitting level. Higher energy of the 5d emitting state and often smaller offset Δr result in a higher thermal stability of the 5d → 4f emission when the size of M increases as shown, for instance, by the thermal quenching of structurally related silicates or borophosphates.[3,60,61] Phonon energies also appear to influence the stability: while in various aluminates or silicates Eu^{2+} exhibits a blue or green emission whose quenching starts above 300 K (e.g. the blue phosphor $BaMgAl_{10}O_{17}$: Eu),[62] in borates the luminescence is generally strongly affected by nonradiative losses at this temperature when the emission lies in the visible.[59,63]

When the lanthanide ion is surrounded by voluminous polarizable anions like chloride, bromide, or sulfide ions, the Stokes shift is generally small. At low temperature, a zero-phonon line is present in absorption and emission spectra, in addition to the band corresponding to transitions involving absorption or emission of phonons (vibronic transitions). Low

phonon energies and small offset Δr result in high thermal stability. For example, in the sulfides CaS and SrS, despite the low position of the emitting state (the lowest-energy absorption band, 4f → 5d(t_{2g}), covers most of the blue and green regions of the visible spectrum, inducing a red or orange color, respectively), quenching starts above room temperature.[64]

The fluorescence lifetimes are around 1 µs.[3] Because the $4f^6 5d$ emitting level contains octets and sextets, the radiative rate of transitions to the ground state $^8S_{7/2}(4f^7)$ is reduced compared with the 5d → 4f transitions of Ce^{3+}.

3.2.4 Charge Transfer Emission

1. Yb^{3+}: When excited in its CT band, located around 200 nm in oxide lattices, Yb^{3+} exhibits an emission consisting of two bands corresponding to transitions from the CT state to the $^2F_{7/2}$ and $^2F_{5/2}$ ($4f^{13}$) states, separated by 10 000 cm^{-1}.[65] The Stokes shift is very high, of the order of 15 000 cm^{-1}.
2. Ce^{4+}: A CT luminescence has been observed for tetravalent cerium in Sr_2CeO_4. This compound shows a blue-white luminescence partially quenched at 300 K.[66]

3.3 Ions with s^2 Configuration

The A elements of the last rows of the periodic table give rise to stable ions having a pair of s electrons (e.g. Tl^+, Pb^{2+}, Bi^{3+}). The excited energy levels corresponding to the transfer of an electron onto a p orbital are indicated in Figure 12. The spin-allowed $^1S_0 \rightarrow {}^1P_1$ transition is the most intense (f close to 1). As a result of strong spin-orbit coupling, the spin selection rule for the $^1S_0 \rightarrow {}^3P_1$ transition is considerably relaxed ($f = 0.1$). This is illustrated in Figure 12 by the excitation spectrum of the Tl^+ emission in KF.[67]

At low temperature, the emission originates from the lowest excited level, $^3P_0$, and is therefore characterized by a long lifetime, of the order of 1 ms. As the temperature is increased,

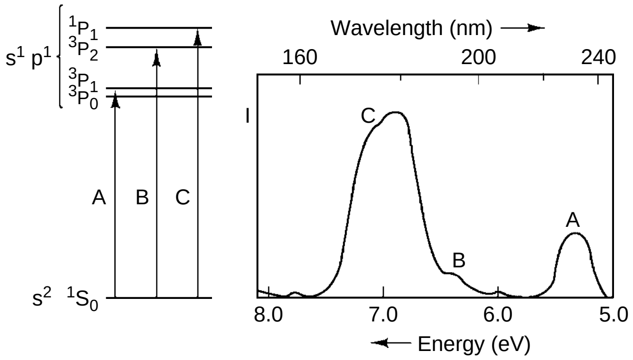

Figure 12 Excitation spectrum of the luminescence of Tl^+ in KF (variation of the emission intensity as a function of the excitation wavelength). (Reproduced by permission of Ref. 67)

Table 4 Influence of the size of the site occupied by the Sb^{3+} or Bi^{3+} ion on the Stokes shift of the np → ns emission[68,69]

Host	Substituted cation radius (Å)	Coordination number	Stokes shift (cm^{-1}) Sb^{3+}	Bi^{3+}
$ScBO_3$	0.745	6	7 900	1800
$LuBO_3$	0.861	6	10 700	2300
YBO_3	0.900	8	14 000	5200
		8	16 300	7700
$GdBO_3$	0.938	8	14 500	–
		8	16 400	–
$LaBO_3$	1.216	9	19 500	9300

the $^3P_1$ level becomes populated, emission from this level becomes dominant, and the lifetime drops to values of a few µs.

The Stokes shift of the np → ns emission is strongly host-dependent with variations from 1000 to 20 000 cm^{-1}.[12] Table 4 lists the values observed for Sb^{3+} and Bi^{3+} in trivalent orthoborates. The Stokes shift increases with the size of the substituted cation, M. This has been ascribed to the trend of s^2 ions to occupy an off-center position. When an electron is transferred onto a p orbital, the ion moves to a more central position. A voluminous site allows large displacements, resulting in high Stokes shift values. The lower the size of the s^2 ion, the larger the atomic shift. Table 4 shows that the Stokes shift is considerably higher for Sb^{3+} (radius $r = 0.76$ Å in VI coordination) than for Bi^{3+} ($r = 1.03$ Å). A larger offset Δr with increasing M size causes stronger thermal quenching.[68,69]

4 DONOR–ACCEPTOR TRANSITIONS

This type of transition has been extensively investigated in ZnS doped with a monovalent d^{10} cation (Cu^+, Ag^+, Au^+) (usually called the activator) and a trivalent ion such as Al^{3+} (coactivator) substituted for divalent zinc. The coactivator can also be Cl^- substituted for S^{2-}. The monovalent cations create deep acceptor states, Al^{3+} or Cl^- form shallow donor levels (0.1 eV for Al) (Figure 13). When electrons are transferred from the valence to the conduction band, for instance, under electron beam irradiation, they are trapped by the coactivator while holes formed in the valence band are captured by Cu^+ or Ag^+, which are oxidized to the divalent state. The energy of the photons emitted depends on the energy difference between the donor and acceptor levels and on the acceptor–donor distance:[70]

$$E = E_g - (E_A + E_D) + \frac{e^2}{K r_{D-A}} \qquad (12)$$

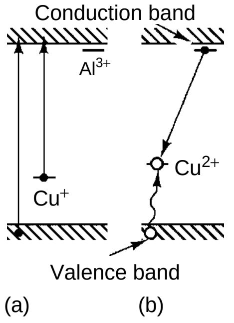

Figure 13 Schematic representation of the mechanism of the green luminescence of ZnS:Cu,Al

where E_g is the band gap of the lattice (3.8 eV for the hexagonal form of ZnS), E_D and E_A are the depths of the donor and acceptor levels, respectively; e the electronic charge, r_{D-A} the intrapair separation, and K the static dielectric constant. The emission band is composed of the emissions produced by the different pairs. The Ag^{2+} and Cu^{2+} levels lie at 1 and 1.4 eV above the top of the valence band respectively. If the monovalent and trivalent ions are incorporated in equal concentration, the donor–acceptor transitions give rise to a band emission in the blue with Ag^{+} and in the green with Cu^{+}. The emission can be displaced to longer wavelengths by decreasing the band gap by substitution of cadmium for zinc. Because the average distance between the trapped electrons and the Ag^{2+} or Cu^{2+} ions decreases, the peak of the emission band shifts toward higher energies with increasing excitation intensity.

The probability of the donor–acceptor transition decreases with increasing intrapair separation:[70]

$$W(r_{D-A}) = W_0 \exp\left(\frac{-(r_{D-A})}{R_B/2}\right) \tag{13}$$

where W_0 is a constant and R_B is the Bohr radius of the shallower state. Consequently since the emission band is composed of the emission bands of donor-acceptor pairs with different separations, a donor–acceptor type emission shows the following characteristics:

- the decay rate becomes faster with increasing photon energy in the emission band;
- the emission band shifts to lower energies during the decay (t-shift).

5 EXCITATION THROUGH THE HOST LATTICE

5.1 Excitation in the UV or VUV

The excitation mechanism consists of electron transitions from the valence to conduction band of the lattice followed by transfer of the electron–hole (e–h) recombination energy to luminescent ions. The electron transferred into the conduction band can be bound to the hole formed in the valence band by coulombic interaction, forming an exciton which can propagate in the lattice up to luminescent ions. The quantum efficiency is generally maximum when the wavelength of incident photons corresponds to energies close to the band gap.[71] The efficiency decrease at shorter wavelengths has been ascribed to two causes: (i) the dissociation of e–h pairs, (ii) the decrease of the penetration depth with increasing absorption coefficient, resulting in surface losses. In plasma display panels, phosphors are excited by a Xe-discharge. The Xe spectrum consists of a line at 147 nm and a band centered at 172 nm. Under these excitation conditions, the most efficient materials are $BaMgAl_{10}O_{17}:Eu^{2+}$ for the blue, $Zn_2SiO_4:Mn^{2+}$ for the green, $Y_2O_3:Eu^{3+}$ or $(Y,Gd)BO_3$: Eu^{3+} for the red.[1,71]

5.2 Cathodoluminescence

Within the material, the incident electron loses its energy by generating e–h pairs or optical phonons.[72]

The efficiency of the process can be written as

$$\eta_{cr} = (1 - r_b).\left(\frac{h\nu_m}{\varepsilon}\right).\eta_t.\eta_r \tag{14}$$

where r_b is the primary back-scattering coefficient, $h\nu_m$ the mean energy of luminescent photons, ε the average energy required to generate one e–h pair, η_t the efficiency for transfer of the e–h recombination energy to luminescent ions, and η_r the quantum efficiency of the activator emission. The back-scattering coefficient increases with the average atomic number of the material atoms.

In efficient materials, η_t and η_r are close to unity. ε depends on the host band gap and phonon energies:

1. ε increases with increasing band gap. For high efficiency, the band gap must be slightly larger than the energy of the photons emitted (with, however, large enough energy separation between the excited state of the luminescent ion and the bottom of the conduction band to prevent ionization). ZnS with a band gap of 3.8 eV is most appropriate for emission in the visible. On the contrary, a high efficiency in this spectral region cannot be expected from fluorides since these materials are characterized by wide band gaps.
2. ε increases with increasing energy of the phonons created. Sulfides are more favorable than oxides regarding this characteristic.

Table 5 indicates the order of magnitude of energy efficiencies, η_{cr}, of various phosphors for accelerating voltages of 20–30 kV.[71,73,74] With sulfides, energy yields of 20% can be achieved; with oxides the highest value is

Table 5 Energy efficiencies, η_{cr}, of cathodoluminescent materials

6–9%	Zn_2SiO_4:Mn, YVO_4:Eu, Y_2O_3:Eu, $Y_3(Al,Ga)_5O_{12}$:Tb, $InBO_3$:Tb, Y_2SiO_5:Tb, $Y_3Al_5O_{12}$:Ce
11–14%	Y_2O_2S:Eu, Gd_2O_2S:Tb, LaOBr:Tb
15–20%	ZnS:Cu,Al, ZnS:Ag,Cl, CaS:Pb, CaS:Ce

9%. Intermediate values are obtained with oxysulfides and oxybromides.

The luminescence can be of the donor–acceptor type. This is the case for ZnS:Ag,Cl and ZnS:Cu,Al used for the blue and green components of TV screens. At low electron beam current density, the intensity of the green phosphor is maximum for Cu concentrations of about 10^{-2} mole %.[74]

For other efficient materials, the luminescence is due to intraatomic transitions. After trapping of a charge carrier by the doping ion, a carrier with opposite charge is attracted, so that electron–hole recombination occurs at the activator site. It has been shown that ions that can change their oxidation state are favorable for high η_t values.[75] Among trivalent lanthanide ions, Ce^{3+} ($4f^1$) and Tb^{3+} ($4f^8$) are hole-trapping centers, whereas Eu^{3+} ($4f^6$) preferentially binds an electron to achieve the half-filled shell structure. In contrast, Gd^{3+} ($4f^7$) forms no stable bound state.

It must be stressed that the criterion for display application is the value of the luminous efficiency, which takes into account eye response. For instance, in the red spectral region (above about 600 nm), eye sensitivity decreases rapidly with increasing wavelength.[12] Despite lower-energy yield, Y_2O_2S:Eu, the red-emitting phosphor used in television screens, has higher luminous efficiency than the copper-doped solid-solution $Zn_{1-x}Cd_xS$ giving similar color, because the major part of the emission is concentrated near the lower limit of the red region.

To obtain high luminance (for instance, for projection television), a high current density of the incident electron beam is necessary.[12,73] Under these conditions, the luminous efficiency of the oxysulfides Y_2O_2S:Eu, Gd_2O_2S:Tb and the sulfides ZnS:Ag,Cl, ZnS:Cu,Al drops. For the oxysulfides, this is due to thermal quenching caused by the temperature rise of the screen.[1] For the ZnS phosphors, this has been ascribed in part to activator depletion, especially at very low activator concentration, and to excited-state absorption and Auger processes.[12,74] In contrast, the current density dependence of the luminescence intensity is close to linearity up to very high values for various oxides such as Zn_2SiO_4:Mn, $InBO_3$:Tb or $Y_3(Al,Ga)_5O_{12}$:Tb for the green and Y_2O_3:Eu for the red. Higher luminous efficiencies can therefore be obtained with these materials than with sulfides.

High current densities are also required in low-voltage field emission displays (300 V to a few kV). The phosphors must have low threshold voltage and some electrical conductivity. Efficient materials under these excitation conditions are $SrGa_2S_4$:Ce for the blue, $SrGa_2S_4$:Eu, Gd_2O_2S:Tb and $Y_3Al_5O_{12}$:Tb for the green, and Y_2O_2S:Eu for the red.[76,77]

5.3 X-ray-excited Luminescence

The mechanisms of X-ray-excited luminescence are similar to those of cathodoluminescence. Conventional radiographs are produced by combination of a photographic film and an intensifying screen, which converts X rays to photons whose wavelength is located in the high-sensitivity region of the film. The luminescent powders used in intensifying screens must show high absorption at the energy of the X rays used (typically in radiology of the order of 50 keV). $CaWO_4$ has long been used. Since 1970, new X-ray phosphors with higher luminescence efficiency and stronger absorption properties have been developed, for example, Gd_2O_2S:Tb, LaOBr:Tm, and $YTaO_4$:Nb.[1,12,34]

Superior images can be obtained using computerized radiography based on photostimulated luminescence.[78] Under X-ray irradiation, electrons are trapped in anionic vacancies, forming color centers (F centers). A scanning of the screen with a laser radiation whose wavelength lies in the absorption bands appearing after X-ray exposure, releases the trapped electrons; the electron–hole recombination energy is then transferred to a luminescent ion. An efficient photostimulable material is BaFBr:Eu^{2+} whose stimulation can be performed with a helium–neon laser ($\lambda = 633$ nm).[1,12]

5.4 γ-Ray-excited Luminescence

Scintillator crystals are luminescent crystals used for the detection of ionizing radiation (γ, neutrons, etc.). Depending on the nature of the radiation and the type of measure, they have to meet various requirements such as an appropriate composition allowing strong absorption of the radiation, fast decay, and stability under irradiation.[1,12,79,80] The highest efficiencies under γ-ray irradiation are achieved with halides such as NaI:Tl (40 000 photons/MeV). The scintillators $Bi_4Ge_3O_{12}$, $CdWO_4$, and $PbWO_4$ have high densities, 7.1, 8, and 8.2 g cm^{-3} respectively. Fast decays can be obtained with BaF_2 and cerium materials such as $YAlO_3$:Ce, $Y_3Al_5O_{12}$:Ce, or CeF_3.

6 ELECTROLUMINESCENCE

Electroluminescent materials are used in the form of powders or thin films. Owing to their high brightness and stability, ac thin film devices are the most appropriate electroluminescent systems for display.[81,82] The main criterion for an electroluminescent material is its ability to have its electrons accelerated loss-freely in electric

fields. Chalcogenides fulfill this requirement. The higher luminous efficiency is obtained with ZnS:Mn, which gives an orange color. The blue can be obtained with $CaGa_2S_4$:Ce, $BaAl_2S_4$:Eu, SrS:Cu,Ag, and SrS:Ce filtered (blue-green emission), the green with ZnS:Tb, and the red with CaS:Eu.[77]

Glossary

Bis-macrocycles: two macrocycles joined together
Calixarenes: basket-shaped macrocycles with phenyl backbones
Catenands: two interlocked macrocycles
Compartmental ligands: macrocycles with 'compartments' for housing more than one substrate
Crown ethers: polyoxa macrocycles
Cryptands: bicyclic macrocycles with aza bridgeheads
Cyclidenes: lacunar tetraaza macrocycles
Expanded porphyrins: macrocycles based on pyrrolic frameworks
Lariat ethers: crown ethers with pendant chains
Sepulchrates: bicyclic caged macrocycles
Spherands: macrocycles with phenyl backbones

Abbreviations

Polyaza macrocycles: $[n]\mathrm{aneN}_m$: n = Number of ring atoms; N_m = Number of nitrogen atoms; Polyoxa macrocycles: n-crown-m: n = Number of ring atoms; m = Number of oxygen atoms; TRI = Tribenzo[b,f,j][1,5,9]triazacyclododecine; TAAB = Tetrabenzo[b,f,j,n][1,5,9,13]tetraazacyclohexadecine.

1 INTRODUCTION

Macrocyclic ligands are defined as cyclic molecules generally consisting of organic frames into which heteroatoms, capable of binding to substrates, have been interspersed. Some reports of 'synthetic' macrocycles (as opposed to the naturally occurring species such as porphyrins, corrins, and chlorins) appeared as early as 1936, when the first synthesis of 1,4,8,11-tetraazacyclotetradecane was reported.[1] Nonetheless, the field only began to blossom in the early 1960s with the pioneering work of Busch[2] and Curtis' discovery of the nickel-mediated condensation of $[\mathrm{Ni(en)_3}]^{2+}$ with acetone.[3] The early macrocycles were synthesized with an eye to mimicking biologically occurring macrocycles such as the porphyrins, corrins, chlorins, and, more recently, the corphins.

Another area of macrocyclic development began in the late 1960s and initial applications were focused toward modeling biological processes such as ion transport. These macrocycles initially included the oxygen-based crown ethers of Pedersen,[4] and the mixed oxygen–nitrogen bicyclic cryptands of Lehn,[5] both of which exhibit high selectivity toward alkali and alkaline earth metal ions. Several years later, the concept of 'preorganized' cavities resulted in the synthesis of the cavitands by Cram.[6]

Since its birth, the development of macrocyclic chemistry has proceeded along two lines:

1. as models of the naturally occurring macrocyclic systems, containing predominantly nitrogen donor atoms; and
2. as receptors designed for recognition and supramolecular chemistry, with a variety of donor atoms and recognition capabilities.

Macrocyclic chemistry has expanded phenomenally since the 1960s to provide exciting and novel chemistry. The award of the 1987 Nobel Prize in Chemistry to Pedersen, Lehn, and Cram is testimony to the importance of this rapidly expanding field.

In such a large subject, this article can only focus on certain aspects, namely those that involve complexation with inorganic substrates. We only consider the synthetic macrocycles, with emphasis on transition metal complexation. Aza, oxa, and, to a lesser extent, thia and phospha macrocycles are also covered. The naturally occurring porphyrins, corrins, corphins, chlorins, and phthalocyanins,[7] as well as the cyclodextrins,[8] are not included. Because of the general complexity of macrocyclic systems and the resulting complicated systematic names, commonly used abbreviations or simplified names will be employed. This review will encompass the synthesis, thermodynamics, structure, and applications of macrocyclic ligands.

2 CLASSIFICATION OF LIGANDS

Two major areas of complexation have developed over the years with regard to synthetic macrocycles. Those with nitrogen, sulfur, phosphorus, and arsenic tend predominantly to form traditional covalent coordination complexes with transition metal ions. A notable exception to this tendency, however, is the rapidly expanding chemistry of the

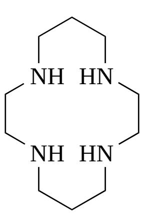
polyammonium macrocycles, which are capable of forming a variety of complexes with anionic substrates. Oxygen-derived macrocycles are noted for complexation with alkali and alkaline earth metal ions, as well as with organic cations and molecular substrates. In this latter situation, associations tend to be electrostatic in nature, and in many instances hydrogen-bonding interactions are vital to complex formation.

Macrocyclic ligands will be classified, for the purposes of this article, as rings with at least nine members and three or more donor atoms. In a number of cases of unique structural units, elegant descriptive names have developed, which more appropriately describe the macrocyclic shape. Macrocycles will be classified as to donor types and, within the donor types, specific classifications of macrocycles will be noted where applicable.

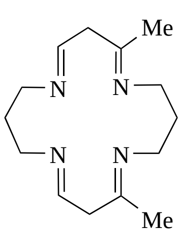
2.1 Polyaza Macrocycles (1)–(10)[9–18]

2.1.1 Simple Polyaza Macrocycles

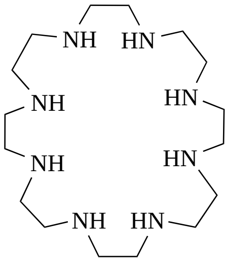
Until recently, the tetraaza macrocycles, such as (**1**) (cyclam) and related ligands with extensive varieties of modifications including differing degrees of saturation and ring size (**2**), had been the most studied, primarily because of the relationship of these molecules to naturally occurring tetraaza macrocycles, such as the porphyrins and corrins. Currently, with interest in metal–metal interactions, increased activity has occurred in the area of larger macrocycles capable of incorporating more than one metal ion, such as (**3**) ([24]aneN_8).[18] Interest in the smaller triaza macrocycles, such as (**4**) ([9]aneN_3) and its variations, has also accelerated in recent years.[14] Added to the simple polyaza macrocycles has been the effort to achieve functionalized macrocycles in order to expand the chemistry of these ligands by combining the rigid structural aspects of the macrocyclic ring with the more flexible and kinetically labile properties of pendant chains, as in (**5**).[11]



(**1**)



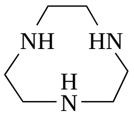
(**2**)



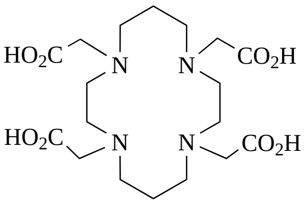
(**3**)

2.1.2 Cyclidenes

Cyclidenes (**6**) are a subset of the polyaza macrocycles and are the lacunar ligands first synthesized and extensively

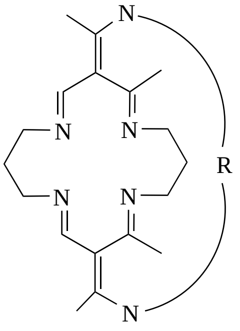


(**4**)

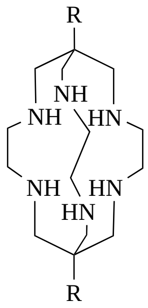


(**5**)

studied by Busch.[19] They coordinate a single metal ion and maintain a ‘persistent void’ which allows access to small molecules within the vaulted cavity.



(**6**)



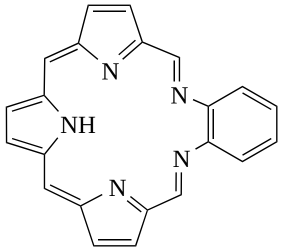
(**7**)

2.1.3 Sepulchrates

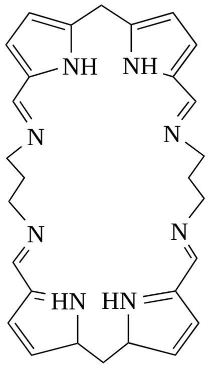
Sepulchrates (**7**) are polyaza cage macrocycles. They are noted for their exceptionally strong hold on encapsulated metal ions.[20]

2.1.4 Expanded Porphyrins

Expanded porphyrins are macrocycles based on the pyrrolic backbone of porphyrins, but are expanded in size to achieve a larger cavity (**8**)[21] or binucleating capabilities (**9**).[22]



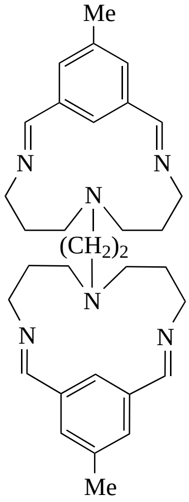
(**8**)



(**9**)

2.1.5 Bis-Macrocycles

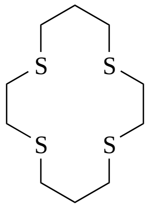
Bis-macrocycles (**10**) provide another mechanism for achieving complexation of more than one metal ion. They are joined by a bridge linking two simple macrocycles.[13,23]



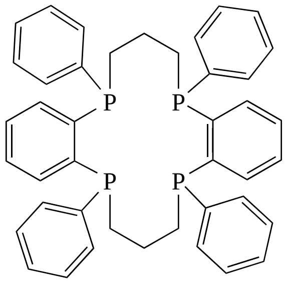
(**10**)

2.2 Polythia, Polyphospha, and Polyarsa Macrocycles

Polythia macrocycles (**11**), the thioether analogs of the crown ethers, have been known since the 1930s.[24] These are the most extensively studied macrocycles in line after the polyoxa and polyaza macrocycles.



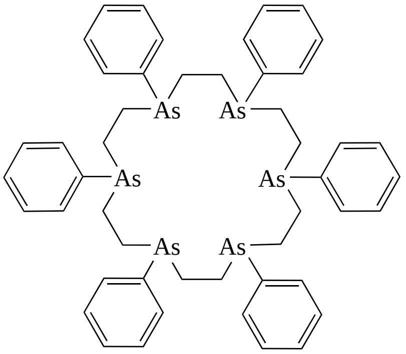
(**11**)



(**12**)

The 'pure' polyphospha macrocycles (**12**) (as opposed to the mixed donor phospha macrocycles) were first reported in 1975.[25] These macrocycles have been found to complex a variety of transition metals, but have not received the same attention as the more readily accessible polyaza and polyoxa macrocycles.

The polyarsa macrocycles (**13**) comprise one of the least common type of macrocycles.[26]

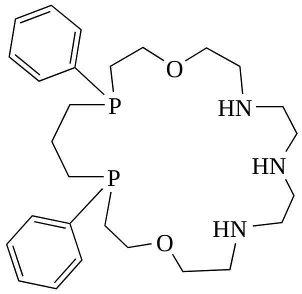


(**13**)

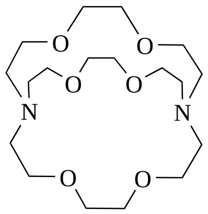
2.3 Mixed Donor Macrocycles

2.3.1 Simple Mixed Donor Macrocycles

The simple mixed donor macrocycles (**14**) at one time were the major source of study of the influence of the incorporation of 'soft' phosphorus and arsenic donors into macrocycles.[27] Mixed oxygen–nitrogen macrocycles have been studied quite extensively, since they serve as bridges for examining the coordination tendencies of the aza macrocycles and the oxa crown ethers.[13]



(**14**)



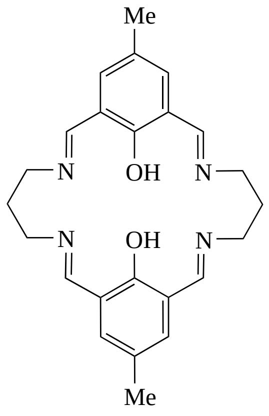
(**15**)

2.3.2 Cryptands

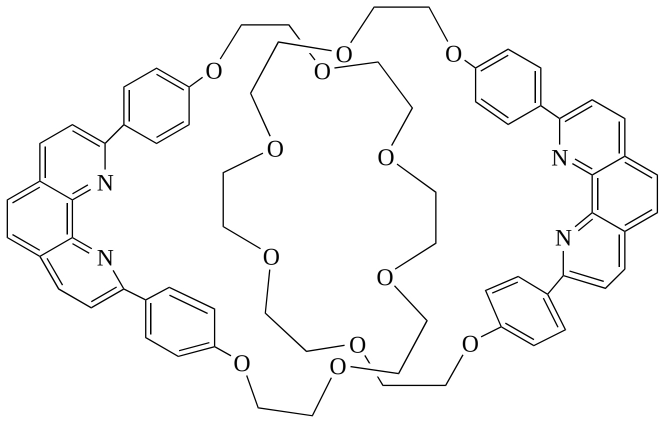
Cryptands (**15**) are bicyclic macrocycles which can contain a variety of donor atoms with bridgehead nitrogen atoms.[5] They are highly selective for alkali and alkaline earth metal ions.

2.3.3 Compartmental Ligands

Compartmental ligands (**16**) are macrocyclic ligands (as well as nonmacrocyclic ligands) which contain 'compartments' for housing more than one metal ion.[28] Only the macrocyclic counterparts will be treated here.



(**16**)



(**17**)

2.3.4 *Catenands*

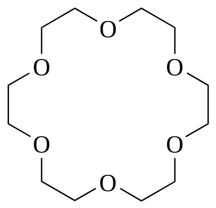
Catenands (**17**) are interlocked macrocyclic ligands, which complex a variety of metal ions.[29]

2.4 Polyoxa Macrocycles

Polyoxa macrocycles, known more commonly as the crown ethers, comprise an extensive area of research, with a repertoire of types and variations.[30] Some of these macrocycles have been utilized predominantly for purposes other than metal ion complexation, and these will not be discussed in depth in this review. Included in this latter category are the polycarbonyls,[31] polylactones,[32] polylactams[33] and carcerands.[34]

2.4.1 *Polyether Macrocycles*

Polyether macrocycles (**18**) are the simplest of the polyoxa macrocycles. The commonly used name for these macrocycles is the crown ethers, due to their crown-like structure in the solid state. These molecules have been extensively studied

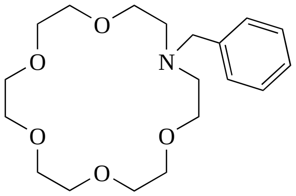


(**18**)

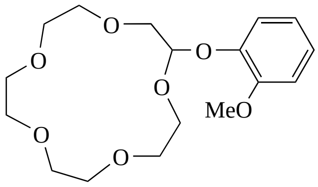
as complexing agents for the alkali and alkaline earth metal ions.[30]

2.4.2 *Lariat Ethers*

The lariat ethers comprise a subset of the polyether macrocycles, and are identified by their pendant chains.[35] They can be categorized as either N-pivot (**19**) or C-pivot (**20**), depending on which type of atom the chain is attached. As for their polyether parents, much of the focus on these macrocycles has been on complexation of alkali and alkaline earth metal ions.



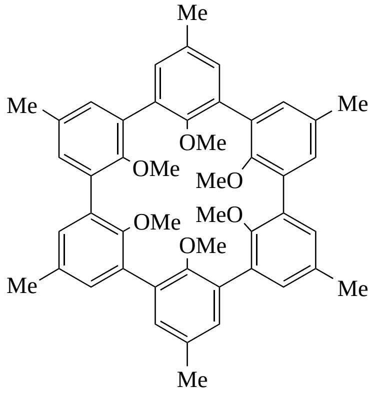
(**19**)



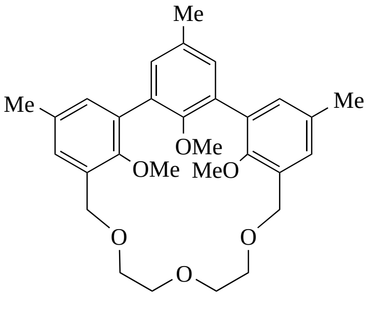
(**20**)

2.4.3 *Spherands and Hemispherands*

These consist of an arrangement of phenyl groups which provide a preorganized cavity for complexation,[36] e.g. (**21**) and (**22**).



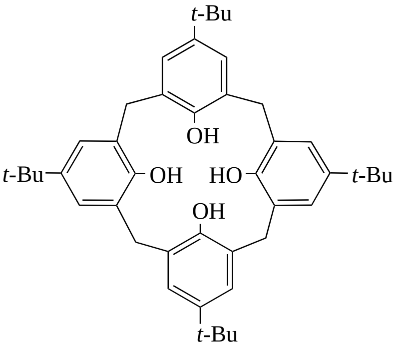
(**21**)



(**22**)

2.4.4 *Calixarenes*

Calixarenes (**23**) are the macrocyclic result of condensations between phenols and formaldehyde[37] and have been referred to as the most easily accessible molecular basket.[38]



(**23**)

3 SYNTHESIS

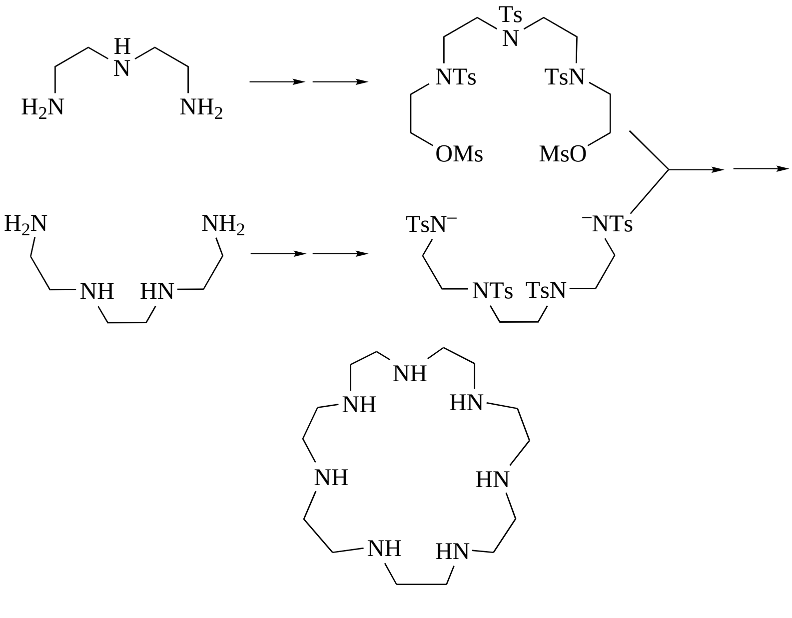
3.1 Polyaza Macrocycles

3.1.1 *Conventional (Nontemplate) Syntheses*

Reviews of synthetic procedures can be found for tridentate and pentadentate macrocyclic ligands with nitrogen donors, mixed nitrogen donors, and sulfur donor macrocycles,[39] the techniques of which can be expanded to other ring sizes. The general procedures will be summarized below.

Cyclic secondary amines, [*n*]aneN_m, are generally prepared by macrocyclization reactions known as the Richman–Atkins procedure.[40] These reactions involve ring closure by condensation of two precursor fragments of the cyclic molecule. In general, one fragment consists of a salt of a sulfonamide, while the other contains two terminal leaving groups, which can vary in identity and include chloride, bromide, hydroxide, or, more often, a sulfonate ester (Scheme 1). The reaction is performed in polar aprotic solvents and may involve high dilution techniques. Simplified routes to tri-, tetra-, and pentaaza systems have been described.[41] A handy synthetic technique for the smaller triaza ring has been described by Alder, where the macrocycle is built by using a single carbon as template.[42] Treatises on the synthesis of pyridine-containing macrocycles[43] and imidazole-containing macrocycles[44] have also been reported.

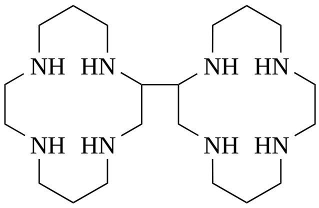
Functionalized macrocycles (**5**) with additional ligating components attached as pendant arms have been an area of focus in efforts to expand the chemistry of macrocyclic receptors by incorporating additional recognition sites. Synthetic techniques for N-functionalized, C-functionalized,



Scheme 1

and bis-macrocycles are known.[11] *N*-Alkylation, the more common of the functionalization routes, is usually achieved by alkylation or acylation of the amino nitrogens using a variety of agents such as chloroacetic acid, ethylene oxide, acrylonitrile, and formaldehyde.[11] Routes for selective alkylations are known, including the use of selective protection and deprotection techniques.[45]

Bis-macrocycles (**10**), another extension of the concept of functionalized macrocycles, can be made by several different methods. One of the more commonly used is the condensation of two precursor chains already joined by the linker.[23] Bis-macrocycles also can be formed from cyclam (**1**) as a by-product bis-macrocycle in low yield (**24**).[46]

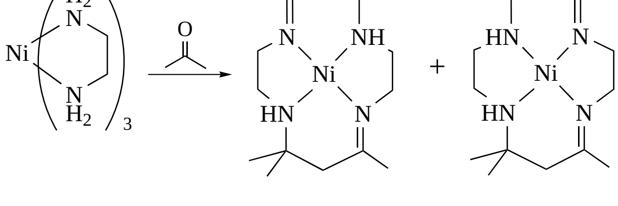


(**24**)

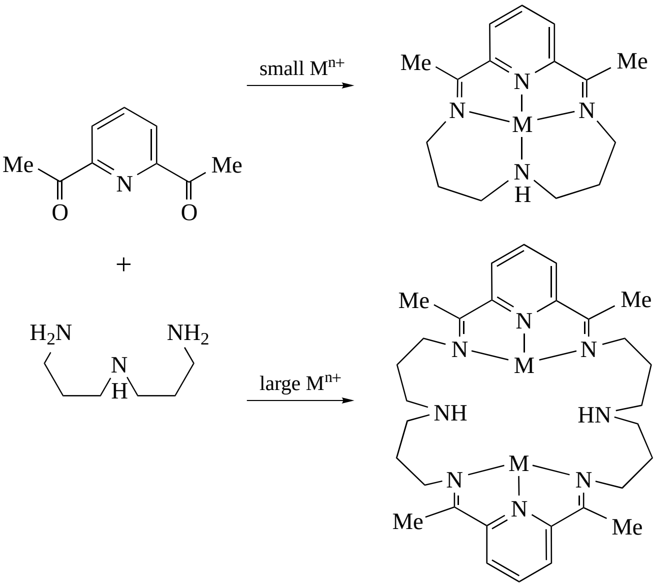
3.1.2 *Template-Mediated Syntheses*

Metal ion template mediation in macrocyclic synthesis has been a part of the field since its inception, its importance having been realized early in the development of this area. Two specific roles for the metal ion in template reactions have been proposed. These are, in turn, kinetic and thermodynamic in origin.[47] In the kinetic template effect, the arrangement of ligands already coordinated to the metal ion provides control in a subsequent condensation during which the macrocycle is formed. The thermodynamic effect serves to promote stabilization of a structure which would not be favored in the absence of a metal ion. Schiff base condensations tend to be dependent on this latter type of template effect. Some of the more routine and general synthetic procedures will be described here. A more in-depth treatment can be found in a review by Curtis, with particular emphasis on general methods as well as modifications of preformed macrocycles.[48]

Carbonyl compounds are commonly used precursors for the polyaza macrocycles, as in the classic synthesis of the Curtis ligand from the condensation of acetone with $Ni(en)_3$ (Scheme 2).[3] 2,6-Diacetylpyridine has provided the

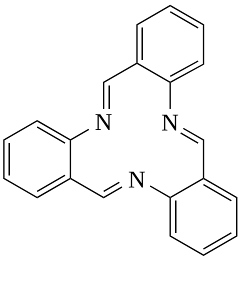


Scheme 2

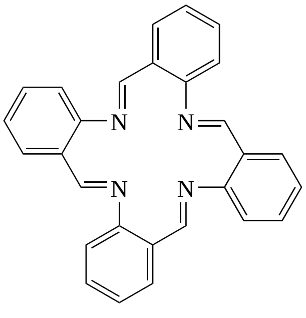


Scheme 3

precursor for a number of pyridine-derived imine macrocycles (Scheme 3), where smaller metal ions as templates tend to implement the formation of 1:1 condensates, while larger metal ions allow for 2:2 stoichiometries.[49] Schiff base condensations can be considered as another variation of the carbonyl condensations (Scheme 4).[50] The expanded porphyrins (**8**) and (**9**)[21,22] and the compartmental ligands (**16**)[28] are usually synthesized by Schiff base condensations. In some instances the macrocyclic analog cannot be obtained via other methods. This is true for the self-condensation of *o*-aminobenzaldehyde, which can yield both tridentate (TRI) and tetradentate (TAAB) macrocycles (**25**) and (**26**).[51]

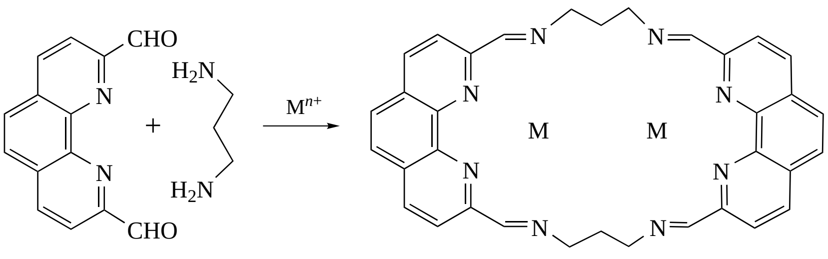


(**25**)



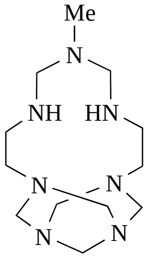
(**26**)

Template-assisted condensations of amines with formaldehyde yield a wide variety of macrocyclic products. Sepulchrates (**7**) can be synthesized from the template-assisted condensation of $[Co(en)_3]^{3+}$ with formaldehyde and ammonia under basic conditions.[20] Primary aldehydes other than formaldehyde have also been used.[52] Caged metal ion complexes in which the metal ion is used as a template are normally



Scheme 4

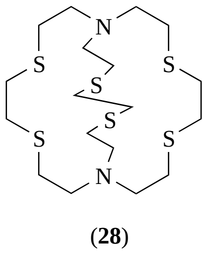
extremely inert, so much so that removal of the metal is often impossible. Nonmetal template syntheses of polyaza cages have also been reported.[53] A number of interesting variations utilizing the template-assisted condensation of formaldehyde and amines have also resulted in structurally new macrocycles such as (**27**).[54]



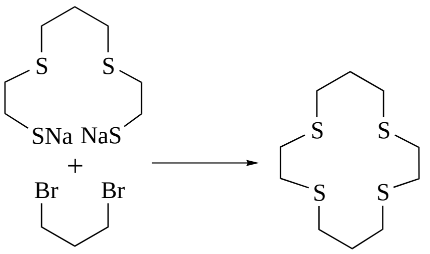
(**27**)

3.2 Polythia, Polyphospha, and Polyarsa Macrocycles

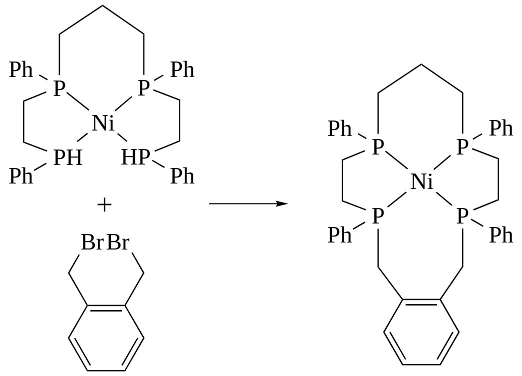
One of the reasons for the relative 'late-blooming' of the thioether macrocycles can be found in synthetic difficulties. While the polyaza and polyoxa macrocycles can often utilize template effects in controlling the critical condensations, polythia condensations are more limited in this area. In general, these macrocycles are made from condensation of the appropriate polythiane with a dibromoalkane (Scheme 5).[55] Synthetic procedures and yields have been greatly enhanced by the addition of high dilution techniques.[56,57] A cage-like sulfur macrocycle has been reported as an analog of the nitrogen-containing sepulchrates (**28**).[58] Mixed nitrogen–sulfur cages can also be obtained.[58]



(**28**)



Scheme 5



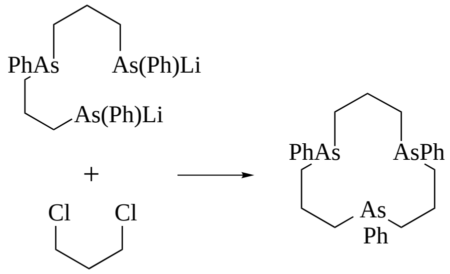
Scheme 6

Polyphospha macrocycles can be made via template condensations of coordinated polyphosphine ligands and dibromoalkanes (Scheme 6).[59,60]

Polyarsa macrocycles can be made by the reaction of lithiated polyarsanes with a dichloroalkane (Scheme 7).[26,60]

3.3 Mixed Donor Macrocycles

Simple mixed donor macrocycles, such as aza–oxa, aza–thia, oxa–thia, and analogous phospha and arsa analogs are generally achieved via combinations of the routes used for synthesis of the 'pure' donor analogs. Since the possibilities are so extensive they will not be treated here, but are found elsewhere.[16,60] New mixed donor phosphorus techniques have been devised for phospha–thia and phospha–aza macrocycles.[61,62]



Scheme 7

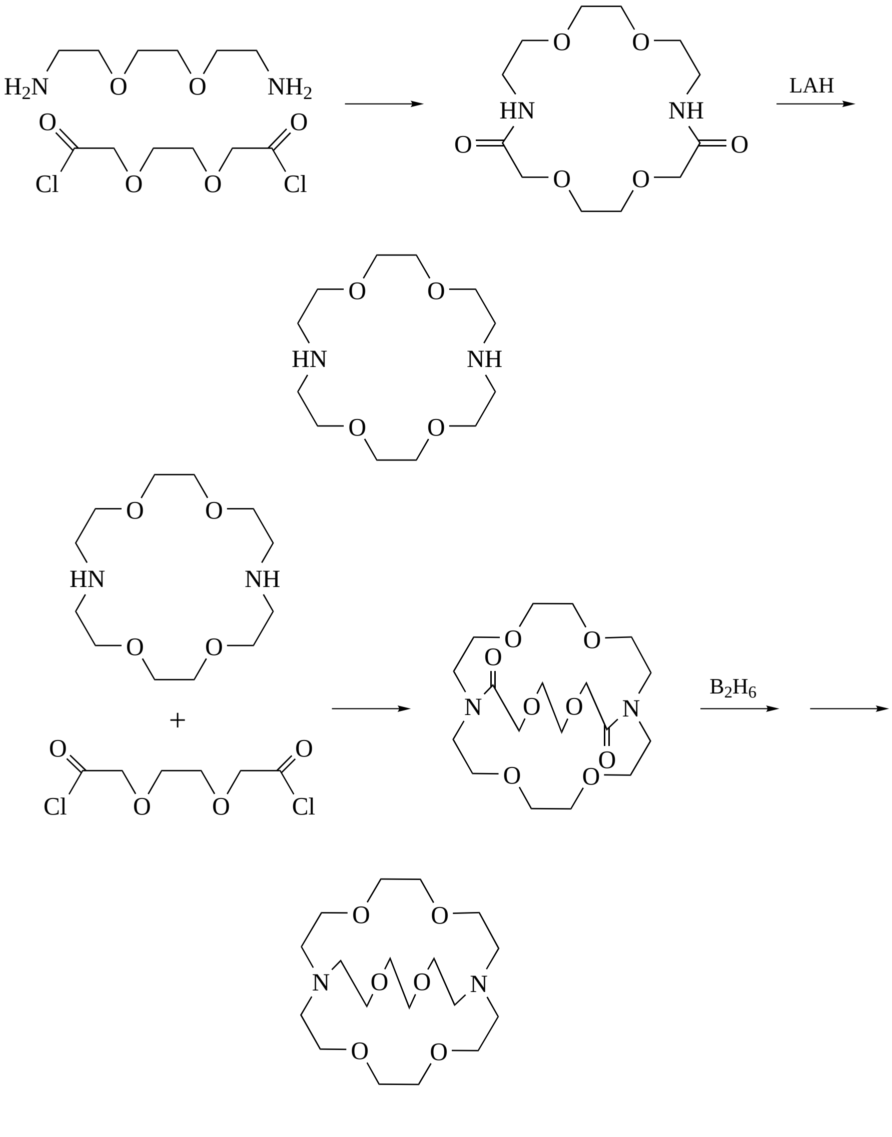
Cryptands are usually synthesized via sequential condensations between a diamine and an acid chloride, which yields a diamide, followed by reduction with $LiAlH_4$ to give the macromonocycle. Condensation with another equivalent of acyl chloride will yield the bicyclic precursor, which can be reduced by B_2H_6 to give the bicycle (Scheme 8).[5]

Compartmental ligands (**16**) are derived from diketonates and triketonates and are usually synthesized from Schiff base reactions of the ketone with a diamine.[28]

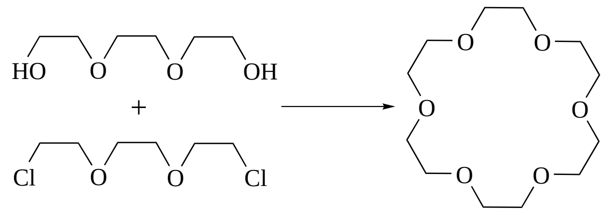
Catenands (**17**) are also made using the metal ion template effect. A bis-complex is formed from an α,α'-disubstituted *o*-phenanthroline. Then the initial product is treated with a diiodoalkane to accomplish the ring closure.[29]

3.4 Polyoxa Macrocycles

Polyethers were originally synthesized by template assistance from an oligo(ethylene glycol), monoglyme, and potassium *t*-butoxide (Scheme 9).[4]



Scheme 8



Scheme 9

Spherands and hemispherands (**21**) and (**22**) are synthesized by ring closure reactions of aryllithium with $Fe(acac)_3$, often using high dilution techniques.[36]

Calixarenes (**23**) are obtained from base-catalyzed condensations of *p*-substituted phenols with formaldehyde.[37]

4 THERMODYNAMICS AND STRUCTURAL ASPECTS

4.1 Introduction

4.1.1 The Macrocyclic Effect

This term refers to the amazing stability of macrocyclic ligands. It was initially described in studies of tetraaza macrocycles with copper(II).[63] For polyaza macrocycles this effect has been attributed to both entropic and enthalpic considerations and considerable controversy raged for a number of years as to which was the predominant factor.[64,65] The conflicting reports are now realized to be extremely dependent on the experimental methods used for the determination of the thermodynamic parameters. Two main types of technique have been employed, each of which has its strengths and weaknesses: the calorimetric titration method and the use of the temperature variation of the stability constants. The controversy has been largely settled by more recent studies.[66,67] Important contributions to the enthalpic term are now attributed to a number of factors, including solvation and conformation changes upon bond formation. Likewise, the entropic considerations include the number of species present and particularly solvation effects. Detailed discussions of the historical development can be found.[13,17]

Related to the macrocyclic effect are the decreased rates of dissociation observed for macrocyclic complexes. Busch and co-workers have coined a term to describe these long-term stabilities incurred by synthetic macrocycles: multiple juxtapositional fixedness. The premise is that straight-chain ligands can undergo dissociative displacements in consecutive steps starting at one end of the ligand and finishing with the opposite end. This is not the case for macrocyclic ligands, for which each dissociated donor is still held in proximity to the metal ion by the rest of the ligand framework.[68]

The macrocyclic effect has been observed for polyaza, polythia, and polyoxa, as well as mixed donor atom, macrocycles.[69]

4.1.2 Selectivity

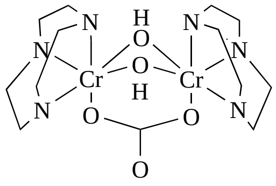
The selectivity of a macrocycle for either a metal ion or another substrate is critically dependent on the structure of the macrocycle and electronic effects, i.e. the types of donor atoms. Some of the important aspects are described below.

1. The number of binding sites is perhaps one of the most crucial influences on the binding properties of the substrate. Electronic effects of the binding of macrocycles with substrates are charge, polarity, and polarizability of the binding sites. For metal ion binding, this means ion pair interactions for negatively charged ligands, ion–dipole and ion–induced dipole interactions for neutral ligands, and the hard–soft acid–base criteria. Nitrogen, phosphorus, and sulfur donors are noted for their complexation of transition metal ions. Oxygen is more likely to complex alkali or alkaline earth metal ions.
2. The arrangement of the binding sites should be such as to maximize the potential ligand–metal ion interactions. In this regard the selection of spacers between donor atoms to allow for the formation of five- and six-member chelate rings has been the most utilized.
3. The preferred conformations of the macrocycles dictate its propensity to bind a metal ion internally or externally to the cavity. The propensity of the lone pair to point in or out of the cavity is also a deciding factor. Hence, it is not always a foregone conclusion that the metal ion will be bound within the macrocyclic cavity.
4. The identity of the macrocyclic framework also plays a major role in structure. For example, saturated hydrocarbon chains provide considerably more flexibility than incorporated aromatic units. Likewise the presence of other functional groups, such as amides or esters, serve to stiffen the macrocyclic framework. Decreasing the flexibility of the macrocycle by adding selected ‘shaping groups’ is the theory behind preorganization, so important in the cavitands. Another method of creating rigidity is to increase the dimensionality of the macrocycle, inherent in cryptand selectivities.
5. The size of the macrocyclic cavity also plays a large role in governing the flexibility of the ligand, and its propensity for metal ion binding.

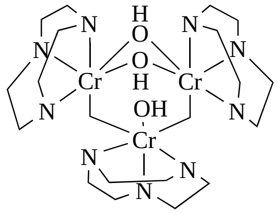
Since the focus of this article is primarily on transition metal chemistry, the structural aspects related to complexation of transition metals will be emphasized, and other aspects of complexation will only be briefly treated.

In addition to the traditional measurement of thermochemical properties, molecular mechanics calculations are now available to supplement and correlate with experimental findings. An extensive review which links the large data base of

thermodynamic and kinetic data with items such as ring size, number and arrangement of ligand binding sites, and solvent effects, for all types of donor atoms including coronands, cryptands, spherands, and nitrogen donors can be found.[69] A more recent series of molecular mechanics calculations have added to this base of thermochemical data and point to structural factors affecting complex stabilities from the viewpoint of steric strain.[70]



(**29**)



(**30**)

4.2 Polyaza Macrocycles

An extensive review of the thermodynamic aspects of polyaza macrocycles has been reported.[17] Other reviews include the chemistry of tridentate and pentadentate aza macrocycles,[16] 1,4,7-triazacyclononane and derivatives,[14] and polyaza macrocycles with pendant chains.[11] In general, the polyaza macrocycles form extremely stable complexes with transition metals of the later transition series, but show reduced affinity for alkali and alkaline earth metal ions compared to the oxa macrocycles.

4.2.1 Triaza Macrocycles

One of the simplest and smallest of the polyaza macrocycles according to definition is 1,4,7-triazacyclononane (**4**). The geometrical constraints of the triaza macrocycles are such that they do not allow for the incorporation of the metal ion within the macrocyclic ring. Hence, these macrocycles are facially coordinated in either a mono- or bis-ligand complex with a variety of metal ions.[14] The macrocyclic effect is observed, and the stability constants of the complexes follow the *Irving–Williams Series*.[17] Both microcalorimetric[71] and stability constant determinations at different temperatures[72] indicate that the effect is most probably enthalpic in origin. The triaza macrocycles also form extremely stable complexes with the heavier main group metals (such as Ga^{III}, In^{III}, Tl^{I}, and Tl^{III}) as well as transition metals. The chemistry of this macrocycle and its derivatives is wide in scope and is treated extensively in a review which includes the base compound and its N-functionalized derivatives.[14] Depending on the appendages employed in N-functionalization, three more coordination sites are potentially available, rounding out the coordination to pseudooctahedral.

The formation of dinuclear and higher nuclearity species is common for the mono-coordinated triazacyclononane, with bridging acetates, hydroxides, and oxides being very common. Extensive studies of the chemistry of the variety of bridged species have been made using the relatively substitutionally inert chromium(III) ion. Different dimers and trimers have been isolated and structurally characterized, as in (**29**) and (**30**).[73,74] Higher nuclear clusters such as an octanuclear iron system are relevant as a model for the iron storage protein ferritin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***).[75]

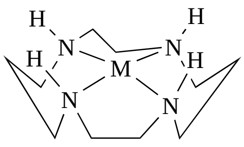
A more 'preorganized' ligand system is derived from the self-condensation of *o*-aminobenzaldehyde.[51] The tridentate form of the ligand (**25**) (TRI) imparts considerable inertness toward substitution. For example, the salts of the $[Ni(TRI)(H_2O)_3]^{2+}$ ion can be resolved into optical isomers.[76] A copper(II) complex of the methyl-substituted tetradentate macrocycle Me_4TAAB, in which bis-coordination occurs, displays a dynamic Jahn–Teller distortion based on crystallographic evidence.[77]

4.2.2 Tetraaza Macrocycles

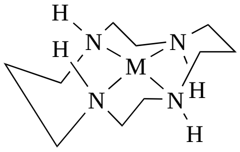
Because of the potential relationship to the naturally occurring porphyrins and porphyrin-analog macrocycles, the tetraaza macrocycles have been the focus of much attention.

Tetraaza macrocycles often, but not always, form a coplanar arrangement of the four nitrogen donors. Empirical force field calculations of free macrocycles from 12- to 16-membered rings indicate that cyclam (**1**) exhibits the least strain with the best planarity. A straightforward assessment of the relationship of hole size to selectivity is complicated by the conformational flexibility of the ligands. Results of studies for the tetraaza macrocycles show that hole size does not appear to be the predominant factor in metal ion discrimination. Rather, the selectivity of these macrocycles is governed by the relative stability of the conformers of the macrocycle which have different metal ion size preferences. An interesting observation regarding the relationship of the tetraaza macrocycles with regard to hole size and metal ion selectivity can be found for the most studied of the simple tetraaza macrocycles, cyclam. Cyclam is proposed to have five configurational isomers, based on the orientation of the amine hydrogens. From molecular mechanics calculations, where the best M–N distance is calculated as that giving the minimum energy, the trans-III analog of [12]aneN_4 (**31**) is found to have an extremely high strain energy of 19.7 kcal mol^{-1} with a best-fit M–N distance of 1.81 Å, compared to the trans-I form (**32**) (10.8 kcal mol^{-1} and 2.11 Å, respectively).[70,78] In general, the larger, more flexible, planar coordination is provided by the trans-I conformer, and often if a metal is too large for the macrocyclic cavity, it will coordinate lying out of the plane of the donor atoms. When the metal ion is not incorporated into the macrocyclic plane, the factors influencing stability are the same as for the acyclic aza analogs, namely that for larger metal ions, as the size of the chelate ring increases from five

to six, the complex stability decreases. A detailed discussion of the thermodynamics of changing chelate sizes for tetraaza macrocycles can be found.[17,78]



(**31**)

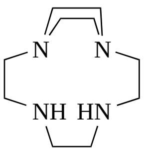


(**32**)

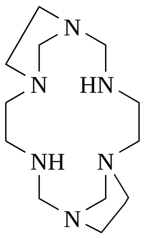
An elegant example of the importance of conformational changes in tetradentate macrocycles is the blue to yellow conversion observed for nickel(II) complexes. The yellow form is the low-spin square planar complex NiL^{2+}, while the blue form is high-spin pseudooctahedral $[NiL(H_2O)_2]^{2+}$. In the blue to yellow conversion the Ni–N bonds contract, which compensates for the breaking of the axial Ni–OH_2 bonds. The reaction is controlled by entropy, and the addition of an inert salt is such as to favor the dissociation of the water molecules. At equilibrium in aqueous solution, both [12]aneN_4 (cyclam) (**1**) and the 15-membered analog, [15]aneN_4, have 99% of the high-spin form present, while the 13- and 14-membered macrocycles exist in predominantly the low-spin square planar form (87 and 71%, respectively).[79]

For the nonplanar octahedral *cis*-coordinated macrocycles [*n*]aneN_4, changes in the ligand field correlate well with the analogous ligand field strengths for nonmacrocyclic analogs, specifically as related to the chelate ring size. A general rule of thumb is that increasing the chelate ring size from five to six increases the stability of complexes of smaller metals compared to larger metal ions. The origin of this effect can be attributed to increases in ring strain energy when metal ions larger than tetrahedral carbon are part of the ring.[78] For the planar-coordinated macrocycles, the equatorial ligand field, as anticipated, is dependent on the ring size. These findings have been related to the calculation of the optimum hole size permitting the macrocycle to adopt its most preferable *endo* configuration. Thus, it has been found that the macrocyclic hole size increases by 10–15 pm for each increment in *n* for [*n*]aneN_4.[79]

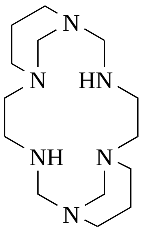
In order to introduce a greater rigidity into the flexible polyaza macrocycles and to implement greater hole size–metal ion size match correlations, reinforced macrocycles such as (**33**) have been created, which contain fused diaza rings.[80] Crystallographic results for the nickel(II) complex indicate that the Ni–N bonds are shortened from the strain-free value of 1.91 Å for diamagnetic nickel to 1.86 Å. Ligand field strength is also found to increase, and this has been suggested as being due to the compression of the bond lengths[80] as well as the presence of tertiary nitrogen donors.[78] In a more recent comparative study of nickel macrocycles with two fused 1,3-diazacyclohexane rings (**35**) compared to two fused 1,3-diazacyclopentane rings (**34**), structural results revealed weaker ligand field strengths for the 1,3-diazacyclohexane compared to 1,3-diazacyclopentane.[54]



(**33**)

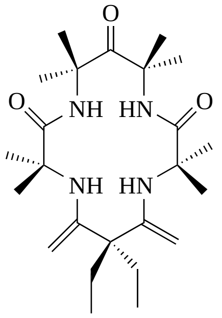


(**34**)

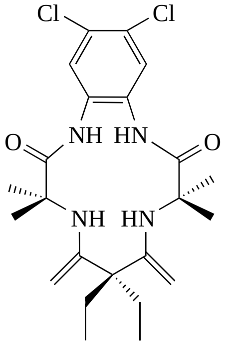


(**35**)

Attempts to achieve macrocycles that are capable of stabilizing highly oxidized transition metal complexes has led to the design of ‘noninnocent’ ligands.[81] The structures of high-valent chromium(V) oxo species with the two tetraamido N ligands (**36**) and (**37**) were determined. Both structures were found to contain distinctly nonplanar amide groups, and in (**36**) all four amides are nonplanar.



(**36**)



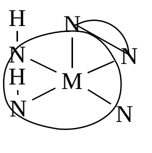
(**37**)

Polyaza macrocycles with pendant arms have been studied extensively, in particular with respect to protonation and complexation as well as to the kinetics of metal complex formation. These aspects are treated in a review by Kaden.[11] Of particular interest is the fact that metal complex formation constants of macrocycles with pendant carboxylates can be 10^3 to 10^4 times higher than for the unsubstituted analogs.

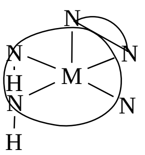
4.2.3 Higher Polyaza Macrocycles

Transition metal complexes of the larger polyaza macrocyclic ligands have been less extensively studied than for the smaller ring systems. For the pentaaza macrocycles, [15]aneN_5 with ethylene bridges appears to form the most stable complexes with most metal ions.[17] Structural data for a variety of pentaaza macrocyclic complexes have been reviewed.[16] The N–H bonds as well as the different sized chelate rings must be considered in calculating the

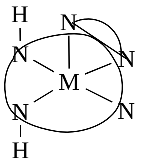
number of possible isomers. For each of the complexes, three configurations of the in-plane N–H bonds are possible: (**38**), (**39**), and (**40**). Crystallographic data indicate that most of the complexes with pentadentate macrocycles have pseudooctahedral geometries. Pentadentate macrocycles also tend to stabilize unusual oxidation states. For example, the nickel(II) complexes of [15]aneN_5 (**41**), [16]aneN_5 (**42**), and one of the isomers of [17]aneN_5 (**43**), are readily oxidized to the Ni^{III} analogs. Also, there is little dependence of $E_{1/2}$ values on the macrocyclic ring size, which has been attributed to the absence of in-plane ring size effects.[16]



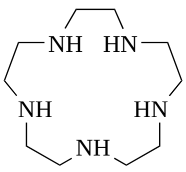
(**38**) *meso–syn*



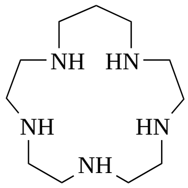
(**39**) *meso–anti*



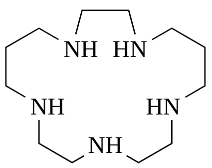
(**40**) racemic



(**41**)



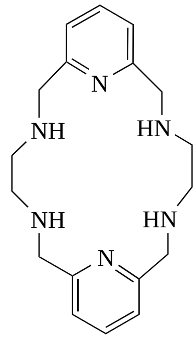
(**42**)



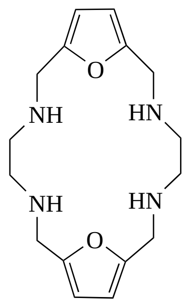
(**43**)

The hexaaza [18]aneN_6 forms complexes with transition metal ions and with certain alkali and alkaline earth and lanthanide ions.[82] For the higher aza macrocycles with seven or more donor atoms, dinuclear complexes become possible. A systematic investigation of both the structural and thermodynamic aspects of copper complexes formed with the larger polyaza macrocycles from heptaaza to dodecaaza has been published.[18] All of the macrocycles were found to form hydroxo species as well as polynuclear complexes. A number of structures have been determined for the higher polyaza macrocycles, both in complexed and noncomplexed forms, and structures range from highly boat shaped to nearly planar.[18,50,83,84]

A review of macrocycles possessing subheterocyclic rings has appeared, which includes pyridine, furan, and thiophene.[85] In a study of formation constants for transition metal ions with pyridine- and furan-containing macrocycles, (**44**) and (**45**), it was found that the pyridine macrocycles follow the Irving–Williams series and bind even more effectively than their saturated analogs (i.e. [18]aneN_6 and [18]aneN_4O_2). The furan analogs showed little tendency to bind, which has been attributed to the increased rigidity of the furan ring.[86]



(**44**)



(**45**)

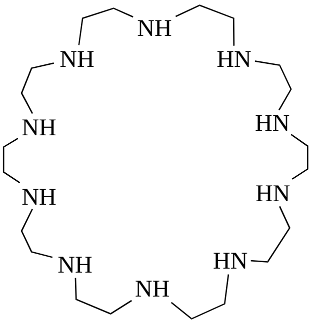
4.2.4 *Anion Coordination*

While the initial interest in polyaza macrocycles involved metal ion coordination, the finding in 1968 by Simmons[87] that diaza bicyclic catapinands can incorporate halide ions into their cavity opened the door on a vast new area of chemistry, that of anion complexation. The thermodynamics of anion binding can be divided into several different areas: that of simple inorganic anions; more complex carboxylate and polycarboxylates; corresponding phosphates, polyphosphates, and nucleotides; and culminating in anionic metal complexes.[17,88–90] Binding is accomplished via both electrostatic and hydrogen-bonding interactions between the protonated macrocyclic amines and the anionic substrates. The general trend appears to be that the increased flexibility of larger polyammonium macrocycles tends to facilitate complexation of more complex anionic substrates.

The results of studies for complexes formed between polyammonium macrocycles and transition metal complex anions indicate that cation–anion electrostatic attraction is a crucial factor in complexation reactions and serves to regulate the stoichiometry of the complexes formed. Hydrogen-bonding, size, and conformational factors also play major roles.[89] Anions can be incorporated in or out of the ring. Two illustrative examples are metal ion complexes with the octaprotonated macrocycle H_8[30]aneN_{10} (**46**). In the complex with $Co(CN)_6{}^{3-}$, the anion lies outside the macrocycle. The $PdCl_4{}^{2-}$ complex is a true ‘inclusion’ situation, however, in which the $PdCl_4{}^{2-}$ is situated along the minor axis of the macrocyclic cavity, and the Cl atoms are out of the frame, forming strong hydrogen bonds with the polyammonium sites.[90]

4.2.5 *Cyclidenes*

Crystallographic results for the cyclidenes (**6**) show that a wide variety of structural ranges can result from designed modifications of the lacunar cavity (or void).[91] The affinity of the cobalt(II) complexes of the cyclidenes for molecular oxygen was found to be very dependent on the identity of the overhead bridge and was found to increase with increasing bridge length. Further design has also allowed for expanding



(**46**)

the capability of these macrocycles beyond simple oxygen binding to oxygenase activity observed for the cytochrome P-450s. This has been achieved by adding piperazine ‘risers’ to increase the cavity size (9 Å high) as well as increasing the hydrophobicity of the molecules, and by adding anthracene and durene ‘roofs’. The crystal structure of the anthracene-bridged derivative shows that the macrocycle is indeed capable of hosting an acetonitrile molecule.

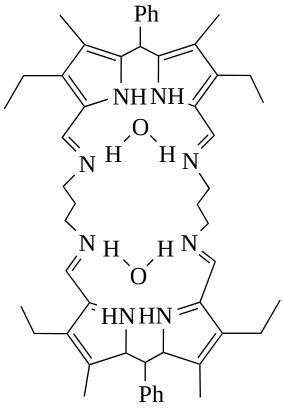
4.2.6 Sepulchrates

Sepulchrates (**7**) are the most noted of the caged macrocyclic ligands and are the nitrogen analogs of the cryptands. The Co–N distances are 1.99 Å for Co^{III} and 2.16 Å for Co^{II} from crystallographic data, and do not vary greatly from other cobalt amines.[20]

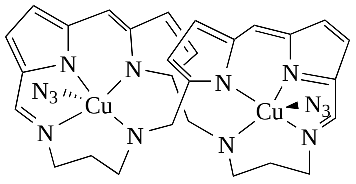
4.2.7 Expanded Porphyrins

A review of expanded porphyrin ligands can be found.[92] The texaphyrins (**8**) can be considered as 22-π-electron benzannulene systems with an 18-π-electron delocalization path, based on crystal structure data as well as NMR. The cadmium complex of the macrocycle is found to be planar with pentadentate coordination of the macrocycle to cadmium, which becomes seven-coordinate as a result of axial coordination to two pyridine molecules. The cavity is nearly circular with a center-to-nitrogen distance of 2.39 Å. Because of the larger size of this macrocycle, metal ion coordination is generally seen with the larger transition metals and lanthanides.

A more flexible expanded porphyrin is the ‘accordion’ porphyrin (**9**).[22] The structural aspects of this macrocycle illustrate the importance of flexibility in achieving unanticipated structures. The free-base macrocycle is elliptical with the inclusion of two water molecules (**47**), while the dicopper(II) complex is highly distorted by means of *exo* and *endo* orientations of the imine groups (**48**).



(**47**)



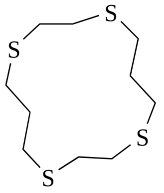
(**48**)

4.3 Polythia and Polyphospha Macrocycles

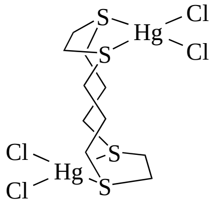
4.3.1 Polythia Macrocycles

The coordination chemistry of thioether macrocycles has expanded greatly only since the mid-1980s, as seen by a number of reviews.[55,93–95] The macrocyclic effect is also noted for thioethers, but to a lesser extent than some of the other macrocyclic ligands. This is due primarily to the reorganizational energy requirements, since a number of the free-ligand thia macrocycles have a tendency to adopt ‘exodentate’ conformations in the uncomplexed form, where the sulfurs are pointed out of the macrocycle (**49**). Macrocyclic thioethers must then undergo a reorganization of their *exo* lone pairs in order to incorporate metal ions within the cavity. It was found in a study of the complexation of a number of open-chain thia ligands and thia macrocycles that the enthalpy changes were essentially identical for both macrocyclic and nonmacrocyclic ligands. Hence, the favorable macrocyclic effect is more attributable to the entropy changes in the sulfur macrocycles.[96] The smaller trithia analog of the extensively studied nitrogen donor triazacyclononane does not require such organization and, as such, has been extensively studied itself.[55] Because of the preference for exodentate sulfurs, metal ion coordination in many cases is external to the cavity (**50**).[97] A comprehensive review of the structural aspects of thia macrocycles can be found.[55]

Considerable effort has been made with regard to conformation analysis of crown thioethers. It has been found that ligand strain is most evident in torsion angles, whereby an examination of the deviations from the optimum values of



(**49**)

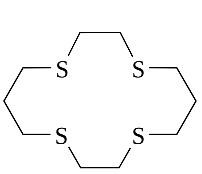


(**50**)

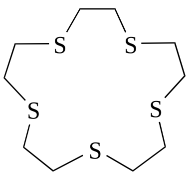
60° for *gauche* or 180° for *anti* configurations can lead to an assessment of the overall strain in the molecules.[93]

Examination of the influence of ring size has been reported for the 12- to 16-membered tetrathia systems with copper(II).[96,98] The results indicate a marked interrelationship between ring size and stability. The stability peaks at 14-membered rings, and the rings are large enough to incorporate the copper only for the 14- to 16-membered systems.

Results from the correlation of stability constants in conjunction with redox data have led to insights regarding the coordination chemistry of thia macrocycles. For example, the electrochemical behavior of a number of copper(II)/(I) redox couples has been investigated,[99] and redox potentials as well as protonation and stability constants of Cu^{I} species were determined for a number of tetradentate and pentadentate thia-derived macrocycles with thia- and mixed thia–aza rings with the basic backbones (**51**) and (**52**). Results of the examination of the stability constants in conjunction with the $Cu^{II/I}$ redox potentials indicate that the stability constants for the Cu^{I} oxidation state are relatively constant regardless of the mixing in of nitrogen donor atoms. Hence, the dramatic increase in the $Cu^{II/I}$ redox potential which is observed in the presence of the sulfur macrocycles can be attributed to a destabilization of the Cu^{II} state rather than stabilization of the Cu^{I} state, contrary to popular belief from the hard–soft acid–base system.

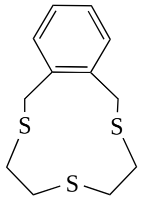


(**51**)

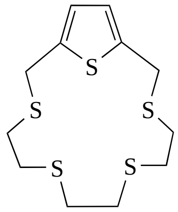


(**52**)

In order to force binding of trithia structural units into an endodentate conformation, one strategy has been to add rigid xylyl groups into the ring to limit the flexibility (**53**).[100] While the conformation of the free ligands is exodentate, a number of transition metal complexes of this ligand have been found to exhibit endodentate coordination, including Mo, Cu, Ag, Pd, and Rh. Results for the bis-macrocyclic silver complex with a variety of noncoordinating anions, indicate that the conformational interconversions of the ligand are low in energy.



(**53**)

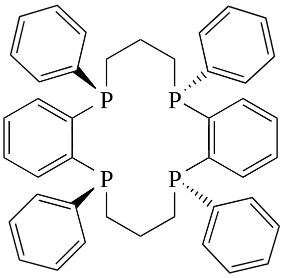


(**54**)

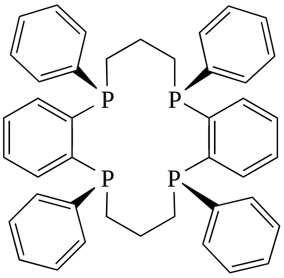
Thiophene units have also been incorporated into the thia crowns (**54**).[101]

4.3.2 *Polyphospha Macrocycles*

Phosphorus macrocycles can exist in a variety of conformations, a number of which are stable. The barrier for inversion of phosphate is 146.4 kJ mol^{-1}.[102] Hence there are five conformations possible for the tetraphosphorus macrocycle (**12**). Two are preferred: the one in which the macrocyclic benzo groups are *trans* (**55**) and that in which they are *cis* (**56**).[60,103]



(**55**)



(**56**)

4.4 Mixed Donor Macrocycles

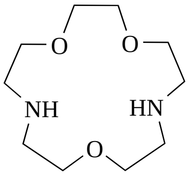
4.4.1 *Simple Mixed Donors*

Much of the work in this area has been reported by Lindoy and co-workers, who have performed extensive studies on the role of hole size in complex stability and rates of complex formation.[13,27,104] Bradshaw, Krakowiak, and Izatt have published an extensive text on the synthesis of aza crowns.[105] A review of tri- and pentadentate macrocyclic ligands also includes mixed donor results as well as the influence of pendant arms.[16] Due to the numerous ramifications of this area, a few key findings will be cited for the simplest systems.

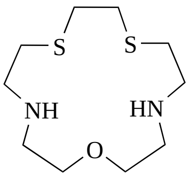
A major focus in the study of mixed metal ion systems has been to examine metal ion discrimination. In particular, two specific mechanisms can be attributed to metal ion discrimination: macrocyclic hole size and what Lindoy has termed as a 'dislocation' mechanism. The key to this

mechanism is the assumption that coordination geometry preferences can be suddenly changed at some point along a series of ligands where gradual changes in the ligand framework are made. Because these changes can occur at different points for different metal ions, discrimination can be achieved. A particularly appealing aspect of the mixed donor aza–oxa systems is the lower ligand field which they provide, which then tends to minimize spin state changes. These systems are treated in a comprehensive review of O_3N_2, O_2N_3, and other pentadentate macrocycles with N, O, S heteroatoms.[104]

Examples of the use of synthetic mixed donor macrocycles in heavy metal ion separations are found in the discrimination of silver from lead. A number of studies indicate that the inclusion of sulfur in macrocyclic sequestering agents shifts the discrimination to silver.[104] An example of this is seen with (**57**) and (**58**). For the aza–oxa macrocycle (**57**) the log K is 5.9 for both silver and lead ions, while the thia-incorporated ligand (**58**) complexes silver more efficiently (log $K = 9.9$) compared to lead (log $K = 5.7$).[106,107]



(**57**)

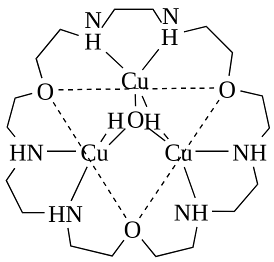


(**58**)

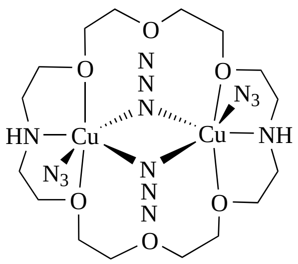
The larger mixed aza–oxa, aza–thia, and aza–and oxa–phospha macrocycles are noted for their ability to complex more than one metal ion and to alter the magnetic properties of bimetallic complexes.[108–110] An example of tri-metal coordination is the tricopper complex of a 27-member ring system (**59**).[108] A classic series of dicopper complexes which illustrates the influence of donor atoms on magnetism are the dicopper structures (**60**)–(**62**).[110] The magnetic properties were found to be extremely dependent on the mode of azide coordination, which is thought to be influenced by the orientation of the orbitals on the metal ions. In complex (**60**), the two copper ions are ferromagnetically coupled with a triplet ground state; in (**61**), the metal ions are antiferromagnetically coupled; and in (**62**), the two copper ions are not coupled.

4.4.2 Cryptands

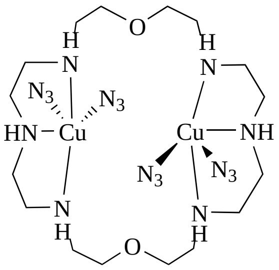
Cryptands (**15**) are noted for their highly selective complexation of alkaline earth metal ions, and for their ring size–metal ion match ability.[5] The thermodynamic properties of these macrocycles have been extensively investigated, and results indicate that the high stability of the



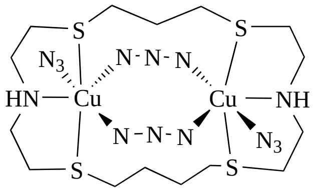
(**59**)



(**60**)



(**61**)



(**62**)

bicyclic macrocycles compared to their monocyclic analogs is enthalpic in origin.[88]

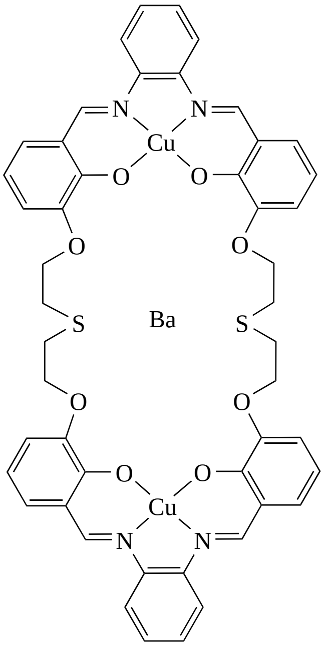
4.4.3 Compartmental Ligands

Compartmental ligands (**16**) provide extensive opportunities for multiple metal ion complexation. An example of a mixed donor ligand incorporating different metal ions is the macrocyclic trinucleating ligand (**63**), which is capable of complexing two ‘soft’ donor metal centers in addition to a ‘hard’ alkali or alkaline earth metal.[111]

4.5 Oxa Macrocycles

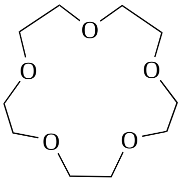
4.5.1 Crown Ethers

In the crown ethers (**18**) the interactions between the ligand and metal ion are considered to be more electrostatic in nature, rather than the covalent binding observed for the transition metal complexes of the aza, thia, and phospha macrocycles. The thermodynamic properties of these macrocycles have been extensively studied, with numerous reviews covering complexation, selectivity, and structural aspects, some with extensive tables of thermodynamic data.[69,70,112–119] Considerable efforts have been made to correlate the interrelationship between cavity size of the macrocycles and stability of alkali and alkaline earth metal complexes. From X-ray and CPK models, cavity radii are determined as 0.86–0.92 Å for 15-crown-5 (**64**), 1.34–1.43 Å for 18-crown-6 (**65**), and about 1.7 Å for 21-crown-7 (**66**).[69] For complex formation between the alkali metal ions and 18-crown-6, the maximum stability

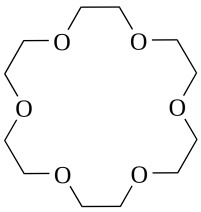


(**63**)

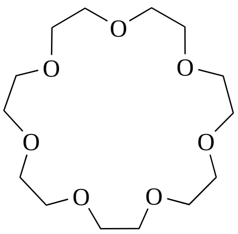
occurs for the potassium ion, which has a radius of 1.38 Å, thus correlating well with the cavity radius. However, 18-crown-6 forms extremely stable complexes with all of the alkali and alkaline earth metal ions. Hence, Gokel argues that the data indicate that the hole size concept is inapplicable, since the binding constants for sodium, potassium, ammonium, and calcium ions are the largest for the 18-crown-6 compared to almost all of the other simple crown ethers.[119] Hancock has proposed that chelate ring size is the critical factor, and that the high stabilities observed for the crown ethers with large metal ions is a result of the presence of five-membered chelate rings. Thus the high affinity of these macrocycles for the potassium ion is explained by the fact that potassium is the right size for the five-membered chelate rings of the crown ethers.[78]



(**64**)

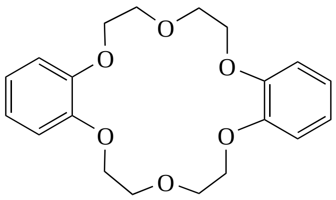


(**65**)

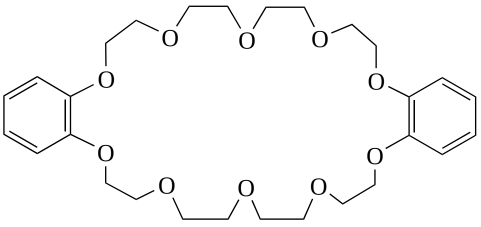


(**66**)

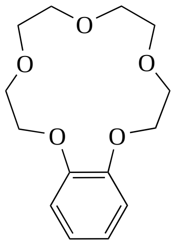
A number of reviews of the structural aspects of crown ethers can be found.[115–117] These structures vary considerably in complexity. An example of the flexibility of the crown ethers can be seen in the variation in the structures as a result of ring size of three different benzo crowns. When the cavity of the crown matches the radius of the metal ion, the metal ion can be readily incorporated in the cavity, such as in the structure of the rubidium thiocyanate complex with the dibenzo-18-crown-6 (**67**). In cases where the cavity of the crown is too large to surround the metal ion snugly, a folded structure can result, as with the dibenzo-30-crown-10 (**68**) and the potassium ion. For very large metal ions incapable of fitting into smaller macrocyclic cavities, sandwich-type structures can occur, as in the benzo-15-crown-5 (**69**) with the potassium ion.[115]



(**67**)



(**68**)



(**69**)

Molecular mechanics studies indicate that the lowest energy conformer of the uncomplexed ligand is not necessarily that required for complexation, i.e. oxygen donors may be exodentate as in the thia macrocycles. This means that in order for complex formation to occur, the ligand must undergo both reorganization as well as desolvation. A general rule of thumb with respect to size, however, is that the larger macrocycles are more flexible and subject to adaptability, while the smaller macrocycles are more rigid and, in that sense, 'preorganized'. Cram has provided an excellent treatise on preorganization.[118] His principle of preorganization is that 'the more highly hosts and guests are organized for binding and low solvation prior to their complexation, the more stable will be their complexes.'[118] ΔG values for a variety of macrocyclic oxygen donors indicate that the 'prearranged' ligands in general bind

their guests more strongly and are, in sequence, the spherands > cryptaspherands ≈ cryptands > hemispherands > crown ethers.[116]

A useful correlation of enthalpy–entropy considerations for complexation has been shown by Inoue, Liu, and Hakushi.[113] The treatment reflects enthalpy–entropy relationships for given types of ligands. The general concept is that as the enthalpic contributions become strong, a higher level of organization is obtained, which will result in unfavorable entropy changes. For a given type of system with similar entropic versus enthalpic considerations, the $T\Delta S$ and ΔH values determined for a series of ligands should thus exhibit a linear relationship. This is found for the macrocyclic crown ethers, the cryptands, lariat ethers, and bis-crown ethers, as well as the acyclic polyethers known as podands. The slopes are all positive with high correlation coefficients. Gokel has suggested that these slopes can be used to assess the ligand flexibility: glymes and podands (0.86) > crown ethers (0.76) > cryptands (0.51).[119]

4.5.2 Lariat Ethers

The lariat ethers (**19**) and (**20**) known to date consist of macrocycles with many different types of podand groups, and much of their complexation chemistry involves electrostatic binding of guests. Reviews of both structural and thermodynamic aspects of the lariat ethers can be found.[120–122] The trends are noted to be relatively similar for both the carbon-pivot and nitrogen-pivot types of lariat ethers. Binding strengths and selectivities are dependent on ring size and in general increase as ligand size increases. Strong selectivities are noted for the potassium ion, as in the crown ethers.

4.5.3 Spherands and Hemispherands

The spherands (**21**) were specifically designed using the concept of 'preorganization' wherein the oxygen donors are arranged in an enforced spherical cavity. Totally prearranged (spherand) and partially arranged (hemispherand, (**22**)) complexes are possible.[118] Due to the structural restraints imposed by the rigidly joined phenyl rings, the spherands are considered to be highly 'preorganized' binding sites. In these macrocycles the lone pair of electrons will always be pointed toward the center of the macrocyclic cavity.

4.5.4 Calixarenes

The calixarenes (**23**) are also highly preorganized molecules which are capable of forming different conformational isomers. The conformational flexibility is determined by the size of the ring, with the preferred conformation becoming more planar as the ring size increases.[37]

5 APPLICATIONS

As macrocyclic chemistry has developed, the variety and scope of the applications of these molecules have continued to multiply. This concluding section is an attempt to provide an overview of only three of the applications of synthetic macrocycles. A particularly insightful treatment can be found in the Nobel Lecture of Jean-Marie Lehn,[123] which describes the concept of supramolecular chemistry from simple recognition, to cation and anion receptors, multiple recognition, catalysis, transport, and molecular devices.

5.1 Ion Transport

Ion transport, especially cation transport, was one of the early focal points in macrocyclic chemistry, revolving primarily around the crown ethers and cryptands. Later efforts have been to provide switches to control the rates of cation transport. Two examples of the types of switches that have been developed include photo switches using cryptands,[124] and electrochemical switches using anthraquinone-derived lariat ethers.[125]

Related to transport capabilities is the use of synthetic macrocycles in analytical chemistry. Because of their selective complexation of a variety of cations, the crown ethers and related macrocycles have been widely used for separations and analyses.[126]

While transport efforts have largely involved metal cations, more recent developments have led to the use of macrocycles for transport of more complex molecules such as nucleosides.[127]

5.2 Catalysis

Catalysis can be broken down into a number of areas, depending on the substrate and the catalytic reaction. One of the prime areas of the initial effort in catalysis has been small molecule activation, such as oxygen with a number of transition metal ion macrocycles[128,129] and carbon dioxide, the latter particularly with cobalt(I) and nickel(I) macrocycles.[130,131] Once the polyammonium macrocycles were found to be able to recognize substrates other than metal ions, other catalysis applications evolved. For example, phosphoryl transfer catalysis with simple polyammonium macrocycles has become quite accessible.[132]

5.3 Magnetic Resonance Imaging

Macrocyclic complexes have gained recognition in magnetic resonance imaging.[133,134] In order to be effective imaging agents, complexes must provide a significant enhancement in the proton relaxation rates of water, as well as be nontoxic, and thermodynamically stable. Hence, macrocyclic ligands with pendant carboxylates, such

as (**5**), have been examined primarily because of their thermodynamic stability.

1 INTRODUCTION

Materials that can be classified as 'Magnetic Oxides' have continued to attract interest and the result is a remarkably high level of research activity over the past decade or so. In this chapter, an attempt will be made to describe some of the major results in this area within the time window from about 1993 to the present. There are a number of ways in which such a discussion could be organized. One approach involves a framework based on the phenomenon or effect exhibited by specific magnetic oxides that have received the preponderance of attention in the literature. Among these are, for example, 'colossal magneto-resistance', low-dimensional magnetism, geometrically frustrated magnetism, and 'half-metallic' ferromagnetism. An alternative is to organize by structure type and chemical periodicity, which has the advantage of being more systematic. While the latter approach will be adopted here, an attempt will be made to cross connect with phenomena of current interest. Before commencing with this survey, we introduce some basic principles of magnetism and magnetic materials.

2 BASIC PRINCIPLES OF MAGNETISM

A brief review of some of the basic principles of magnetism relevant to understanding the detailed behavior of the specific magnetic oxides discussed later in this chapter will be presented. A more expanded discussion is available in Volume I of this series.[1]

2.1 Varieties of Magnetic Ordering

Nearly all of the examples to be discussed later in this chapter involve oxide materials that exhibit some form of cooperative magnetism, that is, correlations between the spins residing on magnetic ions in a lattice of some symmetry. These correlations can exist on length scales ranging from one or only a few neighbors, called short range correlations, to essentially infinity, called long-range order. It may be most instructive to begin with the case in which there is no correlation between the spins, that is, the random state known as paramagnetism.

2.1.1 Paramagnetism

Paramagnetism can be regarded as the analog of the ideal, gaseous state of matter for magnetic systems. Here we assume the spins to be noninteracting and thus, there are no correlations even between spins on nearest neighbors. The mean magnetic moment for noninteracting spins can be calculated by standard statistical methods.[2] The general result for the magnetic moment, M, is $M = N_o\langle\mu\rangle = N_o g\mu_B S B_s(\eta)$, where N_o is Avogadro's number, g the Lande splitting factor, μ_B the Bohr magneton, S is the spin of the electronic system in question (the total angular momentum, $J = L + S$, is appropriate for the f-group elements where the orbital angular momentum is not quenched), η is the ratio of the magnetic to the thermal energies, $\eta = g\mu_B H_z/k_B T$, where k_B is Boltzmann's constant, T is the temperature in Kelvins, and H_z is the relevant component of the magnetic field. The function, $B_{S(J)}(\eta)$ is known as the Brillouin function and is given by equation (1):

$$B_{S(J)}(\eta) = \frac{(S(J) + 1/2)\cosh(S(J) + 1/2)\eta - 1/2\cosh\eta/2}{\sinh S(J) + 1/2\eta\sinh\eta/2} \quad (1)$$

In the limit of $\eta \ll 1$, that is, high temperatures or very low fields, $B_{S(J)}$ reduces to $H_z g\mu_B S(S+1)/3kBT$ or the corresponding expression with J. Defining the magnetic susceptibility as $\chi = M/H_z$ gives equation (2), which is known as the Curie law,

$$\chi = \frac{N_o g^2\mu_B^2 S(S+1)}{3k_B T} = \frac{C}{T} \quad (2)$$

where the Curie constant, C, is defined. This quantity is clearly diagnostic of the spin or total angular momentum. Another quantity in common use is the effective magnetic moment, $\mu_{eff} = [g^2\mu_B^2 S(S+1)]^{1/2}$. The two are related by $\mu_{eff} = [8C]^{1/2}$. While (2) is the equation for a hyperbola, it can be linearized by plotting χ^{-1} versus T and $C = (\text{slope})^{-1}$ of such a plot. The effective moment (or Curie constant) is thus obtained from analysis of data in the high-temperature limit.

In the other extreme, $\eta \gg 1$, the low-temperature or high-field limit, $B_{S(J)}(\eta) \rightarrow 1$ and $M_S = N_o g\mu_B S(J)$, which is called the saturation moment and is obtained from analysis of data at very low temperatures. These two moments are often confused.

2.1.2 Spin-spin Coupling, Long-range Ordered States, and Phase Transitions

In the discussion of paramagnetism above, the possibility of correlations between the spins has been ignored. Spin–spin

correlations are described in terms of a basic pair-wise exchange Hamiltonian of the form (equation 3) (sometimes called the Heisenberg-Dirac-VanVleck Hamiltonian, HDVV)

$$\mathbf{H}_{ex} = -2J\mathbf{S}_A \cdot \mathbf{S}_B \quad (3)$$

where J is a scalar known as the exchange constant and $\mathbf{S}_A$ and $\mathbf{S}_B$ are spin operators on two sites. Note the presence of negative sign and the factor of 2. This is more or less the standard form but one can encounter other forms which omit the factor and reverse the sign. The reader should be aware of this and check the exact form of the Hamiltonian for any reported result. Note that the scalar product demands that the spins be either exactly parallel or antiparallel and that if $J > 0$ the former is found and with $J < 0$, the latter. The origin of the sign and magnitude of J will be discussed in a following section.

Now, when spin–spin correlations are not neglected, there should exist a temperature below which a phase transition to a more organized state will occur. If this state is characterized by order on an infinite length scale (i.e. the length scale of the correlations is essentially the dimension of the sample) this is known as long-range order (LRO). The transition that occurs is analogous to the condensation of a gas to form a crystalline solid. We are not concerned here with a detailed discussion of the voluminous literature on phase transitions of this type (also known as critical phenomena).

The temperature at which the phase transition occurs is called the 'critical' temperature or T_c. Most, but not all, magnetic phase transitions are 'continuous', sometimes called 'second order'. From a microscopic point of view, such phase transitions follow a scenario in which, upon cooling from high temperature, finite size, spin-correlated, fractal like, clusters develop from the random, paramagnetic state at temperatures above T_c, the so-called 'critical regime'. As $T \rightarrow T_c$ from above, the clusters grow in size until at least one cluster becomes infinite (i.e. it extends, uninterrupted, throughout the sample) in size at T_c.[3] As the temperature decreases more clusters become associated with the infinite cluster until at $T = 0$ K all spins are completely correlated.

Continuous phase transitions show anomalies in the specific heat and magnetic susceptibility (or magnetization) at or very near T_c. There is, however, no latent heat as in so-called first-order transitions but of course there is a decrease in spin entropy.

There are three basic types of long-range magnetic order: ferromagnetism, antiferromagnetism, and ferrimagnetism. These are illustrated, along with more complex cases, in Figure 1.

2.1.3 *Ferromagnetism*

This is the simplest case of magnetic LRO, albeit that most rarely found in nature. All of the spins are parallel, from Figure 1. This corresponds to $J > 0$ in equation (3). There is clearly only one possible ferromagnetic spin configuration, no matter how complex the sublattice of the magnetic atoms, although of course the spins will tend to orientate along some preferred direction in the crystal. For historical reasons, the critical temperature for ferromagnets, T_c, is often called the Curie temperature, which has, confusingly, the same symbol, T_c. Ferromagnets possess a net magnetization below T_c, $M = N_o g|\mathbf{S}|$.

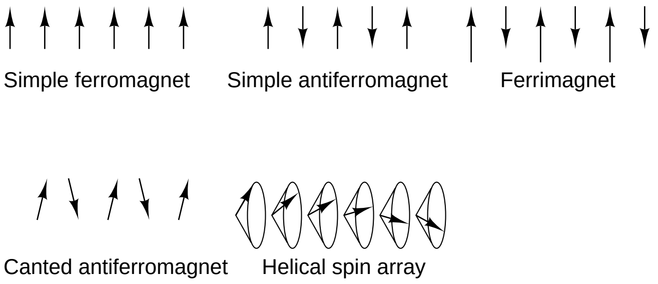

Figure 1 Schematic diagrams representative of various types of magnetic LRO

2.1.4 *Antiferromagnetism*

As seen from Figure 1, in this case the spins are coupled antiparallel, corresponding to the case of $J < 0$ in equation (3). Real antiferromagnetic materials are of course three dimensional and more complex than the one-dimensional situation presented in the figure. In three dimensions, it is convenient to subdivide the magnetic sublattice. The minimum number of sublattices is two, say A and B, with equal numbers of spins on each and with equal spin magnitudes, $|\mathbf{S}_A| = |\mathbf{S}_B|$.

As the spins on A are antiparallel to those on B, the ground state of the entire ensemble is a singlet with $\Sigma_I \mathbf{S}_I = 0$, where I represents the sublattice index. For any given magnetic sublattice symmetry, there are clearly several ways to achieve this condition. Take the simplest case of a primitive sublattice, Figure 2, where three distinct antiferromagnetic spin configurations are shown, the open and closed circles representing antiparallel spins. The nomenclature, A, C, and G, has historical roots as will be described in a later section on perovskite manganates. Note that in each case the periodicity of the 'magnetic' unit cell is greater than the

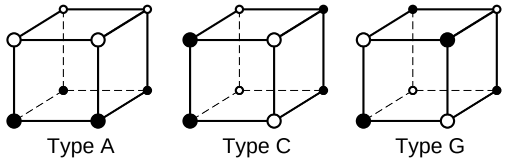

Figure 2 Two possible spin configurations for a collinear anti-ferromagnet on a primitive lattice. The open and closed circles represent spins of antiparallel alignment[5]

primitive, 'chemical' cell. For type G, the magnetic cell is doubled in all three directions: $\mathbf{a}_{mag} = 2\mathbf{a}_{chem}$, $\mathbf{b}_{mag} = 2\mathbf{b}_{chem}$, and $\mathbf{c}_{mag} = 2\mathbf{c}_{chem}$. Type A requires doubling of **c** only and type C, doubling of both **a** and **b**. As will be described later, neutron diffraction can be used to distinguish among the possibilities. Also, for historical reasons, the critical temperature for and antiferromagnet is often denoted the Néel temperature, T_N, after Louis Néel, who first postulated the existence of antiferromagnetism.

2.1.5 Ferrimagnetism

This type of magnetic LRO arises also when there exist at least two magnetic sublattices but for which the magnetizations are unequal. Defining the sublattice magnetization as $M_l = N_l g_l |\mathbf{S}_l|$ where N is the population of spins of magnitude $|\mathbf{S}|$ on sublattice I, ferrimagnetism can arise for the two sublattice case, for example, when $N_A \neq N_B$ or $|\mathbf{S}_A| \neq |\mathbf{S}_B|$ or both. Normally, the spin correlations are such that the inter sublattice coupling is antiparallel, so a net magnetization arises, $M_{net} = |\mathbf{M}_A - \mathbf{M}_B|$. As one might imagine, there exist a large variety of ways to achieve ferrimagnetism by manipulating the crystal chemistry and composition of magnetic oxides.

2.1.6 Canted Antiferromagnetism, Helimagnetism, and Other Noncollinear Orderings

Only LRO schemes that involve collinear spin arrangements have been considered so far. Figure 1 also shows two examples of noncollinear spin orderings, the canted antiferromagnet and the helimagnet.[4] The simpler case is the canted antiferromagnet, where $|\mathbf{M}_A| = |\mathbf{M}_B|$ but for which the angle between the sublattice moments is not precisely 180° but deviates by a small 'canting' angle, usually no more than 1° or 2°, and thus the sublattice magnetizations do not exactly cancel. This gives rise to a small, net magnetization of order $\sim 10^{-2}\,\mu_B$ or so, hence the alternative nomenclature of 'weak ferromagnetism' for this phenomenon. The physical origin of the spin-canting is the anisotropic exchange interaction or D-M interaction (Dzialoshansky-Moriya), which involves the expression $\mathbf{D} \cdot \mathbf{S}_A \times \mathbf{S}_B$, where **D** is a vector (rather than the scalar J in equation 3) and the vector product is taken rather than the scalar.[6] The D-M interaction is allowed only when there does not exist a center of inversion symmetry at the midpoint of a vector connecting $\mathbf{S}_A$ and $\mathbf{S}_B$, so canted antiferromagnetism is fairly common in low symmetry materials.

In other more complex cases, the spins can take on a configuration that is not well approximated as a perturbed collinear configuration and such is the case for the spiral or helimagnetic ordering depicted in Figure 1. Noncollinear configurations are also observed in the family of so-called geometrically frustrated materials to be discussed later.

2.1.7 Short Range Order (SRO) and Low-dimensional Magnetic Correlations

Normally, the conditions of a high concentration of magnetic centers and strong exchange coupling between them is sufficient to guarantee the occurrence of magnetic LRO at finite temperatures. This is generally true only when the magnetic sublattice is clearly three dimensional, that is, when the anisotropy of the exchange interactions is small.

For cases in which the magnetic lattice dimensionality is one (chains) or two (planes), magnetic *Short Range Order* (SRO) can develop and persist over a wide temperature range, often many tens of kelvins. Effectively, this is an expansion of the critical regime discussed above, which is normally only a few degrees at best for three-dimensional systems. As well as lattice dimensionality, the spin dimensionality must be considered to provide a complete picture. Spin dimensionality is a somewhat more subtle concept that can be best introduced by considering an expansion of the HDVV Hamiltonian into its components as in equation (4)

$$\mathbf{H}_{ex} = -2[J_{xx} S_{xA} S_{xB} + J_{yy} S_{yA} S_{yB} + J_{zz} S_{zA} S_{zB}] \quad (4)$$

Three cases are identified, (1) $J_{xx} \sim J_{yy} \sim J_{zz}$, with spin dimensionality three, called the Heisenberg model, (2) $J_{zz} \gg J_{xx} \sim J_{yy}$, with spin dimensionality one, called the Ising model and (3) $J_{zz} \ll J_{xx} \sim J_{yy}$, with spin dimensionality of two, the XY model. There are thus nine possible space/spin dimensionality categories and in Table 1 are shown the correlations with LRO and SRO. Thus, only four combinations permit LRO and three spatial dimensions are normally required, the one exception being the two dimensional Ising case.[7]

There exist many examples, some of which will be discussed in later sections, of metal oxides with crystal structures that enable low-dimensional magnetic correlations and whose magnetic properties are thus dominated by SRO. One canonical structure is the so-called K_2NiF_4 type, adopted by many magnetic oxides, shown in Figure 3. Here layers of corner-sharing NiF_6 are separated by KF layers resulting in a considerably more facile intraplanar exchange pathway than between planes. Note that the magnetic sublattice has body-centered tetragonal symmetry, which also contributes to the magnetic two dimensionality. If the Ni^{2+} spins within a layer are coupled antiferromagnetically, the spins in the next

Table 1 Space and spin dimensionalities and consequences for magnetic LRO

	Spatial dimension		
Spin dimension	1	2	3
1	SRO	LRO	LRO
2	SRO	SRO	LRO
3	SRO	SRO	LRO

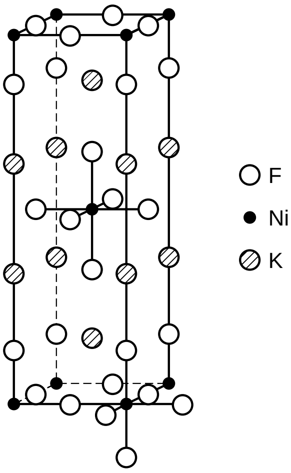

Figure 3 The chemical unit cell of the K_2NiF_4 structure

layer will see four ↑ and four ↓ moments and the interplanar coupling will be 'cancelled' by symmetry. The result of both the distance and symmetry effects can result in ratios $J_{\text{intra}}/J_{\text{inter}} \sim 10^3-10^4$, which ensures the observation of SRO over a wide thermal range.

As all crystalline materials are three dimensional, ultimately one expects to see a 'cross-over' to LRO at some temperature for all nominally low-dimensional magnetic materials. This will occur even if the exchange that couples the chains or planes is very weak. For example, for a planar magnetic material, the critical temperature for the cross-over depends most strongly on the length scale of the correlated region (called, not surprisingly, the 'correlation length') in the planes and is estimated as $T_c \sim \zeta^2_{\text{intra}} J_{\text{inter}} S^2/k_B$, where ζ is the correlation length and J_{inter} is the interplanar exchange constant.[8]

While the spatial dimensionality is generally obvious from the crystal structure (although interesting exceptions exist), engineering various spin dimensionalities can be more subtle. This is normally done by taking advantage of the presence or lack of anisotropy in the g-tensor of magnetic ions. For example, the second two terms in equation (4) will nearly vanish with respect to the first, if $g_z \gg g_x$, g_y, thus giving an Ising model, and the opposite situation provides XY like behavior. When the three components are comparable, the Heisenberg model emerges. Good Heisenberg candidates are ions with orbital singlet ground states, such as half-filled shell d^5 or f^7 ions, examples being Mn^{2+}, Fe^{3+}, Gd^{3+}, or Eu^{2+} and half-filled crystal field states, t^3_{2g} (Cr^{3+}, Mn^{4+}) or $t^6_{2g}e^2_g$ (Ni^{2+}) or even $t^6_{2g}e^3_g$ (Cu^{2+}). Anisotropic spin dimensionalities come from ions with unquenched orbital angular momentum such as high-spin Co^{2+} ($t^5_{2g}e^2_g$) or Fe^{2+} ($t^4_{2g}e^2_g$) for d-group ions or Dy^{3+}, Ho^{3+}, and others in the f-group series. Depending on the details of the crystal field interaction, these ions can be either Ising or XY.

3 THE ORIGIN OF SPIN–SPIN COUPLING IN OXIDES – SUPEREXCHANGE AND DOUBLE EXCHANGE

As most magnetic oxides are electrical insulators, the dominant exchange mechanism is superexchange. The basis of this interaction was described more than 50 years ago by Anderson.[9] Several versions of the theory accessible to inorganic chemists or solid-state chemists exist.[5] Qualitatively, the fundamental idea is illustrated with the aid of Figure 4. Consider a linear array M_A–O–M_B with half-filled d_z^2 orbitals on the M's overlapping a p_z orbital on the oxide ion. The ground-state spin–spin correlations can be predicted by recourse to the Pauli principle. If the d_z^2 orbital on M_A mixes with the left hand lobe of the p_z orbital and electron transfer p_z to d_z^2 occurs, then the antiparallel spin–spin correlations are dictated by the Pauli principle. The same applies to the interaction of M_B with the right hand lobe of p_z and the overall spin-spin correlation between M_A and M_B is antiferromagnetic. Anderson has shown using a perturbation theory treatment that the exchange constant J (equation 3) for the above example is given by

$$J = \frac{-2b^2_{AB}}{U} \tag{5}$$

where b_{AB} is the electron transfer integral ($p_z \rightarrow d_z^2$) that is proportional to the overlap between the two orbitals and U is the correlation energy, that is, the additional electron–electron repulsion due to having two electrons in the same orbital (after the transfer). This interaction involving two half-filled orbitals is always antiferromagnetic.

Consider another case in which the d_z^2 orbital on M_A is still half-filled but that on M_B is empty. Assume also that unpaired electrons reside on M_B but in an orbital that is orthogonal to d_z^2, say d_{xz}. The electron transfer from $p_z \rightarrow d_z^2$ (M_B) now must be such that the spin is parallel to the spin in the d_{xz} orbital and the overall spin–spin correlation between M_A and M_B is now ferromagnetic. An attempt to illustrate this situation is shown below:

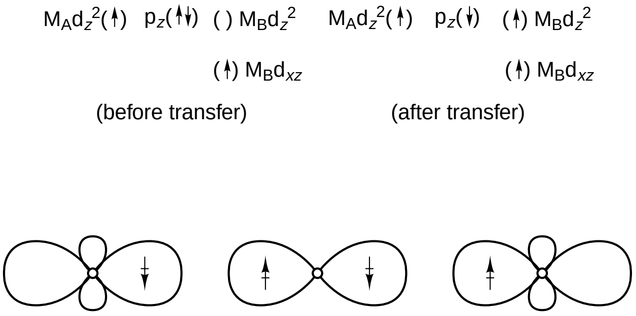

Figure 4 Orbital overlaps and spin correlations in a linear M_A–O–M_B array involving d_z^2–p_z–d_z^2 orbitals

Table 2 Net sign and relative magnitude for selected M_A–O–M_B superexchange interactions[5,10]

Interaction	180°	90°
d^3/d^3 (t_{2g}^3/t_{2g}^3) [Cr^{3+}, V^{2+}, Mn^{4+}]	AF (weak)	AF or F (weak)
d^5/d^5 ($t_{2g}^3e_g^2/t_{2g}^3e_g^2$) [$Mn^{2+}$, Fe^{3+} high spin]	AF (strong)	AF (weak)
d^3/d^5 ($t_{2g}^3/t_{2g}^3e_g^2$) [Cr^{3+} /Fe^{3+}]	F(weak)	AF(weak)
d^3/d^8 ($t_{2g}^3/t_{2g}^6e_g^2$) [Cr^{3+} /Ni^{2+}]	F(moderate)	?
d^8/d^8 ($t_{2g}^6e_g^2/t_{2g}^6e_g^2$) [$Ni^{2+}$ /Ni^{2+}]	F(strong)	AF or F(weak)

The value of J is now

$$J = \frac{2b_{AB}^2}{U \times J_{intra}/U} \tag{6}$$

where J_{intra} is the Hund's rule intra-atomic exchange constant. In general, for this case the overall interaction will be smaller in magnitude than that in (5) by the factor J_{intra}/U, which means a factor of 10 or so.

From the brief account above, it is clear that both the sign and magnitude of J depend strongly on orbital overlaps, orbital symmetry, and orbital filling. Goodenough and Kanamori have developed a well-known set of rules for qualitative prediction of the sign of J and its relative magnitude for two limiting M_A–O–M_B geometries, 180° and 90°.[5,10] Selected examples are shown in Table 2.

These rules should be treated as a rough guide and it should be borne in mind that in real oxides, the M_A–O–M_B angle is rarely exactly 180° or 90°. Also, the net exchange coupling for any real case is an algebraic sum of J for each of many pathways of varying sign and magnitude. As a result of the fact that most superexchange pathways tend to favor antiferromagnetic spin configurations, in the vast majority of magnetic oxides, antiferromagnetic correlations predominate. There are still not more than a handful of insulating oxides that are ferromagnetic.

The problem of calculating superexchange J's from first principles is still formidable and while progress has been made, especially with the development of modern computer codes, a discussion of this topic lies outside of the scope of this chapter.

A second exchange mechanism is found in some oxides, especially the manganates to be described later, called double exchange. Double exchange was first proposed by Zener, again some 50 years ago.[11,12] This mechanism assumes that a subset of the d electrons is highly mobile, hopping rapidly between two ions of the same element and coupling more localized spins in a ferromagnetic manner. The best examples are the mixed valence manganate perovskites containing Mn^{3+} ($t_{2g}^3e_g^1$) and Mn^{4+} (t_{2g}^3), formally. Here the localized electrons are in the t_{2g}^3 sublevels and the itinerant electron occupies the e_g^* levels, which are broadened into bands in the solid. Since the hopping of the electron from site to site occurs without change of spin, Hund's rule again requires that the local moments in the t_{2g}^3 levels be parallel, that is, ferromagnetically coupled.

4 KEY EXPERIMENTAL PROBES OF MAGNETIC OXIDES

4.1 Magnetic Susceptibility and Magnetization

The most important and basic technique is the measurement of the dc magnetic susceptibility or magnetization. The widespread availability of modern magnetometers based on Superconducting Quantum Interference Device (SQUID) sensors has rendered such measurements more or less routine in a large region of H−T space from 2 K to 700 K and applied fields from 0 to >6T. The quantity actually measured is the magnetic moment or magnetization, M, which is converted to susceptibility by dividing by the applied field, $\chi = M/H$. For the oxides of interest here, one expects strong spin−spin correlations that will be manifested as deviations from the Curie law, equation (2). These deviations can usually be accommodated by the Curie-Weiss law,

$$\chi = \frac{C}{T - \theta} \tag{7}$$

where θ is known as the Weiss constant which has the dimensions of temperature and therefore, of energy as $k_B\theta$.

The significance of θ is most easily demonstrated by application of the mean or molecular field theory (MFT).[2,13] The central idea here is that magnetic moments on neighboring atoms give rise to an internal or exchange or 'molecular' field, H_i, in addition to any applied field as in (8)

$$H_i = H_{appl} + \sum_{j=1}^{n} \gamma_{ij} M_j \tag{8}$$

where H_i is the molecular field at atom i from n sets of equivalent neighboring atoms, j, and γ_{ij} is the coupling constant, which can be expressed as $\gamma_{ij} = n(2Z_{ij}J_{ij})/N_o g^2\mu_B^2$.

Z_{ij} is the number of neighbors on a given sublattice and n is the number of sublattices needed to describe the magnetic lattice. It is clear that γ_{ij} depends directly on J_{ij}, the HDVV exchange constant. Returning to the definition of the susceptibility and substituting H_i for H we get $M_i = C/nT \times H_i$ and substituting equation (8) for H_i a set of linear equation results, which can be manipulated to give

$$M = \frac{CH_{appl}}{T\left(1 - \dfrac{C}{nT}\displaystyle\sum_{j=1}^{n}\gamma_{ij}\right)} \text{ or } \chi = \frac{C}{T - \dfrac{C}{n}\displaystyle\sum_{j=1}^{n}\gamma_{ij}} \tag{9}$$

which has the form of the Curie-Weiss law, where

$$\theta = \frac{C}{n}\sum_{j=1}^{n}\gamma_{ij} = \frac{2S(S+1)}{3k_B}\sum_{j=1}^{n} Z_{ij}J_{ij} \tag{10}$$

Thus, θ is equal to the algebraic sum of all of the exchange interactions acting on a given atom. It follows that the sign of θ is diagnostic of the net exchange, and $\theta > 0$ for net ferromagnetic exchange and $\theta < 0$ for net antiferromagnetic exchange. As well, $k_B\theta$ sets the energy scale for the magnetic exchange and one expects to see deviations from the simple Curie law at temperatures near θ.

Two caveats should be raised here. First, the identification of the sign and magnitude of θ with exchange forces must be treated with caution. Single ion effects can also result in a Curie-Weiss susceptibility showing fairly large, negative θ values. Famous cases are Ti^{3+} in a cubic crystal field and many 4f group ions.[14] Secondly, the MFT is too simple a model to describe magnetic systems in detail, especially near T_c and at low temperatures. The theory is the exact analog of the van der Waals model for the imperfect gas and (while not obvious from the above) assumes an interaction of infinite range. As the superexchange interaction is very short range, depending on orbital overlaps, corrections are needed but a discussion of these lies outside the scope of this chapter.

4.1.1 Susceptibility and Magnetization of Ferromagnets and Antiferromagnets

The magnetic susceptibility of a paramagnet, a ferromagnet, and an antiferromagnet are contrasted in Figure 5 in terms of the Curie-Weiss law, plotted in the usual linearized form, χ^{-1} versus T. Note that the temperature intercept at $\chi^{-1} = 0$, which is θ, is zero for the paramagnet, >0 for the ferromagnet and <0 for the antiferromagnet. In performing such an analysis it is important to use data at 'high' temperatures, relative to any critical temperature, T_c, which might be present. In general, the minimum temperature to begin fitting should be at least $2T_c$. A useful check of whether the Curie-Weiss paramagnetic regime has been reached is to compare the derived Curie constant with the expected value. Good agreement is usually a sign that the data are well into the paramagnetic regime for systems which show LRO.

The susceptibility for both ferromagnets and antiferromagnets show strong deviations from the C-W law near and below T_c. For a ferromagnet, χ diverges to very large values, reflecting the onset of parallel spin correlations and becomes strongly dependent on the magnitude of the applied field, owing to the presence of microscopic 'domains'. It is thus better to talk about the magnetization. The MFT can be used again to give a prediction for the expected behavior by substituting Hi (equation 8) into the Brillouin function (equation 1) and plotting in reduced units, $\sigma = M(T)/M(0)$ versus $\tau = T/T_c$, which gives the results of Figure 6. So, one expects a sharp rise just below T_c and an approach to saturation, $\sigma \to 1$ as $\tau \to 0$. At saturation, $M_s = M(0) = g\mu_B SN_o$. The problem of determining T_c experimentally for a ferromagnet from magnetization data is nontrivial owing to the aforementioned critical regime. The most reliable methods are to use either heat capacity data (later section) or to measure the magnetization in zero applied field (to eliminate domain effects). The latter is best done using neutron scattering (later section).

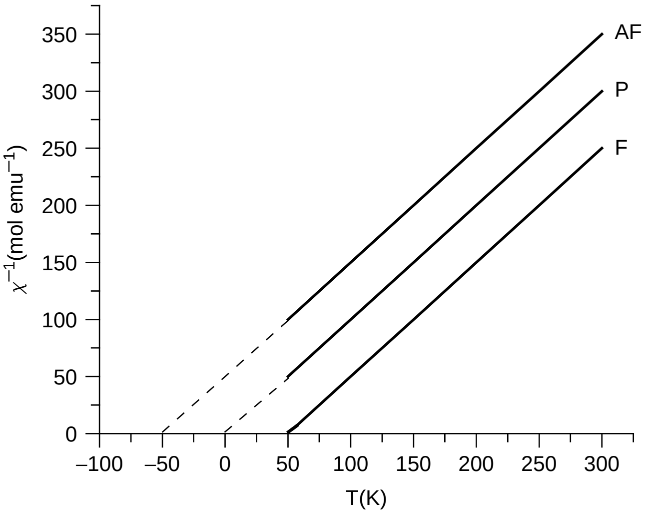

Figure 5 Idealized Curie-Weiss law behavior for a paramagnet, P, an antiferromagnet, AF, and a ferromagnet, F. The simulation has been done assuming C = 1.0 and $|\theta| = 50$ K

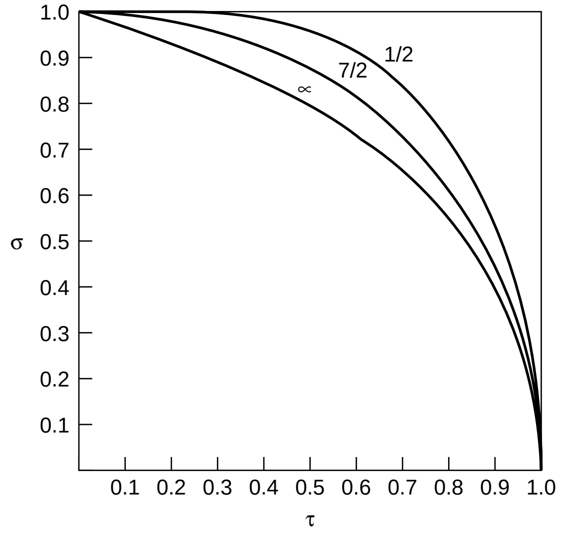

Figure 6 Brillouin functions describing the behavior of the magnetization of a ferromagnet or a single sublattice of an antiferromagnet in the range $T < T_c$. $\sigma = M(T)/M(0)$ and $\tau = T/Tc$. The curves are labeled for different S. (Reprinted from Ref. 13, © 1966, with permission from Elsevier)

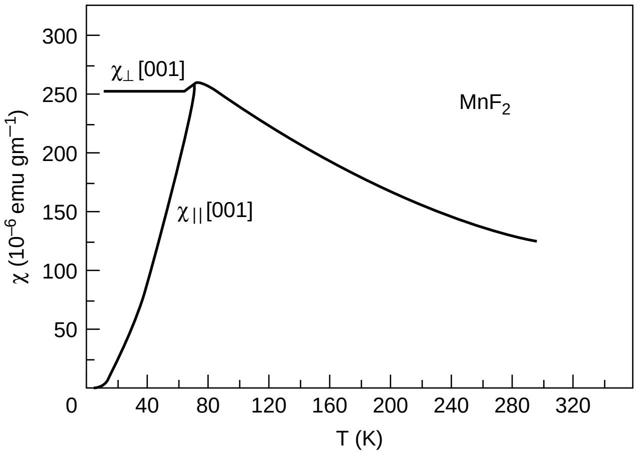

Figure 7 Magnetic susceptibility for a single crystal of MnF_2. The preferred direction is [001][5]

For an antiferromagnet there is a sharp cusp in χ near T_c (T_N) as illustrated by data for MnF_2 Figure 7, below which the susceptibility decreases owing to the build up of antiparallel spin correlations. An initially surprising fact about antiferromagnets is that the total susceptibility does not fall to 0 as $T \rightarrow 0$ as illustrated in Figure 7. This is due to magnetocrystalline anisotropy, that is the spins will always find a preferred direction in the crystal. Data taken with the applied field normal to the preferred direction will show temperature independence. This arises because the field induces a small net misalignment of the nominally antiparallel spins (Figure 8). In a polycrystalline sample, one measures the random, powder average $\langle\chi\rangle = 1/3\chi_{\parallel} + 2/3\chi_{\perp}$ which decreases only to a value of $\sim 2/3\chi_{max}$ at $T = 0$.

The canted antiferromagnet shows ferromagnetic like behavior for the susceptibility and magnetization but can

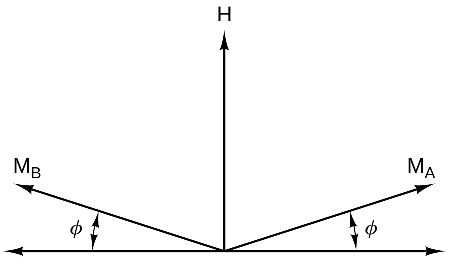

Figure 8 The result of applying a magnetic field normal to the preferred spin direction for an antiferromagnet. The spins are misaligned by a small angle ϕ, giving rise to a small, net moment

be distinguished from a true ferromagnet by the observation of $\theta < 0$ and a $M_s \sim 10^{-2}$ or $10^{-3}\,\mu_B$.

The ferrimagnet shows very complex susceptibility and magnetization behavior, which have been described in texts.[5] The ferrimagnet can be distinguished from a true ferromagnet again by the observation of $\theta < 0$ and that $M_s = |MA - MB|$.

4.1.2 Susceptibility and Magnetization for Materials Exhibiting SRO

The most common case is for antiferromagnetic SRO correlations. SRO usually results from the nature of the spatial dimensionality, which limits the spin–spin interactions to dimensions of 0 (isolated oligomers, dimers, trimers, etc.), 1 (chains), or 2 (planes). The common feature of the susceptibility of such systems is (usually) the presence of a very broad maximum, quite distinct from the rather sharp feature seen near T_c for an LRO antiferromagnet. The finite-sized oligomers can usually be solved exactly and analytic solutions are available.[2,14,15] SRO in extended systems, spatial dimensionality 1 or 2, have also been

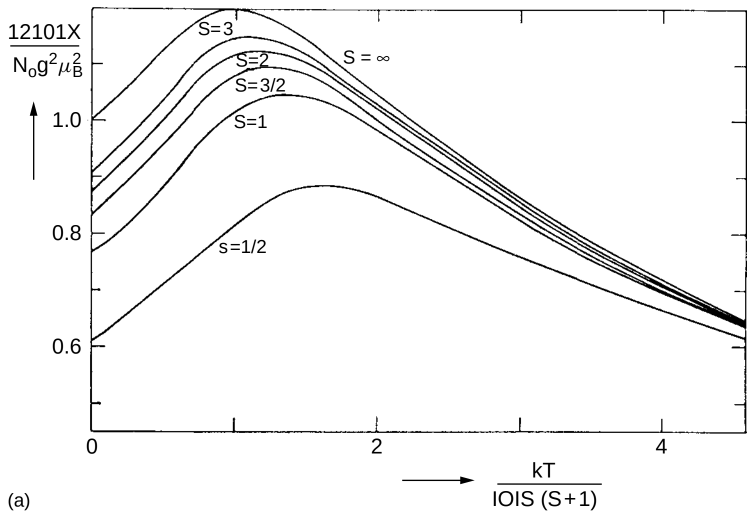

Figure 9 Calculated reduced susceptibility curves for the one-dimensional Heisenberg model for various S. (Reprinted from Ref. 2 with permission from Springer Verlag)

studied intensively. In general, only numerical solutions exist but these are considered to be of an accuracy sufficient for comparison with experiment.[2,8] Typical calculations are shown in Figure 9, where reduced χ is plotted versus reduced T for one-dimensional Heisenberg systems of various spins. The precise details of the curves depend on S and the space and spin dimensionalities. Fitting the data to the models allows extraction of J values.

For systems exhibiting ferromagnetic SRO, no maximum occurs in χ versus T. The best way to detect ferromagnetic SRO is to plot χT versus T. As χT is proportional to $[\mu_{\mathrm{eff}}]^{1/2}$ or C, such a curve will deviate from the horizontal in a positive sense as T is decreased. An example is shown for $PbMnBO_4$, which is a good approximation to a ferromagnetic chain (it also shows ferromagnetic LRO below 31 K) (Figure 10).[17] The data can be compared to a model due to Fisher and J_{chain} can be estimated.[18]

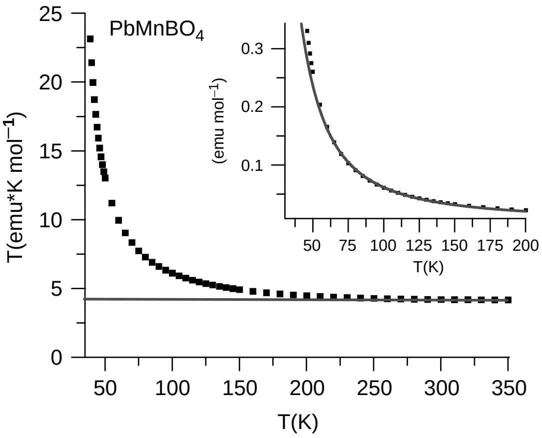

Figure 10 Evidence for one-dimensional ferromagnetic correlations in $PbMnBO_4$. Note the positive deviation from the horizontal $\chi T = C$ line with decreasing temperature. The inset shows a fit to Fisher's model for a linear ferromagnet with $S = 2\,J/k_B = +11$ K is found for the intrachain coupling constant. (Reprinted with permission from Ref. 17, © 2003 American Chemical Society)

It is important to reiterate that there is no true phase transition involved in SRO (refer to Table 1). As already mentioned, for most materials showing SRO there will be a cross-over to LRO at some temperature. A clear example is the oxide $La_3O_sO_7$, which is quasi-one dimensional and from the data (Figure 11), the broad maximum at ~125 K, the SRO signature, is easily distinguished from the sharp maximum, the LRO signature, at ~50 K.[19] It is not uncommon to find, even today, authors claiming the presence of an 'antiferromagnetic' transition from observation of a broad susceptibility maximum.

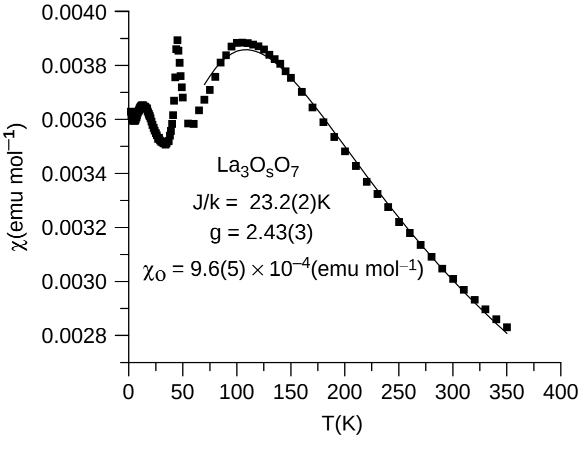

Figure 11 The temperature dependence of the susceptibility for $La_3O_sO_7$, a quasi-linear antiferromagnet showing both SRO (broad maximum near ~125 K) and the cross-over to LRO (sharp peak at ~50 K). (Reprinted from Ref. 19, © 2002, with permission from Elsevier)

4.2 Heat Capacity

Heat capacity measurements give information complementary to magnetic susceptibility and magnetization. This complementarity arises naturally from thermodynamics.[2] This technique has also become much more available as instrumentation based on the relaxation method has been marketed widely in the past few years. The heat capacity diverges at T_c and thus provides a very precise measure of T_c, as seen in Figure 12. The shape of the anomaly resembles the Greek

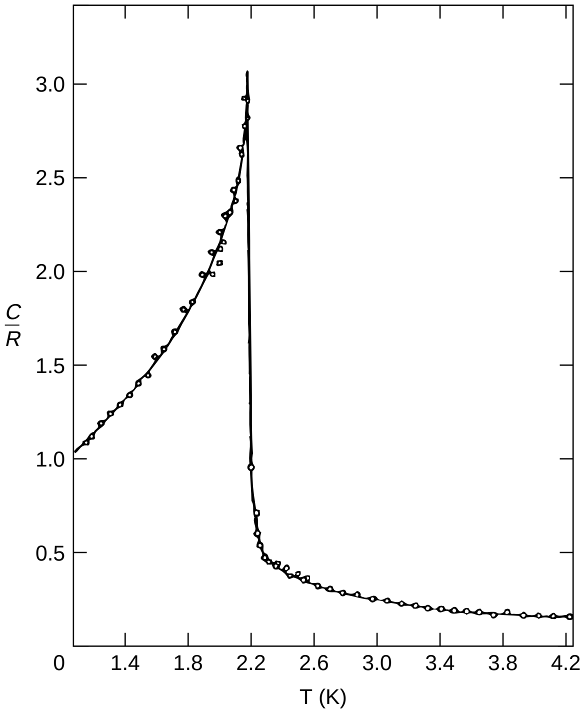

Figure 12 Divergence of the heat capacity at T_c for ferromagnetic $GdCl_3$. (Reprinted from Ref. 13, © 1966, with permission from Elsevier)

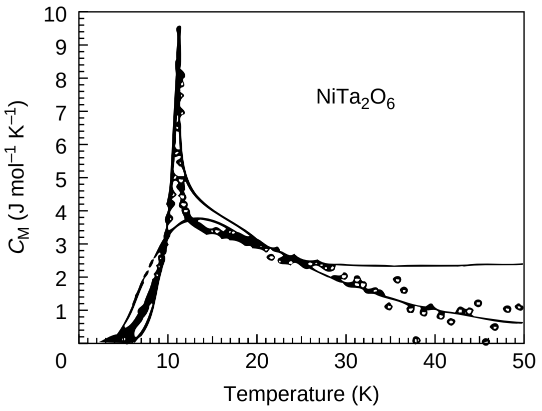

Figure 13 Heat capacity for the tri-rutile oxide $NiTa_2O_5$ showing features due to SRO (broad maximum near 20 K) and LRO (sharp λ – peak near 10 K). (Ref. 20. Reproduced by permission from EDP Sciences)

letter lambda and it is often known as the λ–anomaly. As with the susceptibility, heat capacity data are also sensitive to SRO, giving broad maxima instead of the sharp λ-like feature. This is illustrated in Figure 13 for $NiTa_2O_6$, which shows both broad SRO and sharp LRO features. Finally, a quantity known as the magnetic entropy can usually be isolated, although this requires a means of estimating and subtracting the heat capacity of the lattice. From the standard relationship between entropy, S, and the heat capacity, C,

$$\Delta S_{mag} = \int \frac{C_{mag}}{T} \quad (11)$$

it is possible to measure the magnetic contribution to the entropy and compare with the theoretical prediction that $\Delta S_{mag} = R\ln(2S + 1)$.

4.3 Neutron Scattering

Neutron scattering remains the single most useful technique to probe the magnetic properties of matter. Through the de Broglie relationship, neutrons with a velocity appropriate to a kinetic energy equivalent to k_BT where $T \sim 300$ K have a distribution of wavelengths with a maximum slightly greater than 1 Å, comparable to wavelengths used in X-ray diffraction. Such ‘thermal’ neutrons are the principal product of fission reactors and are also produced by particle accelerators at facilities called spallation sources.

Neutron diffraction is complementary to X-ray diffraction and is used widely as a tool for structure refinement in oxide chemistry. For example, the expressions for the structure factor F_{hkl} are compared for both radiation types below:

$$F_{hkl} = \Sigma f_i \exp 2\pi i(hx_i + ky_i + lz_i) \quad (X - rays)$$
$$F_{hkl} = \Sigma b_i \exp 2\pi i(hx_i + ky_i + lz_i) \quad (Neutrons) \quad (12)$$

where the atomic scattering factor for x-rays, f_i, is replaced by the scattering length for neutrons, b_i. As well, the neutron, by virtue of its spin, has a magnetic moment and thus will be sensitive to magnetic fields owing to unpaired electron density. One can define a magnetic scattering length, p, given by:

$$p = \frac{e^2\gamma}{2mc^2} gSf \quad \text{(for d electrons)} \quad (13)$$

where e and m are the electronic charge and mass, c is the velocity of light, γ the nuclear magneton, and f is a ‘form factor’, which is a strong function of scattering angle. As it turns out, p is of the same order of magnitude as b for most elements and therefore the magnetic scattering will be of the same order of magnitude as the ‘chemical’ scattering and contributions from the two sources will be superimposed in the same experiment and can be scaled conveniently. One can define a magnetic structure factor in an analogous manner

$$F_{hkl}(mag) = \Sigma p_i \exp 2\pi i(hx_i + ky_i + lz_i) \quad (14)$$

It can be shown that what is actually measured in a neutron diffraction experiment is the component of S (or J), which is normal to the scattering vector (which is in turn normal to the scattering plane, hkl), and the total diffracted intensity is then proportional to

$$F^2_{hkl}(total) = F^2_{hkl}(chem.) + q^2F^2_{hkl}(mag) \quad (15)$$

where $q^2 = \sin^2 \alpha$ and α is the angle between the scattering and magnetic moment vectors. Thus, from a neutron diffraction experiment one can, in principle, determine the dimensions and symmetry of the magnetic sublattice and the magnitude and spatial orientation of the magnetic moments, that is, the magnetic structure. An example is shown in Figure 14 for $CoSb_2O_6$, a tri-rutile structure oxide with $T_c = 12.6$ K. Data sets at 298 K and 7.5 K are compared and the latter shows many more reflections, which can be ascribed to LRO. Two possible magnetic structures are shown.

It should be noted that magnetic scattering can also be observed in X-ray diffraction but the intensities of the magnetic reflections are only 10^{-4} at best relative to the normal scattering and these experiments are usually done at synchrotron sources. There is no method of determining a magnetic moment from X-ray scattering. There does exist a technique called resonant magnetic X-ray scattering in which the magnetic intensities can be enhanced by factors of $\sim 10^4$ but this works for only a few elements and there is no detailed theory for scaling the magnetic intensity to extract magnetic moments.

Neutron diffraction/scattering can also probe SRO and low-lying excited states called spin waves, but this discussion lies again outside the scope of this article.

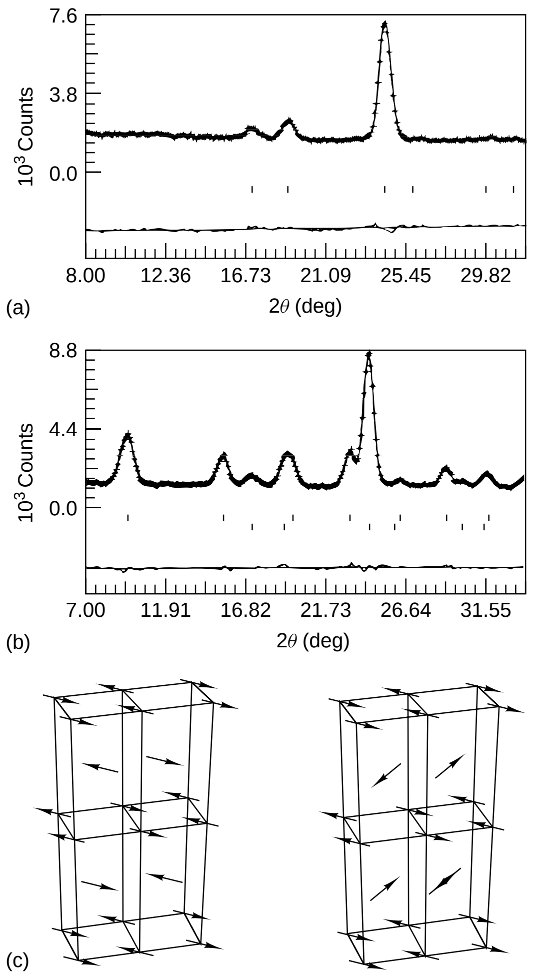

Figure 14 Neutron diffraction data for $CoSb_2O_5$, an antiferromagnet with $T_c = 12.6$ K. (a) Data at 298 K. (b) Data at 7 K, showing the presence of many new reflections due to the AF LRO. 5 SURVEY OF SELECTED RECENT RESULTS FOR MAGNETIC OXIDES

5.1 Perovskites and Ruddlesden–Popper Phases

It is not surprising that perovskite oxides continue to attract unusual levels of attention. In this category, we include the Ruddlesden–Popper phases of compositions $(AO)(ATO_3)_n$ where A is a large cation, either a divalent alkaline earth or a trivalent lanthanide, and T is a transition element. The index, n, enumerates the number of perovskite ATO_3 units intergrown with rock salt AO layers.

Idealizations of the crystal structures of both the Ruddlesden–Popper phases from $n = 1$, 2, 3, and ∞ (the parent perovskite) are shown in Figure 15.

We begin with the first-row transition elements.

5.1.1 ATO_3, T = Ti

The rare earth titanates crystallize in an orthorhombically distorted form of the perovskite structure, commonly known as the $GdFeO_3$ type, found widely for other $LnTO_3$ materials and described in Pnma (Pbnm in earlier literature) (Figure 16). As the Ln^{3+} ions are too small for 12-fold coordination, the TO_6 octahedral tilt to accommodate a lower coordination number, which is near 9-fold.

As a result the T–O–T angles are significantly less than the ideal 180° in cubic perovskite and vary directly with the radius of the Ln^{3+}, which permits the angles to be tuned by changing the Ln^{3+} radius. The rare earth titanates are unique among $LnTO_3$ materials in that the sign of the Ti–Ti coupling changes from antiferromagnetic for Ln = La, Ce, Pr, Nd, and Sm to ferromagnetic for Gd to Lu.[22] $NdTiO_3$ and $SmTiO_3$ have been reinvestigated. Earlier reports had suggested that $NdTiO_3$ failed to show long-range magnetic order, in spite of the fact that order is observed in all other $LnTiO_3$ perovskites. More recent data indicated an antiferromagnetic transition near 100 K.[23] This was finally confirmed by a neutron diffraction study in which a G-type(G_zF_x) magnetic structure was found on the Ti sublattice, $T_N = 100$ K, while the Nd sublattice was polarized in a F_xC_y structure. Ti(3+) and Nd(3+) ordered moments were 0.99(5) and 1.11(5) μ_B, respectively.[24] The various types of magnetic structure exhibited by perovskites G,A,C, and CE are depicted in Figure 17. $SmTiO_3$ with $T_N = 52$ K had not been investigated in much detail owing in part to the obstacle of an extremely high absorption for thermal neutrons by Sm. This problem was solved using short wavelength neutrons from a 'hot' source and a single-crystal sample. The use of a single crystal allowed the unambiguous determination of the magnetic structure as G_{xy} on Ti^{3+} ($0.72\mu_B$) and C_z ($0.43\mu_B$) on Sm^{3+}.[25] Much attention has also been paid to unraveling the origin of the unprecedented change in the sign of the Ti^{3+}–Ti^{3+} exchange coupling from antiferromagnetic to ferromagnetic as the radius of the Ln^{3+} ion is decreased by sweeping through the lanthanide series.

To this end, much attention has been directed to detailed experimental and theoretical studies of antiferromagnetic $LaTiO_3$ and ferromagnetic $YTiO_3$. While there may not yet be a consensus, a very interesting explanation has been offered by Mochizuki and Imada.[16] Here the key is the orbital ordering of the t_{2g} electrons due to crystal field splitting. The term 'orbital ordering' will also arise in the discussions of many other magnetic oxides, especially T = Mn, but the origin in that case has more to do with Jahn–Teller ordering. There is some confusion in the literature regarding which case is anomalous but it is now generally thought that it is the G-type AF order on $LaTiO_3$. Mochizuki pointed out that the often ignored crystal field of nearly D_{3d} symmetry due to the Ln^{3+} sublattice

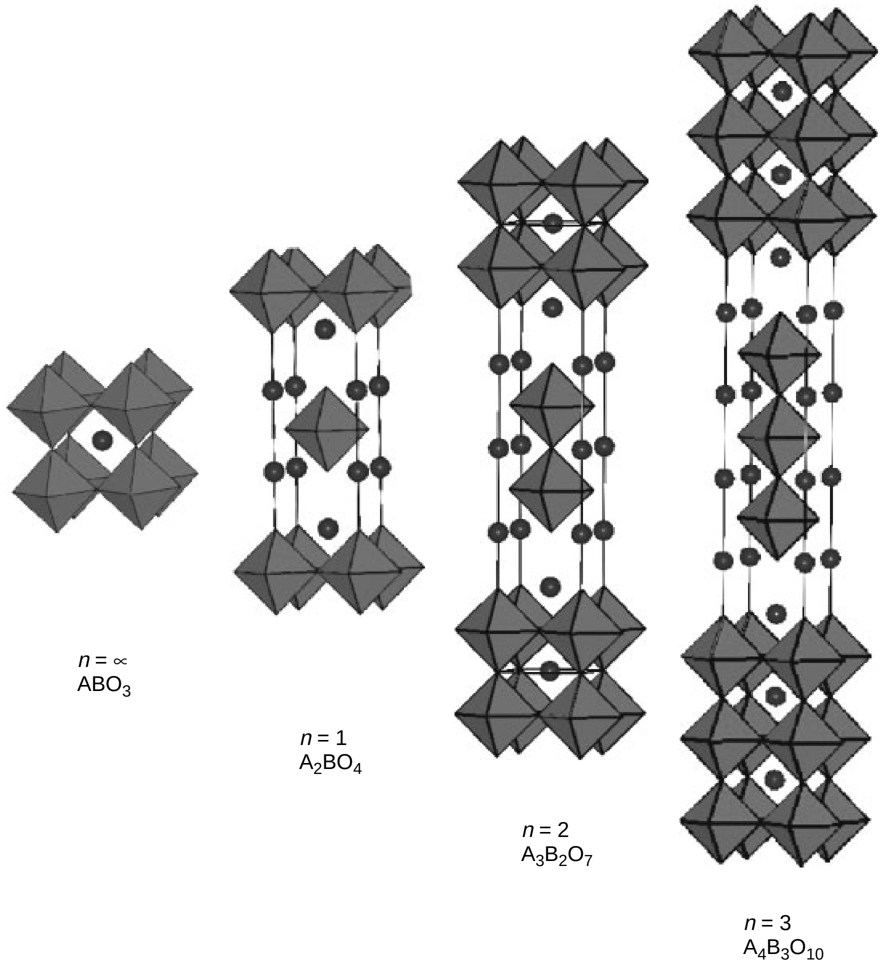

Figure 15 Idealized crystal structures of the Ruddlesden–Popper phases, $(AO)(ABO_3)_n$, $n = \infty$, ABO_3; $n = 1$, A_2BO_4; $n = 2$, $A_3B_2O_7$; $n = 3$, $A_4B_3O_{10}$. The corner-sharing BO_3 octahedrals are shown in polyhedral representation while the A atoms are shown as spheres

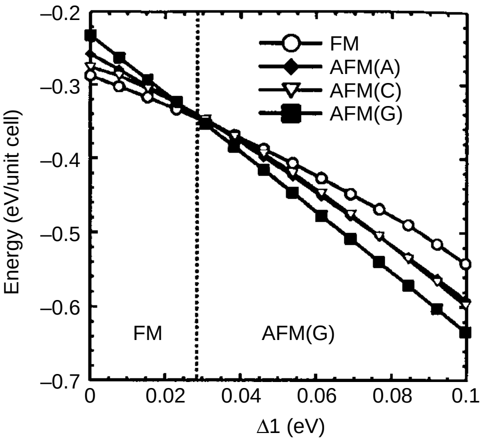

Figure 20 Dependence of the magnetic structure on the crystal field splitting, Δ (see Figure 4), in $LnTiO_3$ perovskites.[16] (Ref. 16. Reproduced by permission of Physical Society of Japan.) Note that for $\Delta > 0.03$ eV, the antiferromagnetic type G (see Figure 17) structure is favored

splits the t_{2g} set into three orbital singlets (Figure 18). In the lowest lying state, the orbitals point along the diagonals of the TiO_6 octahedra (Figure 19). Finally (Figure 20), detailed calculations show that the magnetic ground state is a strong function of the crystal field splitting separating the lowest level from the next highest, Δ in Figure 18. Note the cross-over from G-type AF to ferro F as Δ increases and it is generally regarded that Δ increases as the Ln^{3+} radius decreases (La^{3+} to Y^{3+}). Evidence for a splitting of the t_{2g} levels in $LaTiO_3$ has been inferred recently from a structural study at low temperatures.[27]

5.1.2 ATO_3, $T = Mn$

Excluding the cuprate superconductors, manganese perovskite oxides that exhibit the so-called ‘colossal’ magneto-resistance (CMR) effect constitute, probably, the most extensively studied set of materials over the past decade or so. Several review articles exist.[28–32]

Most attention has been focused on manganates with the perovskite or a related Ruddlesden–Popper type structure, that is, $AMnO_3$ or $A_3Mn_2O_7$. These structures are illustrated in Figure 15, where they are described in the conventional manner in terms of the intergrowth of layers of AO and $AMnO_3$ composition of general formula $(AO)(AMnO_3)_n$. In this notation, the parent perovskite is $n = \infty$ and the various Ruddlesden–Popper variants are labeled in terms of the number of perovskite ($AMnO_3$) layers intergrown with rock salt (AO) layers. Thus, all of the attention has been directed toward the $n = \infty$ and $n = 2$ structure types.

What is ‘colossal’ magneto-resistance (CMR) (or even magneto-resistance)? Magneto-resistance is any change in the resistivity of a material induced by an applied magnetic field and is usually expressed as $(\rho_0 - \rho_H)/\rho_0$ where ρ_0 is

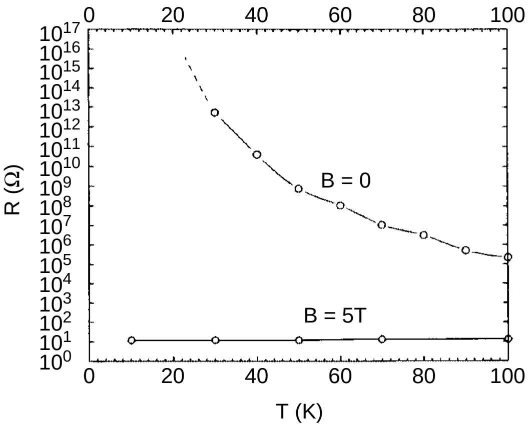

Figure 21 The colossal magneto-resistance (CMR) effect exemplified in $Pr_{0.7}Ca_{0.3}MnO_3$. (Reprinted with permission from Ref. 33, © 1998 American Chemical Society)

the resistivity in zero field and ρ_H is the resistance in a field. The effect is normally seen only in metallic conductors, although there are exceptions, and is a very weak effect in normal metals of the order of a few percent. A larger effect, termed 'giant' magneto-resistance, is exhibited by artificially produced magnetic multilayers in which very thin films (a few nanometers) of a ferromagnetic metal alternate with nonmagnetic layers. Here the effect is due to the so-called spin valve phenomenon and is of a few tenths of a percent. Colossal magneto-resistance (CMR) is illustrated in Figure 21,[33] where the change in resistance can be several orders of magnitude.

CMR occurs for very specific compositions of the type $A_{1-x}A'_xMnO_3$ where $A = Ln^{3+}$ (a lanthanide) and $A' =$ a group 2 ion such as Ca^{2+} or Sr^{2+} and $x \sim 1/3$. Nonetheless, the entire 'solid solution' series, $x = 0$ to 1, has been extensively investigated. In general, an extraordinarily rich 'phase diagram' is found as a function of the ratio of Mn^{3+}/Mn^{4+} and this is presented in Figure 22.[34] In fact, the evolution of magnetic structures had been known since the pioneering work of Wollan and Koehler in the 1950s.[35] The details of the phase diagram depend very strongly on the identity of the Ln^{3+} and A^{2+} species, which will be discussed in a following section. Thus, not all of the magnetic ground states shown in Figure 22 will be realized in every case. Nonetheless, the succession of phases is, beginning with Ln^{3+} Mn^{3+} O_3, A ($x = 0.0$ to $\sim$0.10), F ($x = 0.10$ to $\sim$0.50), CE ($x \sim 0.50$), C ($x > 0.5$ to $\sim$0.80) and G ($x > 0.85$ to 1.00), A^{2+} Mn^{4+} O_3. The magnetic structures represented by the symbols A, F, CE, C, and G are shown in Figure 3. That the CE ground state requires charge and orbital ordering such that Mn^{4+} ions have only Mn^{3+} ions as nearest neighbors (Figure 23) has been known for some time.[26] The phenomenon known as 'charge ordering' is thought to result at least in part from Coulomb repulsion, which acts to avoid (4+) – (4+) nearest neighbors and the local requirements of the Jahn–Teller Mn^{3+} ion. Charge ordering implies a structural phase transition indicated in Figure 22 as T_{CO}.

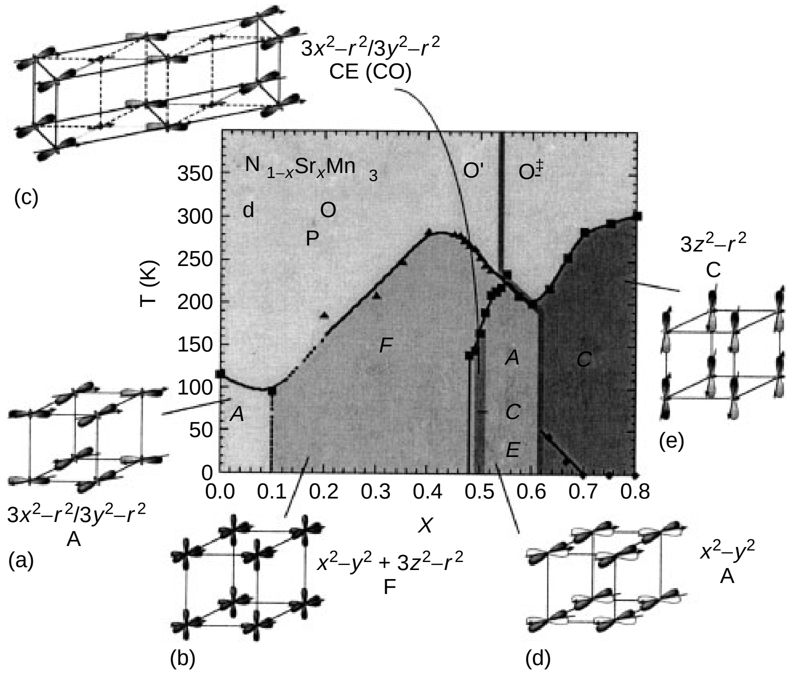

Figure 22 The extraordinarily rich 'phase diagram' of perovskite $Ln_{1-x}{}^{3+}A_x{}^{2+}MnO_3$, illustrated by $Nd_{1-x}Sr_xMnO_3$. (Reprinted from Ref. 34, © 1999, with permission from Elsevier)

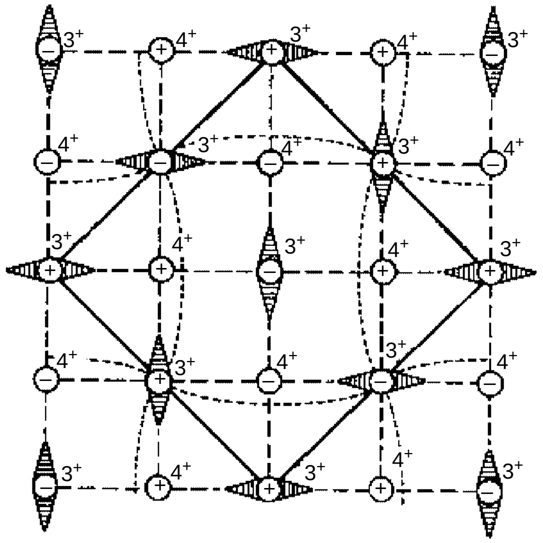

Figure 23 One layer of the CE magnetic structure, illustrating charge ordering between Mn^{3+} and Mn^{4+}

Charge and Orbital Ordering. Again, essentially all of the above had been known since roughly the 1950s. What is relatively new is the realization and experimental verification that in addition to magnetic and charge ordering, the spatial ordering of the e_g orbitals on the Jahn–Teller Mn^{3+} ions must be involved. This connection is shown in Figure 22 for $Nd_{1-x}Sr_xMnO_3$.[34] These orbital orderings have been deduced from synchrotron X-ray scattering studies, which have become possible within the last few years.

Also new is the apparent observation of charge ordering for x values away from 0.50, particularly $x \sim 2/3$, although the precise form of the ordering is somewhat controversial.

Two competing models are the so-called 'bistripe' model and the Wigner crystal, both of which involve ordered regions with F, AF, and frustrated near neighbor links as seen in Figure 24.[36]

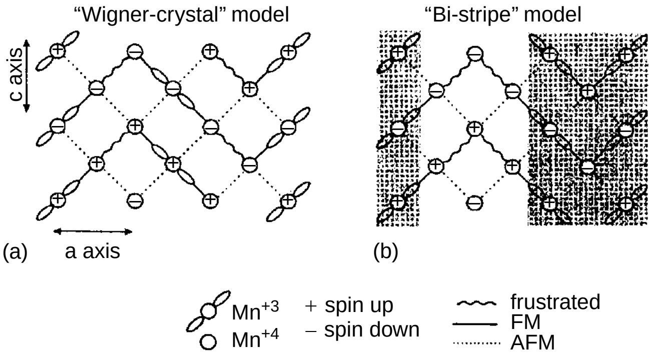

Figure 24 Possible models for charge ordering near $x \sim 2/3$ in $Ln_{1-x}A_xMnO_3$, the Wigner crystal versus the bistripe model. (Reprinted with permission from P.G. Radaelli, D.E. Cox, L. Capogna, S.-W. Cheong, M. Marezio, *Phys. Rev.*, 1999, **B59**, 14440. © 1999 by the American Physical Society)

In addition to the perovskites of the type $A^{2+}_{1-x}Ln^{3+}_{x}MnO_3$, other dopings have been investigated, for example, the introduction of the tetravalent cations Ce^{4+} and Th^{4+} in place of the trivalent lanthanides. In principle, for each tetravalent dopant ion, two Mn^{4+} ions are reduced to Mn^{3+} and one expects the phase diagram to reflect this and for the most part this is the case.[37] Another approach is to dope with oxide vacancies, for example, $CaMnO_{3-x}$, which also introduces two Mn^{3+} ions per introduced O^{2-} vacancy. In fact, a modest MR effect is seen for $x = 0.06$ and 0.11.[38] As well, a usual charge ordering is reported for the $x = 0.11$ phase, which is required to explain the neutron diffraction data in the magnetically ordered state. Here layers of Mn^{3+} ions order in every fourth layer in the G-type magnetic structure known for $CaMnO_3$ (see Figure 25).[39]

Effect of A-site Disorder and Cation Radius on $T_c(T_{mi})$ and T_{CO}. The effect of changing the contents of the A-site on the various transition temperatures of interest, T_c (Curie temperature for ferromagnetism), which is generally the same as T_{MI} (the metal/insulator transition temperature) and T_{CO} (the charge ordering transition temperature), can be quite large as in Figure 26[40] Attfield was able to show that $T_c(T_{MI})$ correlated very well with the statistical variance, σ, of the A-site ions, that is, $\sigma = \Sigma y_i r_i^2 - \langle rA \rangle^2$. Here the r_i are the standard Shannon radii for 9-fold[41] coordination, y_i

the concentration of the i^{th} ion on the A-site, and $\langle rA \rangle$ is the mean A-site radius. An example is shown in Figure 27.[42] Ultimately, these effects were traced to systematic changes in the MnO_3 framework, which work to bend the Mn–O–Mn angles to smaller values, leading to more narrow bands and localization with increasing σ_A^2.[43]

Manganates with $n = 1$ and 2 Ruddlesden–Popper Phases. The $n = 1$ manganates are less studied, primarily because the CMR effect is generally not found. A moderate effect, ~60%, has been demonstrated for $Ca_{1.92}Pr_{0.08}MnO_4$ at 7T.[44] Charge, orbital, and magnetic order are reported for $La_{0.5}Sr_{1.5}MnO_4$, which has the 1:1 Mn^{3+}/Mn^{4+} composition.[45,46]

The all Mn^{4+} materials, A_2MnO_4, A = Ca, Sr, show strong two dimensional AF correlations and, eventually, long-range AF order.[47] A^{2+} $LaMnO_4$ materials, with all Mn^{3+}, are also two dimensional AF materials with three-dimensional AF order at lower temperatures with one notable exception, $BaLaMnO_4$. In spite of a paramagnetic moment equal to the spin only value for Mn^{3+}, this compound does not order to 1.5 K.[48] In fact, addition of only ~30% Ba to $SrLaMnO_4$ (which orders at 130 K in the standard AF structure for materials with the $n = 1$ structure) quenches completely the long-range AF order.

The $n = 2$ RP phases do show the CMR effect and have attracted much attention.[49] A recent review surveys the field.[50] A phase diagram for $La_{2-2x}Sr_{1-2x}Mn_2O_7$ is shown in Figure 28.[51] Note that the ferromagnetic Curie temperatures are low, ~126 K, relative to the perovskite manganates, and that the magnetic structures found are different. Both of these effects result from the layered crystal structure. The types of magnetic structure are illustrated in Figure 29.[51] A singular feature of some of the $n = 2$ materials is the occurrence of phase separation in the CMR regime. That is, the materials Nd_{2-2x} Sr_{1+2x} Mn_2O_7, $x = 0$ and 0.10, actually comprise two phases with very similar lattice constants and compositions. This was discovered in high-resolution neutron diffraction experiments.[52] Also, these Nd-based phases are never either metallic nor ferromagnetic, yet show a moderate MR, >10%. This also illustrates an important feature of the $n = 2$ RP

phases, namely, the fragility of the ferromagnetic regime as the size of the Ln^{3+} ion is decreased.

5.1.3 *ATO_3, T = Fe*

$SrFeO_3$. The synthesis of oxygen stoichiometric $SrFeO_{3-\delta}$ with $\delta \sim 0$ generally requires high O_2 pressures of at least 6 GPa to stabilize the Fe^{4+} state.[53] The crystal structure is cubic Pm3m. The material is an unusual metallic antiferromagnet with $T_N = 134$ K and a spiral spin structure that has been interpreted as arising from competition between nearest neighbor ferromagnetic exchange interactions and further neighbor antiferromagnetic interactions.[54] Fe^{4+} is in either the HS state ($t_{2g}^3e_g^1$) or a hybrid (d^5L), where L is a ligand hole.[55] Either doping with Co, $SrFe_{1-x}Co_xO_3$, or oxygen vacancies, $SrFeO_{3-\delta}$, induces ferromagnetism as seen in Figure 30 for the Co-doped materials.[34] In the Co-doped system, the ferromagnetism is thought to result from exchange between LS Co^{4+} (t_{2g}^5) and HS Fe^{4+} ($t_{2g}^3e_g^1$). A small MR effect (few %) is seen in the Co-doped compounds.[56]

Vacancy-doped $SrFeO_{2.81}$ shows MR of ~90% at low temperature, ~70 K. This is proposed to result from Fe^{4+}/Fe^{3+} CO at this temperature.[57]

5.1.4 *ATO_3, T = Co*

$LaCoO_3$. This perovskite contains Co^{3+} and the crystal structure is rhombohedral. While the basic properties have been studied since the 1960s,[58] a consensus interpretation has emerged only recently. Typically, the magnetic susceptibility shows a behavior similar to that in Figure 31.[59] The susceptibility is essentially zero at low temperatures (after allowance for a low concentration of paramagnetic impurities, which give a Curie tail) and rises sharply near 90 K–100 K and then falls with increasing temperature. It is natural to assume that the ground state is nonmagnetic LS Co^{3+} (t_{2g}^6 e_g^0, S = 0) and that the susceptibility rise is due to a spin state transition. The question remaining is whether the lowest lying excited spin state is HS ($t_{2g}^4e_g^2$, S = 2) or intermediate spin, IS, ($t_{2g}^5e_g^1$, S = 1). For some time, the HS state was implicated but much evidence, experimental in the direct measurement of the paramagnetic scattering from polarized neutron diffraction,[60] detailed fitting of the susceptibility and the observation of a Jahn–Teller lattice distortion,[61] and theoretical calculations of the relative energies of the three possible spin states[62] seem to indicate the IS state.

$SrCoO_3$. High pressures are required to stabilize the rare Co^{4+} state and produce a reasonably stoichiometric $SrCoO_{3-x}$. Post annealing of melt grown single crystals in 1.0 to 1.6 kbar O_2 can achieve $x = 0.03$.[63] At this stoichiometry, the structure is reported to be cubic. It has been known for sometime that $SrCoO_3$ is ferromagnetic with T_c reported from 190 K to 220 K and a saturation moment of 1.5 μ_B/F.U.[63] In the paramagnetic

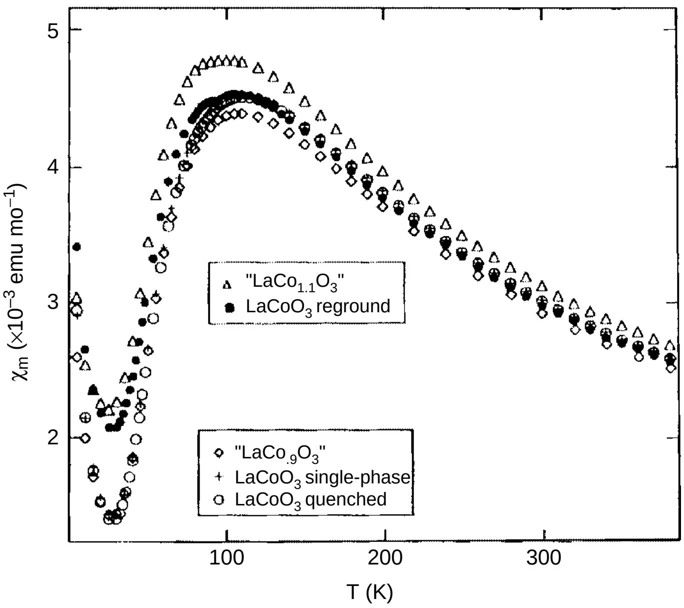

Figure 31 Typical magnetic susceptibility of $LaCoO_3$. (Reprinted from Ref. 59, © 1995, with permission from Elsevier)

regime, a $\mu_{eff} = 3\,\mu_B$ is found. Again, until recently the ground state was thought to be LS Co^{4+} ($t_{2g}^5e_g^0$). However, discrepancies with the Co 2p X-ray absorption spectra have led to a new interpretation. It has been proposed that strong hybridization with the ligand p states can actually result in an IS (intermediate spin), S = 3/2 ground state rather than the LS, S = 1/2.[64] The IS state can be thought of as an HS d^6 configuration with a ligand hole antiferromagnetically coupled to the e_g levels giving S = 1.5. The IS state is also consistent with the observed ferromagnetism through a Zener double exchange.[11,12]

$La_{1-x}Sr_xCoO_3$. Substitution of Sr^{2+} for La^{3+} induces both ferromagnetism and metallic behavior, which parallels observations in the related manganates. Indeed, a large magneto-resistance was reported for thin films with $0.15 < x < 0.20$.[65] A possible phase diagram of remarkable complexity is shown in Figure 32.[66] Compositions up to $x = 0.5$ have been studied in detail. While a detailed discussion of the phase diagram is beyond the scope of this article, salient facts are that an insulator to metal transition occurs near $x = 0.3$ and strong ferromagnetic correlations appear even at $x = 0.1$. Originally, it was not clear that true long-range ferromagnetic order was present in these materials but neutron scattering seems to show its existence for substitution levels in the range $0.10 < x < 0.30$[67] and possibly to 0.50[68] but this is somewhat controversial at present. There is evidence for a highly inhomogeneous microstructure involving hole-rich metallic, ferromagnetic domains formed about the substituted Sr^{2+} ions and hole-poor regions with properties more like $LaCoO_3$.[67]

5.1.5 ATO_3, T = Ru

In addition to the more commonly investigated 3d transition elements, there has been much interest in perovskite oxides involving 4d and 5d elements. The most intensely studied materials have been the 'ruthenates' and the story is quite complex. $SrRuO_3$ was identified as a ferromagnetic, metallic oxide as early as 1968 with $T_c = 160$ K.[69] At that time, $CaRuO_3$ was characterized as an antiferromagnetic metal with $T_N \sim 110$ K. With the report of superconductivity in Sr_2RuO_4 (n = 1RP phase) at $\sim$1 K,[70] many laboratories began systematic explorations of the properties of the RP ruthenates. Brief reviews focusing on the magnetic and transport properties have been published, which provide a convenient summary of work up to $\sim$1999[71] and for more recent results.[72] However, owing to difficulties in crystal growth and control of intergrowth between the structurally similar RP phases, the facts regarding the true properties of the various materials have only recently been established. Beginning with the $n = \infty$ phases, $CaRuO_3$ is now regarded as a paramagnetic metal that is highly susceptible to doping induced magnetic anomalies.[73] For $n > 1$, the Ca-based materials show a variety of behaviors. Ca_2RuO_4 is an antiferromagnetic insulator (AFI), $T_N = 110$ K. $Ca_3Ru_2O_7$ is metallic and AF with $T_N = 56$ K but undergoes a MI transition at 48 K. On the other hand, the Sr-based ruthenates are all metallic. Sr_2RuO_4 is metallic and superconducting below 1 K as mentioned and $Sr_3Ru_2O_7$ is metallic and paramagnetic. It has been argued very recently that the ferromagnetism once ascribed to this compound is due in fact to the $n = 3$ phase, $Sr_4Ru_3O_{10}$, which is a ferromagnetic metal with $T_c = 105$ K[74] and of course the $n = \infty$ member, $SrRuO_3$, is a metallic ferromagnet, as mentioned. The difference in the degree of

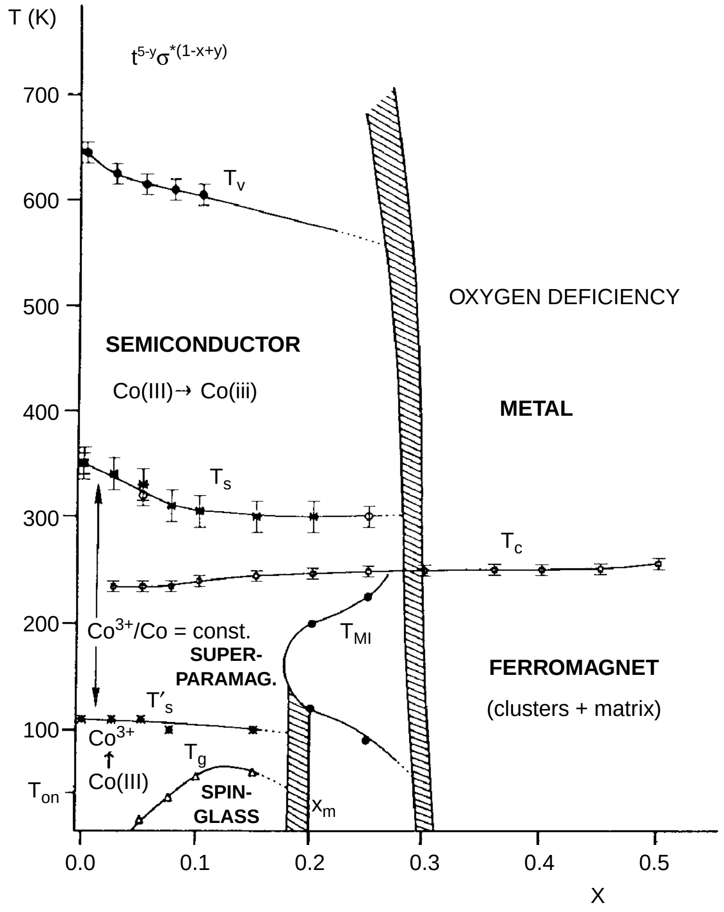

Figure 32 Phase diagram of the $La_{1-x}Sr_xCoO_3$ system. (Reprinted from Ref. 66, © 1995, with permission from Elsevier)

electron localization can be attributed to the difference in Ru–O–Ru bond angles, which are more acute for the Ca-based materials. For example, while Sr_2RuO_4 crystallizes in the ideal I4/mmm structure for which the Ru–O–Ru angles connecting corner-sharing octahedra are rigorously 180°, Ca_2RuO_4 is described in orthorhombic Pbca wherein the corresponding angles are significantly more acute, ~151°.[75] The structures of $Ca_3Ru_2O_7$ and $Sr_3Ru_2O_7$ are both distorted from I4/mmm.[76] In the case of $Ca_3Ru_2O_7$, the AFI state can be destroyed by application of a very large field, 28T, giving rise to a CMR effect.[77]

5.2 Other Perovskite – Based Magnetic Oxides

5.2.1 B-site Ordered Double Perovskites

In perovskites of the type $AA'BB'O_6$, ordering of the B-site ions may occur if the differences between ionic size and formal charge is sufficiently large. The crystal chemistry of these complex perovskites has been reviewed recently.[78] More than 300 materials can be identified as 'double perovskites' so only a few compounds will be described here. Attention will be focused on perovskites for which there is significant crystallographic order between the B and B′ ions. For 1:1 B-site order, the idealized, cubic structure can be described as a 'rock salt' type, since the B and B′ ions form a NaCl supercell (Figure 33). Factors that determine B-site ordering are the differences in ionic radius and formal charge as seen in Figure 34.[78] Guidelines that can be deduced are that Δ(IR) ≥0.2 Å and Δ(FC) ≥2 for 'rock salt' order although a few exceptions exist. The use of the 'rock salt' label in Figure 34 does not imply always Fm3m symmetry. The true symmetry is a function of the A-site/B-site size ratio. Twelve possible symmetries have been identified from group theory analysis,[79] with the most common cases being tetragonal, I4/m, and monoclinic, $P2_1/n$, with the ideal Fm3m being somewhat rare. As well, the observation of superlattice reflections does not imply that the B-site ordering is complete. In many important cases. it has been shown that partial ordering occurs and that the extent of ordering is a strong function of preparation details.

Magnetic B-site ordered perovskites are of interest in at least two contexts, 'half-metallic ferromagnets', which show a large MR due to intergrain effects, and geometric magnetic

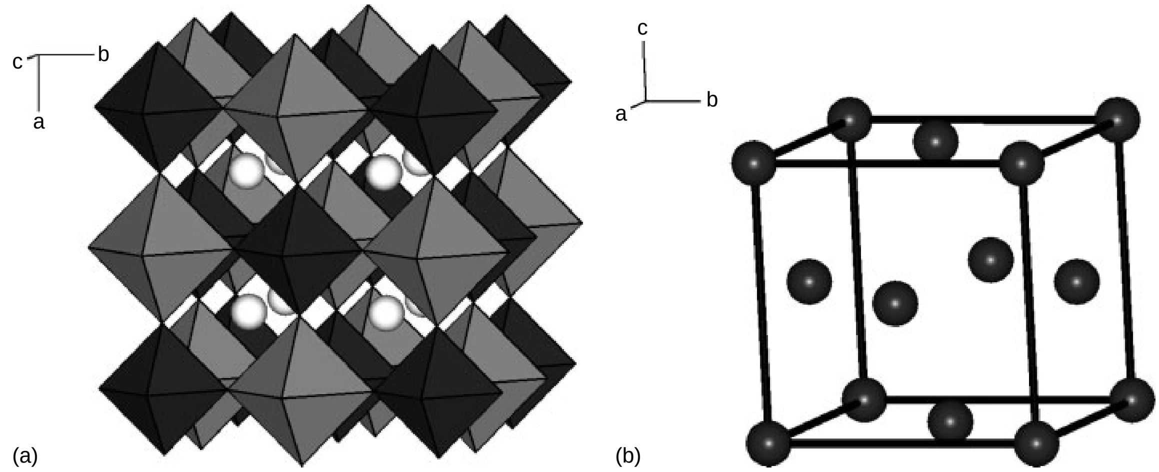

Figure 33 Unit cell of the B-site ordered double perovskite, $A_2B'B''O_6$.(Fm3m). (a) The light grey octahedral represent the B″ sublattice, the dark grey octahedra the B′ sublattice, and the white spheres the A_2 sublattice. (b) The fcc sublattice for either the B′ or B″ sublattice

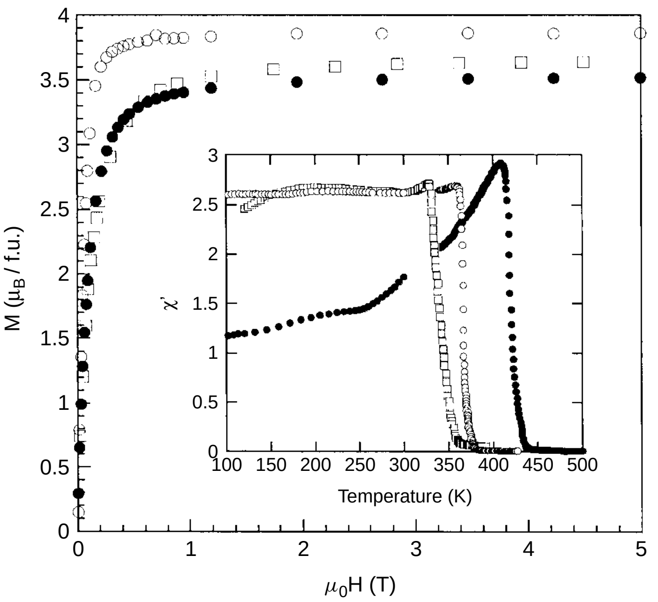

Figure 35 Ferromagnetism in Sr_2FeMoO_6 with $T_c > 400\,K$. (Ref. 82. Reproduced by permission of IOP Publishing Ltd)

frustration. Materials in the latter category will be discussed in a following section. The most intensively studied perovskite in the former class is Sr_2FeMoO_6 while many variants $A_2BB'O_6$ where A = Ca, Sr, or Ba, B = Cr, Mn, Fe, Co, and B′ = Mo, Re have also received attention.

Sr_2FeMoO_6. While this material has been known since 1963,[80] intense interest was sparked by the announcement of room temperature MR in 1998.[81] The material is ferro or ferrimagnetic with $T_c > 400\,K$ and a metallic conductor, Figure 35.[82] This unusual combination of properties can be explained in terms of the 'half-metallic ferromagnetic' electronic structure model, Figure 36.[83] Note that the Fermi level lies in a gap with respect to the spin-up polarized DOS but within the t_{2g} spin-down band which has contributions from both Fe 3d and Mo 4d states, that is, the material is insulating with respect to the spin-up states but metallic with respect to spin-down and the unequal population of the spin states gives rise to a spontaneous ferromagnetic moment, hence the nomenclature 'half-metallic ferromagnet'.

The crystal structure is clearly tetragonal, most likely I4/m, at room temperature although a transition from cubic Fm3m to I4/m accompanies the magnetic phase transition near 400 K in the samples studied (Figure 37).[84] The issue

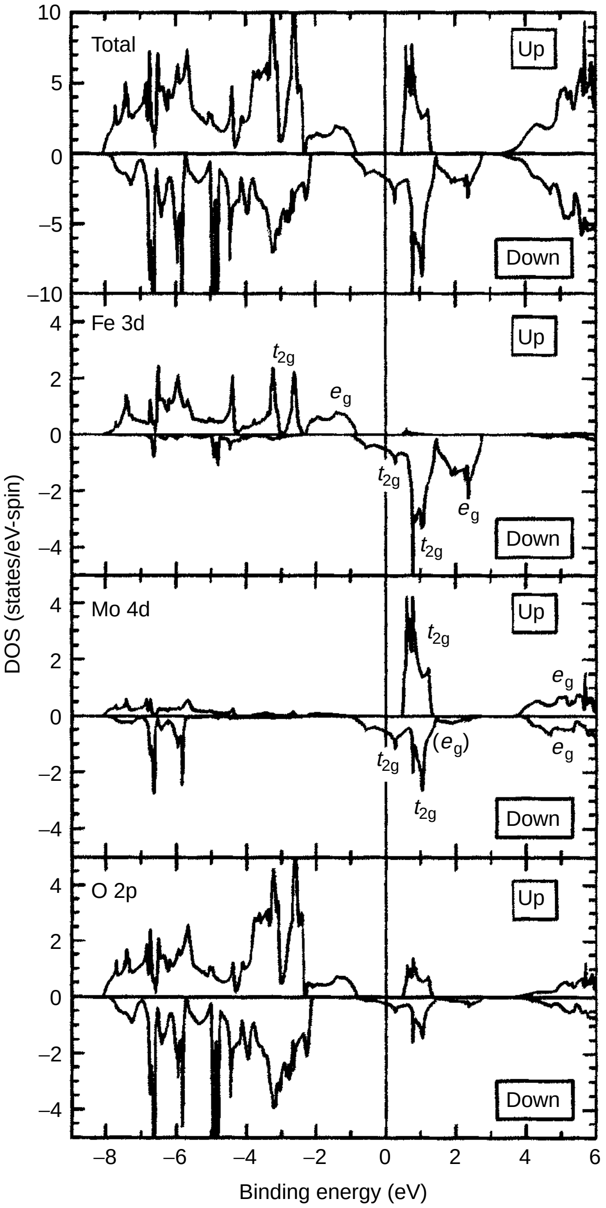

Figure 36 Band structure calculations for Sr_2FeMoO_6 showing 'half-metallic' ferromagnetic character. (Reprinted with permission from T. Saitoh, M. Nakatake, A. Kakizaki, H. Nakajima, O. Morimoto, Sh. Xu,Y. Moritomo, N. Hamada, Y. Aiura, *Phys.Rev.*, 2002, **B66**, 035112. © 2002 by the American Physical Society)

of the extent of B-site order has been debated. This is quantified in terms of antisite disorder (ASD), that is, the fraction of Fe and Mo site interchanged. In single-crystal samples prepared by float zone melting, ASD levels of less than 5% are reported but for powder samples prepared at lower temperatures it is claimed that the antisite disorder level (ASD) can be tuned with annealing temperature with values up to 80%.[85] Not surprisingly, sample properties such as T_c and saturation magnetization are a strong function of ASD.

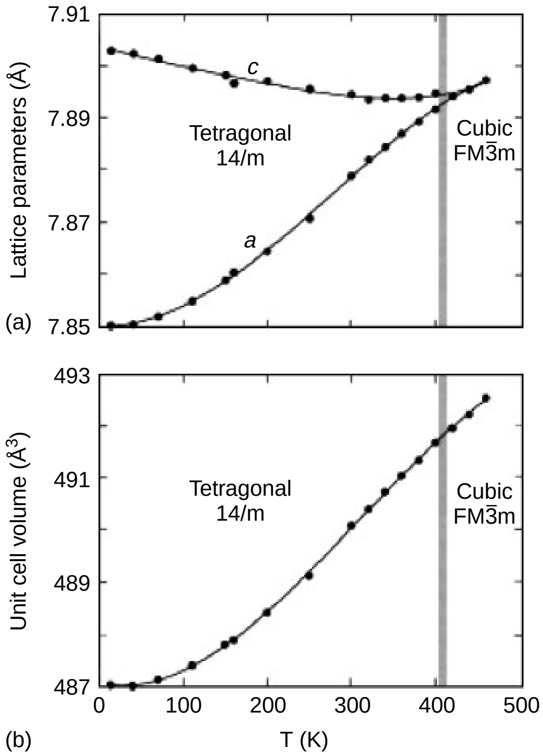

Figure 37 Cubic to tetragonal structural transition in Sr_2FeMoO_6 at T_c. (Reprinted with permission from O. Chmaissem, R. Kruk, B. Dabrowski, D.E. Brown, X. Xiong, S. Kolesnik, J.D. Jorgensen, C.W. Kimball, *Phys.Rev.*, 2000, **B62**, 14197. © 2000 by the American Physical Society)

As well, the issues of the oxidation states of Fe, Mo and the magnetic structure have been debated. A mixed valency according to the equilibrium

$$Fe^{3+} + Mo^{5+} = Fe^{2+} + Mo^{6+} \tag{16}$$

has been proposed. Various relevant techniques such as ^{57}Fe Mössbauer and core-level X-ray spectroscopies seem to support such a formulation although it seems clear that the picture $Fe^{3+} + Mo^{5+}$ is a good first approximation.[86,87] Neutron diffraction results seem consistent with HS Fe^{3+} ($\mu_{\text{spinonly}} = 5\,\mu_B$, $\mu_{\text{obs}} = 4.3\,\mu_B$) and a moment of $\sim 1\,\mu_B$ on Mo^{5+}, which is also consistent with the measured bulk saturation moment on the best ordered samples of $\sim 3.6\,\mu_B$.[83,88]

Finally, the MR effect in this and related double perovskites is not of the same origin as the bulk effect seen in perovskite manganates but is due to spin dependent scattering at grain boundaries via a charge carrier tunneling mechanism.[81] The advantage and promise of the double perovskites is that the MR effect of several percent occurs at room temperature and at quite low fields in the mT range.

5.2.2 *A-site Ordered Double and Triple Perovskites*

In addition to B-site ordering, A-site order can occur although its observation is much more rare. A-site ordering is seen only when the large Ba^{2+} ion is present in company with a Ln^{3+} ion. Both double, $LnBaT_2O_{5+\delta}$, where T = Fe or Mn, and triple, $LnBa_2T_3O_{8+\delta}$, where T = Fe, perovskites of this type have been reported recently.[89–91]

In these cases, A-site ordering results in a doubling or tripling of one of the perovskite unit cell axes, hence the nomenclature. Note also that the oxygen content is always less than the fully stoichiometric level, $5 + \delta$ instead of 6, and $8 + \delta$ instead of 9, for the double and triple perovskites, respectively. A consequence of this is that the coordination environment of at least one set of T ions is 5-fold pyramidal rather than 6-fold octahedral.

Figure 38 shows both structures. The $LnBaT_2O_5$ phases are compositionally similar to the well-known brownmillerites, such as $Ca_2Fe_2O_5$, but the structure is very different. In the brownmillerites, the B-site coordination geometries are distorted octahedral and tetrahedral, not 5-fold square pyramidal. The $LnBa_2Fe_3O_8$ materials are of course directly related to $YBa_2Cu_3O_7$! Another consequence of the oxygen stoichiometry in the $LnBaT_2O_5$ materials is that the T element is present in a mixed valence state, T^{2+}/T^{3+} as found in magnetite, Fe_3O_4.

$LnBaFe_2O_{5+\delta}$. These exist for Ln = Nd – Y(Ho), spanning a reasonable range of Ln^{3+} radii from relatively large (Nd^{3+}) to relatively small(Ho^{3+}) The materials must be prepared within a narrow range of pO_2 (oxygen partial pressure) between 10^{-15} and 10^{-16} and δ is a strong function of pO_2.[89]

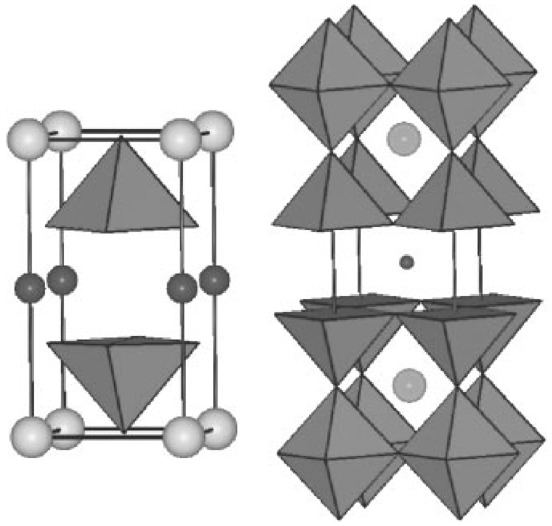

Figure 38 Crystal structures of the A-site ordered double (a), $LnBaT_2O_5$, and triple (b) perovskites. Of particular interest is the occurrence of fivefold square-planar sites

The crystal symmetry varies with δ, being Pmmm for $\delta < 0.04$ and transforming to P4/mmm for $\delta > 0.1$. All materials in the series order antiferromagnetically at high temperatures with $T_N = 435$ K (Nd) and 432 K(Ho), with essentially no size dependence. The antiferromagnetic order seems odd at first as both Fe^{2+} and Fe^{3+} are formally present. This is explained as resulting from a situation in which the Fe ions are electronically equivalent (at higher temperatures) and are considered as $Fe^{+2.5}$. However, for all materials in this series, a CO transition (analogous Verwey transition in Fe_3O_4) occurs at lower temperature, ~200 K (Ho) or ~300 K(Nd), into a HS Fe^{3+} and a Fe^{2+} state, which can be seen in neutron diffraction, calorimetry,, and magnetic susceptibility.[92] A change in magnetic structure accompanies the Verwey transition. This is shown for $TbBaFe_2O_5$ in Figure 39.[93]

YBa_2MnO_5. Only the Ln = Y phase has been studied in much detail for the T = Mn materials. In sharp contrast to the T = Fe phases, evidence for short range CO is

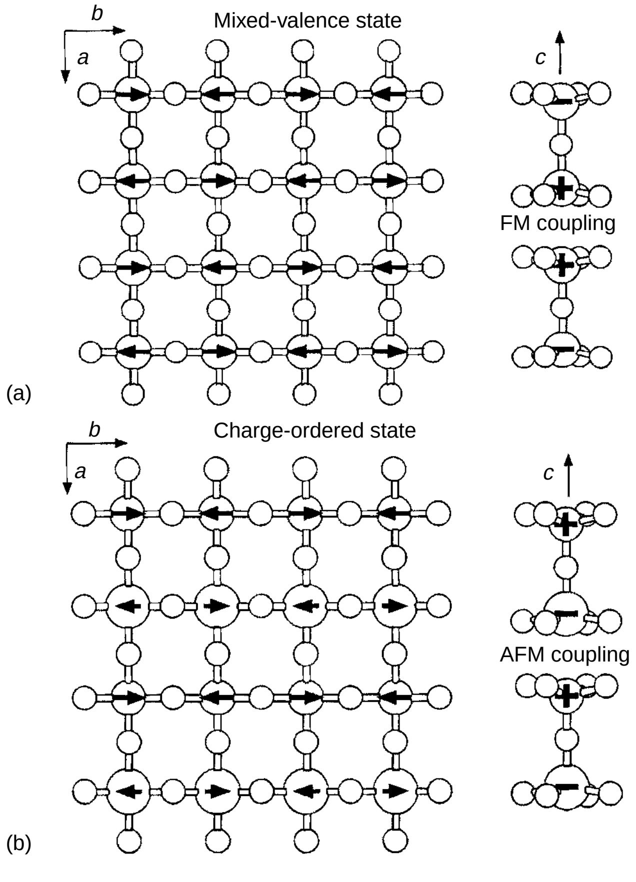

Figure 39 Change in the magnetic structure for $TbBaFe_2O_5$ at the charge ordering or Verwey transition. (a) Mixed valence state. (b) Charge ordered state. (Reprinted with permission from P. Karen, P.M. Woodward, J. Linden, T. Vogt, A. Studer, P. Fischer. *Phys. Rev.*, 2001, **B64**, 214405. © 2001 by the American Physical Society)

found even at 300 K, well above the transition to long-range ferrimagnetic order below 167 K.[94] Figure 40 shows the valence and magnetic ordering model for this material.

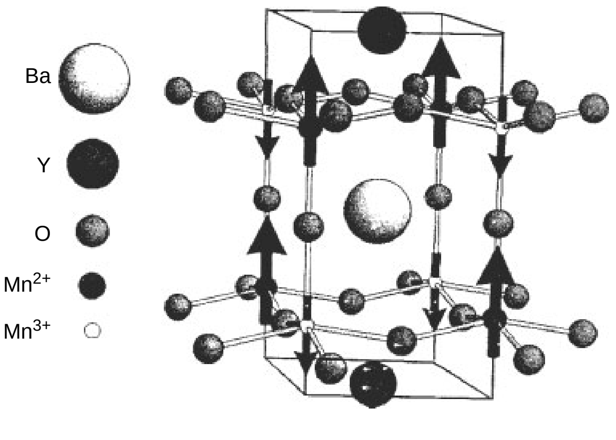

Figure 40 Charge and magnetic order in YBa_2MnO_5. (Ref. 94. Reproduced by permission of Royal Society of Chemistry)

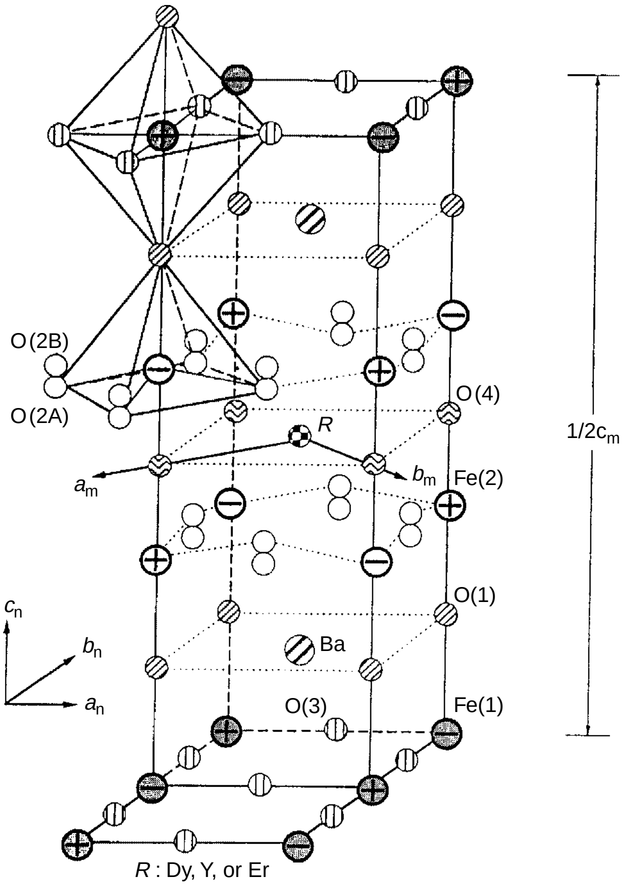

Figure 41 Magnetic structure of $YBa_2Fe_3O_8$. Only one-half of the magnetic cell is shown. (Reprinted from Ref. 91, © 1998, with permission from Elsevier)

$LnBa_2Fe_3O_8$. Only the small Ln^{3+} ions, Dy, Y, Er, give the triple perovskite structure, described in P4/mmm. Larger ions show only a disordered cubic Pm3m cell and no perovskite phase forms for ions smaller than Er.[91] These materials all order magnetically well above room temperature, $T_N \sim 650$ K. The magnetic unit cell is related to the chemical cell as $a_{mag} = b_{mag} = \sqrt{2}a_{chem}$, $c_{mag} = 2c_{chem}$ and the magnetic structure is shown in Figure 41.

5.2.3 *Pillared Perovskites*

Recently, an unusual series of perovskite related materials has been reported with the composition $La_5T_3T'O_{16}$, where $T = Mo^{4+}$ or Re^{5+} and $T' = Mo^{4+/5+}$, Mg^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+}.[95,96] The structure can be visualized as a 'pillaring' of corner-shared octahedral layers of $TT'O_6$ by dimeric edge-sharing T_2O_{10} units as in Figure 42. For the Re^{5+} based series, the Re_2O_{10} dimer is diamagnetic and involves a Re=Re double bond. The Re^{5+} and T'^{2+} ions order crystallographically in the perovskite layers as expected given the +3 difference in formal charge. As Re^{5+} ($5d^2$, S = 1) is magnetic in these compounds, the perovskite layers are in principle 2D ferrimagnets. Evidence for this is shown in Figure 43 for $La_5Re_3CoO_{16}$ where a plot of χT versus T displays first decreasing values of the effective moment with decreasing temperature indicating antiparallel correlations between Co^{2+} (S = 3/2) and Re^{5+} (S = 1) followed by a sharp increase at lower temperatures when finite ferrimagnetic clusters form. The strong decrease at still lower temperatures is due to long-range antiferromagnetic order between the ferrimagnetic layers. In spite of the rather large interlayer separation of >10 Å, ordering temperatures as high as 161 K ($La_5Re_3MnO_{16}$) or even 200 K ($La_5Mo_4O_{16}$) are seen (Figure 44).[97,98] The long-range ordered AF ground state

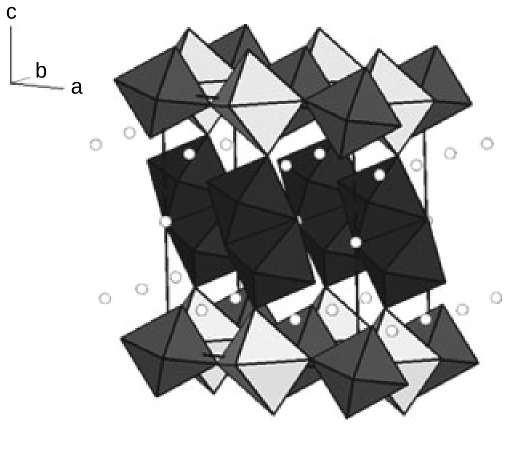

Figure 42 Crystal structure of a pillared perovskite material, $La_5Re_3MnO_{16}$. The grey and white octahedra represent the $MnReO_6$ site-ordered perovskite like layers and the black octahedra, the Re_2O_{10} edge-sharing dimers. The white spheres show the La ion positions

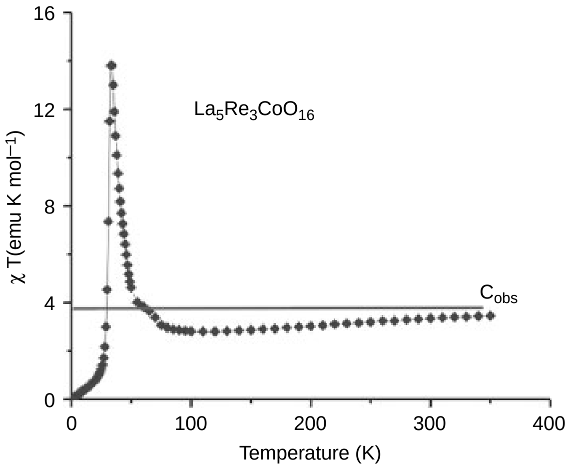

Figure 43 Evidence for short range ferrimagnetic correlations in $La_5Re_3CoO_{16}$. Note the negative deviation from the horizontal $\chi T = C$ line at high temperatures and the strong positive deviation at low temperatures. (Reprinted from Ref. 99, © 2003, with permission from Elsevier)

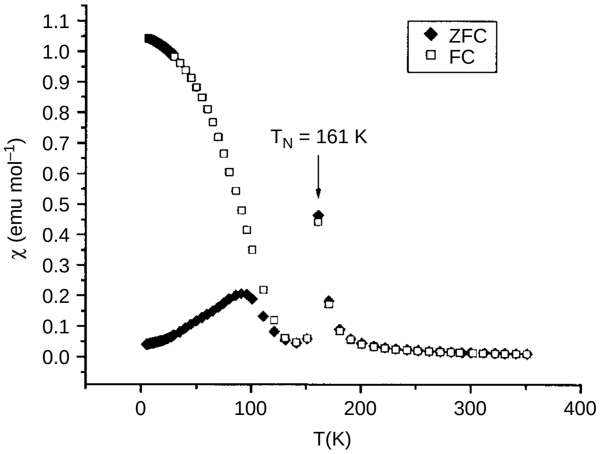

Figure 44 Evidence for long-range magnetic order in $La_5Re_3MnO_{16}$ at $T_c = 161\,K$. (Reprinted from Ref. 98, © 2002, with permission from Elsevier)

has been confirmed from neutron diffraction for $La_5Re_3FeO_{16}$ ($T_N = 155\,K$), which consists of AF order of the ferrimagnetic layers with ordered moments of $3.0\,\mu_B$ on Fe^{2+} ($S = 2$) and $1.5\mu_B$ on Re^{5+} ($S = 1$) (Figure 45).[99] The AF structure can be destroyed by relatively weak applied fields(0.5T), where meta-magnetic or spin flop transitions are observed.

5.3 Low-Dimensional Oxides, Materials with 2H-Perovskite Related Structures

5.3.1 *Sr_4PtO_6 Structure Compounds*

Other oxides with composition analogous to perovskite, that is, ABO_3, exist but with a very different condensation

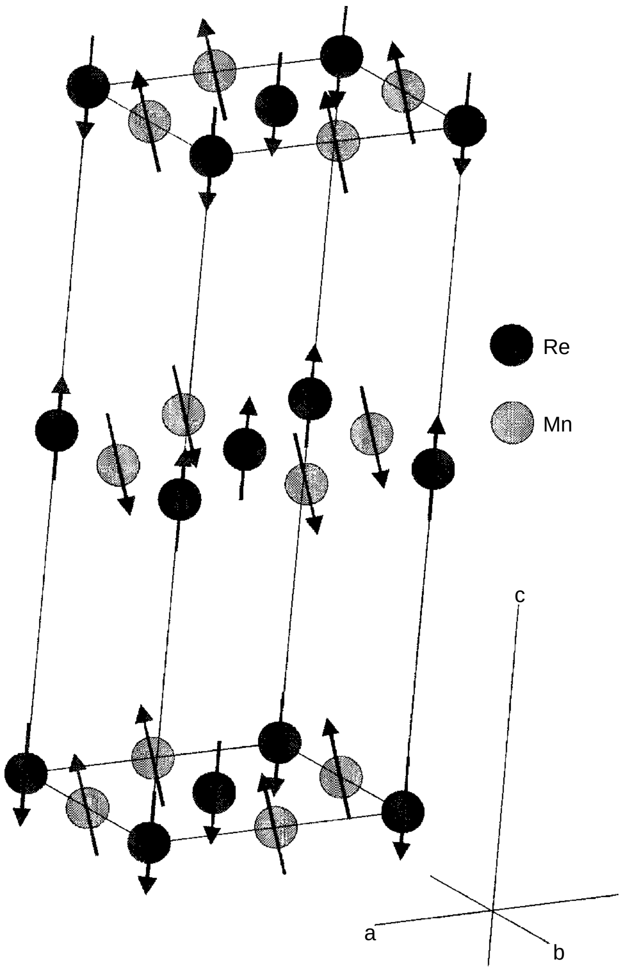

Figure 45 The magnetic structure of $La_5Re_3MnO_{16}$ in which ferromagnetic layers couple antiferromagnetically. (Reprinted from Ref. 98, © 2002, with permission from Elsevier)

scheme for the BO octahedra. In the so-called 2H-perovskite structure, the octahedra share opposite faces forming linear chains. Many other structures share this motif and the crystal chemistry has been reviewed.[100] In particular there has been considerable interest in materials that are isostructural with Sr_4PtO_6, the structure of which is shown in Figure 46.[100] Here the linear chains feature alternating face-sharing sites of octahedral and trigonal prismatic geometry, the latter being rather rare in oxide crystal chemistry.

The Sr_4PtO_6 structure type is highly versatile to substitution on the in-chain Sr site and the Pt site and perhaps is better formulated as $A_3A'BO_6$, where A′ and B can be magnetic or nonmagnetic transition metal ions from the 3d, 4d, and 5d series. There is, thus, considerable scope for tuning the sign (F or AF) of the intra and interchain exchange and the spin dimensionality (Heisenberg, Ising, or XY) as well and these opportunities have been exploited.

In principle, one would expect 1D magnetic correlations to dominate but the interchain separation is not sufficiently great

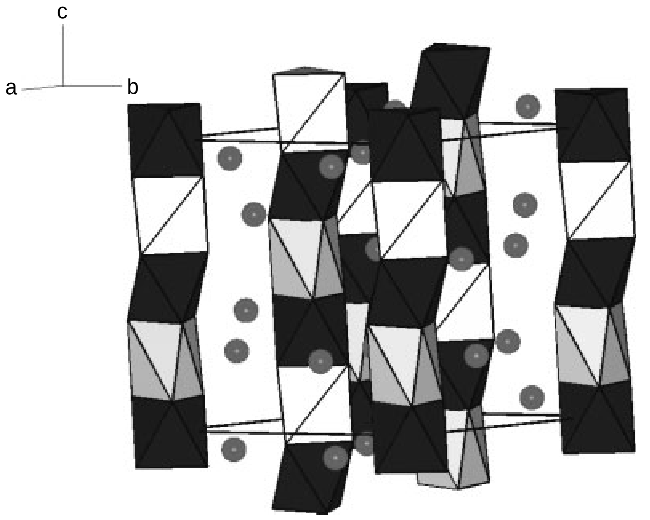

Figure 46 Crystal structure of Sr_4PtO_6 materials, which can also be written $Sr_3(SrPtO_6)$. Infinite chains of alternating face-sharing PtO_3 octahedra(dark grey) and SrO_3 trigonal prisms(light grey) are formed. The remaining Sr^{2+} ions are represented by grey spheres

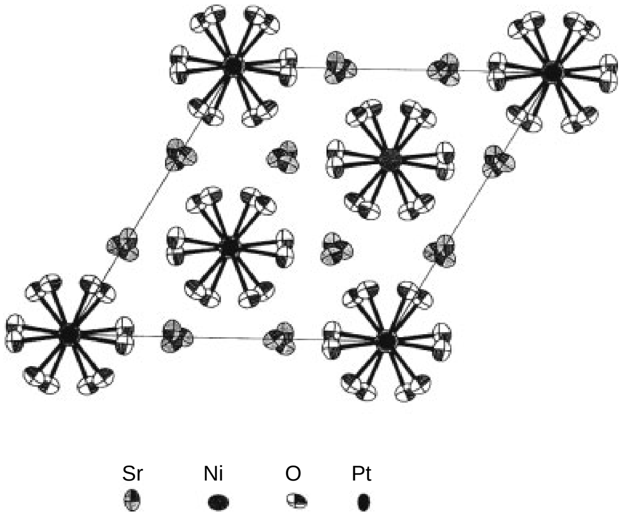

Figure 47 The crystal structure of Sr_3NiPtO_6 along the chain direction showing the trigonal lattice of chains. Note also the relatively close interchain separation. (Reprinted with permission from Ref. 101, © 1999 American Chemical Society)

to isolate the chains completely as seen in the projection of the structure parallel to the chain direction (Figure 47).[101] As well, the chains themselves form a trigonal lattice, introducing an element of geometric frustration (to be discussed in more detail in the following section) into the mix.

Sr_3ABO_6, $B^{4+} = Ir,Pt$; $A^{2+} = Co,Ni,Cu,Zn$. Systematic studies on the above series illustrate the variety of magnetic phenomena that can be obtained by chemical

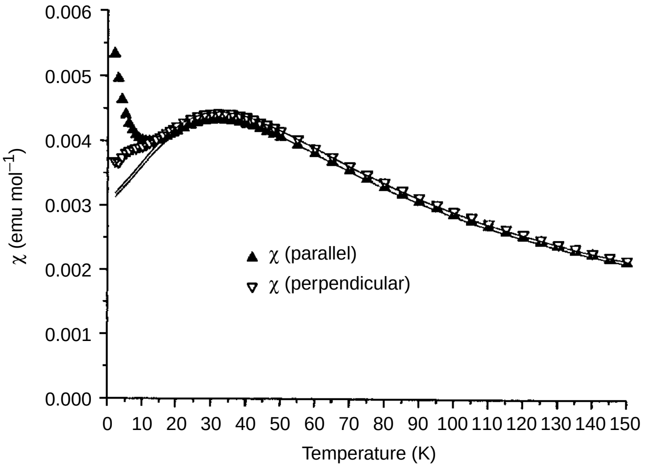

Figure 48 Magnetic susceptibility of Sr_3CuPtO_6 showing linear chain, S = 1/2, AF Heisenberg behavior. The ZFC/FC divergence near 10 K is likely a sign of long-range AF order due to inter chain coupling. (Reprinted with permission from Ref. 101, © 1999 American Chemical Society)

tuning.[101–103] The Pt-based materials have LS Pt^{4+} (t_{2g}^6) in the octahedral sites and the divalent TM ions in the unusual trigonal prismatic sites, thus only that site is magnetic. Data for single crystals of the $A = Ni^{2+}$ (S = 1) material show no obvious short range magnetic correlations but can be fitted to a paramagnetic model with large zero field splitting, D/k = 94 K, which implies a single ion ground state singlet.[101] Apparently, magnetic order can be induced by application of a field >4T. The $A = Cu^{2+}$ compound behaves as a Heisenberg S = 1/2 linear chain system (Figure 48),[101] but with a significant ratio of $J_{inter}/J_{intra} \sim 1/3$. Evidence for long-range AF order is also evident from the ZFC/FC divergence near 10 K.

When $B = Ir^{4+}$ (t_{2g}^5, S = 1/2), there are obvious changes. For A = Ni, deviations from the Curie-Weiss law set in below 150 K and show a strong dependence on applied field, suggesting intrachain F interactions but a nearly singlet ground state at low temperatures suggesting AF interchain coupling, but a conclusive judgment cannot be deduced from the available data. The Sr_3CuIrO_6 phase, where both sites are S = 1/2, shows unequivocal intrachain F correlations (Figure 49)[103] while Sr_3ZnIrO_6, where only the Ir site is S = 1/2, is a Heisenberg alternating chain AF. Finally, by exploiting the fact that for $A = Cu^{2+}$, the B = Pt phase is AF and the B = Ir phase is F with respect to intrachain correlations, a random quantum (S = 1/2) spin chain material can be realized for $Sr_3CuPt_{0.5}Ir_{0.5}O_6$ and the experimental susceptibility curves are in excellent agreement with detailed theory.[104]

$Sr_3A^{1+}Ru^{5+}O_6$ and $Ca_3A^{1+}Ru^{5+}O_6$, A = Li, Na. This series features the Ru^{5+} ion (t_{2g}^3, S = 3/2) as the only magnetic species. In general, these materials show only weak evidence

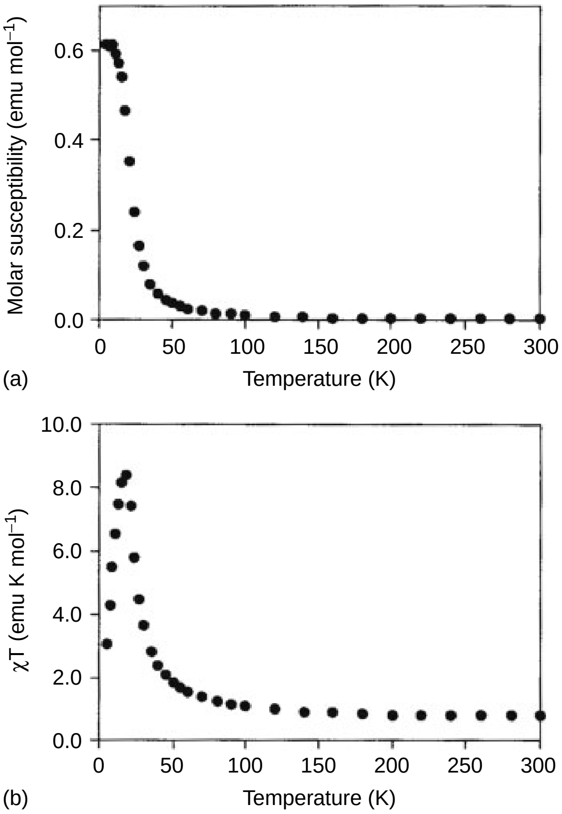

Figure 49 Magnetic susceptibility (a) for Sr_3CuIrO_6 and χT versus T (b), giving clear evidence for intrachain ferromagnetic correlations. (Reprinted from Ref. 103, © 1995, with permission from Elsevier)

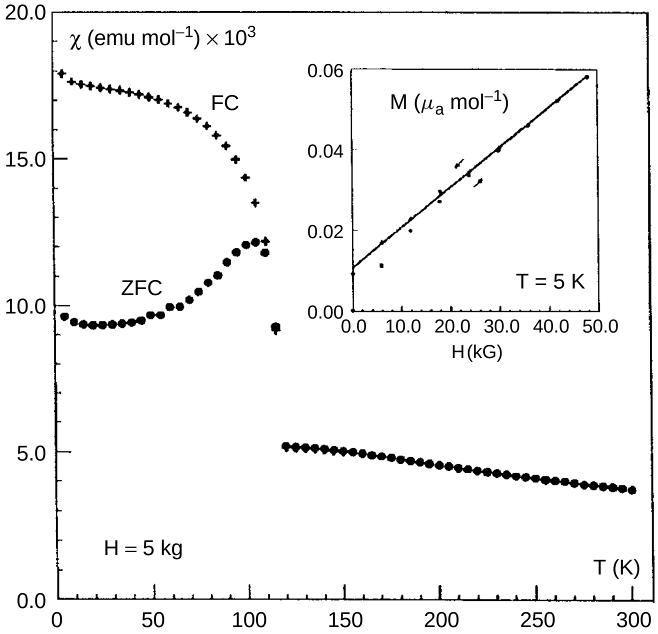

Figure 50 Long-range, three-dimensional magnetic order for Ca_3LiRuO_6 near 120 K. (Reprinted from Ref. 105, © 1997, with permission from Elsevier)

for intrachain magnetic correlations and all show large, negative Weiss temperatures and long-range AF magnetic order at rather high temperatures, $T_N = 120$ K(Ca,Li) to 70 K (Sr,Na) (Figure 50).[105] Thus, in this set of compounds the interchain correlations seem to be dominant, exactly opposite to the case just discussed above. Similar observations are reported for other B = Ru compounds such as Ca_3CoRuO_6, which exhibits long-range 3D order at relatively high temperatures with little evidence for intrachain correlations.[106]

$Ca_3B^{2+}Mn^{4+}O_6$, B = Ni, Zn. Examples in which both the A(trigonal prismatic) and B(octahedral) sites are occupied solely by 3d transition elements also exist. Cases in which Mn^{4+} (t_{2g}^3, $S = 3/2$) occupy the octahedral sites have been studied.[107] Ca_3NiMnO_6 gives indications of significant intrachain SRO in the form of a broad susceptibility maximum near 100 K, whereas AF long-range order, albeit of a complex spiral type, sets in only below 20 K according to neutron diffraction results. Not surprisingly, the corresponding Zn phase shows no evident intrachain coupling and $T_N = 25$ K.

$Ca_3Co_2O_6$. This interesting material with the same ion, Co^{3+}, on the octahedral and trigonal prismatic sites is perhaps the best studied material in this structure class. While it seems reasonably clear that Co^{3+} is LS, $S = 0$ on the octahedral site, the spin state for the A site Co^{3+} appears to be an effective $S' = 1$, brought about by a highly anisotropic g-tensor, wherein $g_z \sim 4.5$.[108] The intrachain exchange coupling is unequivocally F with $\Theta_c = 28(3)$ K.[109] Long-range order appears to set in below 25 K but the ground state is complex and highly sensitive to applied fields (Figure 51), which shows a large number of meta-magnetic type transitions.[110]

5.4 Geometrically Frustrated Magnetic Materials

The final broad category of magnetic oxides to be discussed in this chapter are those that are subject to what is known as geometric magnetic frustration (GFM). Most of the key materials in this class are either rare earth or d group transition metal oxides or both. What is meant by geometric frustration? In principle, the Third Law of Thermodynamics dictates that $S \rightarrow 0$ as $T \rightarrow 0$. For magnetic systems at high temperatures, spin disorder makes a significant contribution to the total entropy. As the temperature decreases, the magnetic entropy can be quenched by formation of long-range ordered states of the type that have been discussed in the preceding sections. In nature, most such ordered states are AF. However, for particular lattice geometries or topologies, an impediment can arise to entropy removal, as illustrated in Figure 52, which shows possible AF spin orderings on 'plaquettes' of various simple geometries such as the square (c,d,e), the equilateral triangle (a), and the tetrahedron (b).[110] For a square

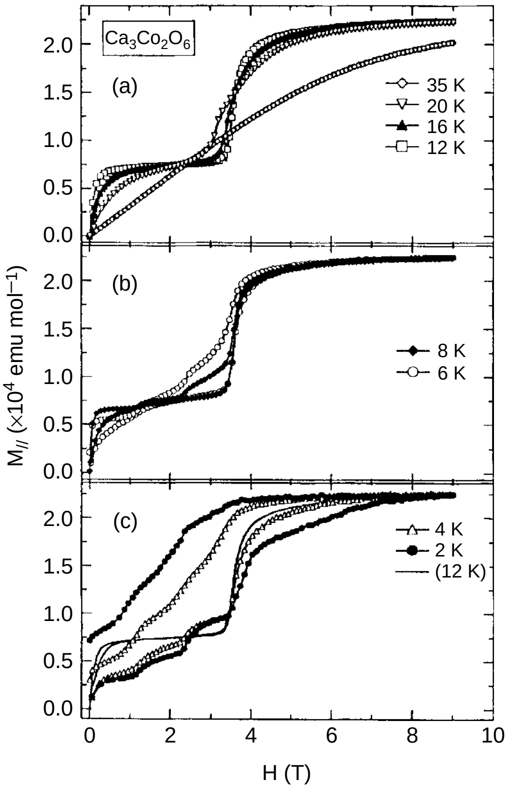

Figure 51 Complex behavior in applied magnetic fields of $Ca_3Co_2O_6$. (Ref. 108. Reproduced by permission of Physical Society of Japan)

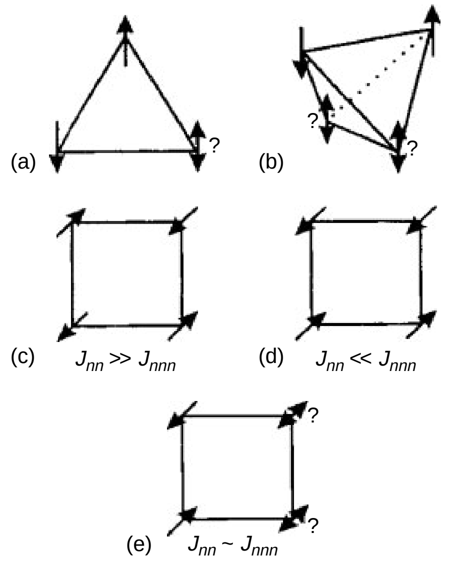

Figure 52 AF spin correlations on 'plaquettes' of square-planar, triangular, and tetrahedral geometries. (Ref. 110. Reproduced by permission of Royal Society of Chemistry.) Plaquettea a, b, and e picture geometrically frustrated situations

plaquette with the condition $J_{nn} \gg J_{nnn}$ or $J_{nnn} > J_{nn}$ (J is the magnitude of the exchange coupling interaction between either nearest neighbor, nn, or next nearest neighbor, nnn, spins), there is no difficulty in finding an AF ordering but for the triangular case it is clear that only two of the three spins can be rigorously antiparallel, one corner is always unsatisfied or 'frustrated'. The situation is worse for the tetrahedron wherein two of the four nn interactions are frustrated. Even the square lattice can be frustrated if $J_{nn} \sim J_{nnn}$, although this situation may be difficult to realize experimentally. In general, the combination of a triangular plaquette motif and $J_{nn} < 0$ (i.e. an AF constraint) are necessary conditions for geometric magnetic frustration. In general, systems with $J_{nn} > 0$ (F constraint) are not frustrated with one notable exception to be discussed later.

In real materials, the spins reside on the sites of infinite lattices, which can be considered to arise from the condensation of plaquettes. Figure 53 shows a representative but not exhaustive set of frustrating lattices, which involve the condensation by either corner or edge-sharing of triangles or tetrahedra.[110] Such lattices are quite common in nature, especially the edge-sharing triangular and face-centered cubic lattices and even the pyrochlore lattice, so geometric frustration is not a rare condition.

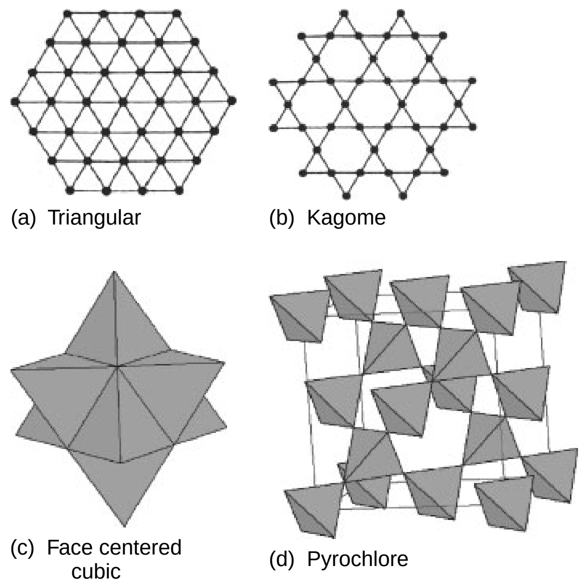

Figure 53 Representative 'frustrated' lattices in two and three dimensions. (Ref. 110. Reproduced by permission of Royal Society of Chemistry)

5.4.1 *Experimental Signs of the Presence of Geometric Frustration*

A commonly used criterion is the so-called frustration index, which is simply the ratio of the modulus of the Weiss temperature to the 'ordering' temperature, $|\Theta_c|/T_O$, where ordering can be of the usual long-range type or a

more exotic variety such as spin-glass freezing.[111] The idea here is that the quantity $k_B\Theta_c$, where k_B is Boltzmann's constant, sets the mean field energy scale for magnetic exchange coupling. Therefore, some form of magnetic order is expected at a temperature near Θ_c/n where n is number ranging from 1 → ∼4 for nonfrustrating lattices. For many geometrically frustrated materials, one finds $|\Theta_c|/T_O > 10$, although there can be exceptions. Another fairly reliable sign is the absence of evidence of a long-range ordered ground state from neutron diffraction or specific heat measurements at the lowest temperatures, often $T < 1$ K as discussed in the following section.

5.4.2 *Ground States in Geometrically Frustrated Magnets (GFM's)*

Noncollinear 120° or 109° States: Chirality. Some frustrated materials find a truly long-range ordered state but one in which the spin arrangement is not collinear, such as those depicted in Figure 54, the 120° and 109° structures, which can arise on the triangular and pyrochlore lattices, respectively.[110] These are clearly AF ground states as the vector sum of the spins = 0 for each plaquette. The 120° structure is commonly found for oxides with triangular magnetic sublattices but the 109° case is known for only one material, the metastable pyrochlore form of FeF_3. Note that these noncollinear structures possess chirality, a concept familiar to chemists (Figure 55), and, thus, the ground state is degenerate.

Spin Glasses, Spin Liquids, and Spin Ices Macroscopic Degeneracy. Another ground state commonly found in GFM materials is the spin glass (SG) state, although its occurrence

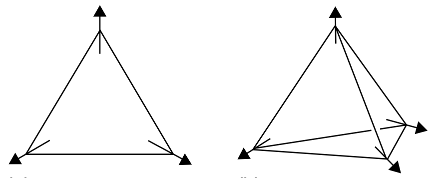

Figure 54 Noncollinear AF magnetic structures, 120° for the triangular lattice and 109° for the tetrahedral lattice. (Ref. 110. Reproduced by permission of Royal Society of Chemistry)

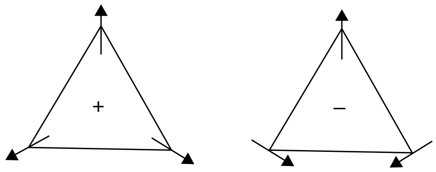

Figure 55 Chirality in the 120° triangular lattice

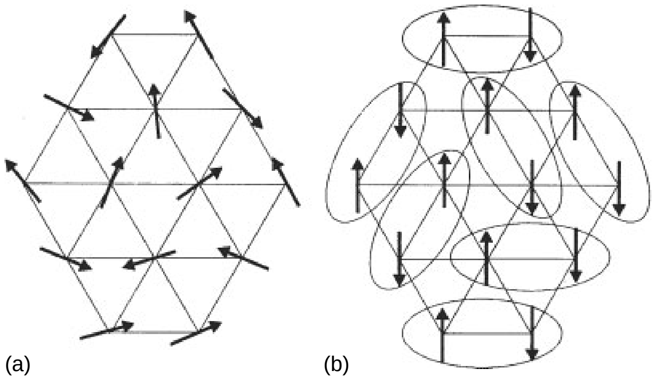

Figure 56 Representations of the spin glass (a) and spin liquid (b) ground states

is not understood in detail. Here the spins literally freeze into a random, static array below a characteristic temperature, T_f, which is akin to the glass transition temperature, T_g, in positional glasses or polymeric materials (Figure 56(a)). Normally, both positional disorder and frustration are considered to be twin necessary conditions for the formation of the spin glass state but many GFM's exhibit something like a canonical SG state in the apparent absence of detectable positional disorder, as will be discussed later. A striking feature of the SG state is that it is essentially infinitely degenerate. That is, there exists a nearly infinite set of random spin orientations with essentially the same energy.

An even more exotic possibility is the spin liquid (SL) as first proposed by Anderson (with apologies to Linus Pauling) for quantum, $S = 1/2$, spins. Here (Figure 56(b)), the spins form singlet dimers, as in Pauling's valence bond theory, but the state remains dynamic and fluctuating to $T = 0$ K. The SL state is quite remarkable in that long-range static order is never realized in spite of strong spin–spin correlations. The SL state is rare. Equally exotic is the spin ice state, which will be discussed in more detail in the context of some pyrochlore structure oxides in a following section.

Most of the key GFM materials are oxides and a brief description of some of these follows. There exist a number of fairly recent reviews including References.[110–115]

5.4.3 *Rare Earth Transition Metal Pyrochlores*

The Pyrochlore Structure. This structure is described in Fd3m and contains 88 atoms per unit cell, so figures of the full structure can be confusing. There are some similarities with the perovskite structure in that two ions of very different size are involved, the larger is usually a Ln^{3+} ion and the smaller a T^{4+} ion. A network of corner-sharing octahedra forms of composition TO_3 but the network is very rigid relative to perovskite. A partial view of the network is shown in Figure 57. The T–O–T angle is constrained near a value of ∼130°, and is not a strong function of the size of the

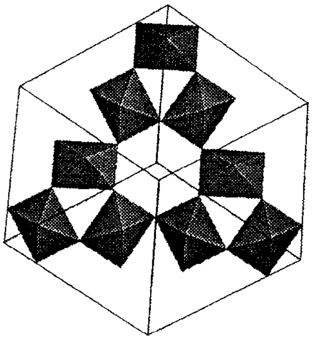

Figure 57 Part of the corner-sharing B_2O_6 network in the pyrochlore structure. The A^{3+} ions reside in the hexagonal channels

Ln^{3+} partner. The Ln^{3+} ions occupy the large hexagonal channels and are 8-fold coordinated in a highly distorted site with two very different Ln–O distances and pronounced axial symmetry (Figure 58). The axis of symmetry is along the various ⟨111⟩ directions of the cubic pyrochlore cell, a fact that will be of great importance in the so-called 'spin ice' materials. The Ln^{3+} ions and the T^{4+} ions occupy the 16d and 16c sites, respectively, in Fd3m. In both cases, the site topology consists of a corner-sharing network of tetrahedral, one of the canonical frustrated lattices of Figure 53.

$Ln_2Ti_2O_7$.Ln = Gd, Tb, Dy, Ho. The rare earth titanates that crystallize in the so-called pyrochlore structure have received much attention. Here only the Ln^{3+} site is magnetic as Ti^{4+} is a $3d^0$ ion. These four materials exemplify the variety of exotic magnetic phenomena that can be found in frustrated pyrochlores.

$Gd_2Ti_2O_7$ represents the case where the Ln single ion magnetism should be simplest as Gd^{3+}, $4f^7$ ($^8S_{7/2}$), has no orbital contribution to first order and will be least affected by the axial crystal field. The compound obeys the Curie-Weiss law down to ∼10 K, giving

$\mu_{eff} = 7.9\,\mu_B$, as expected for $S = 7/2$ and $\Theta_c = -9.6$ K. Measurements on $(Gd_{0.02}Y_{0.98})_2Ti_2O_7$ show that $\Theta_c \to 0$ K, indicating that Gd–Gd interactions determine Θ_c for the

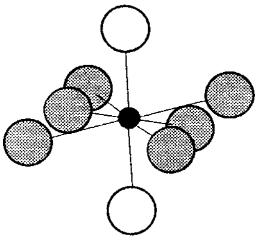

Figure 58 Coordination of the A-site in the pyrochlore structure. The axial oxygens (open circles) are at ∼2.2 Å and the equatorial oxygens (grey circles) are at ∼2.6 Å. (Ref. 110. Reproduced by permission of Royal Society of Chemistry)

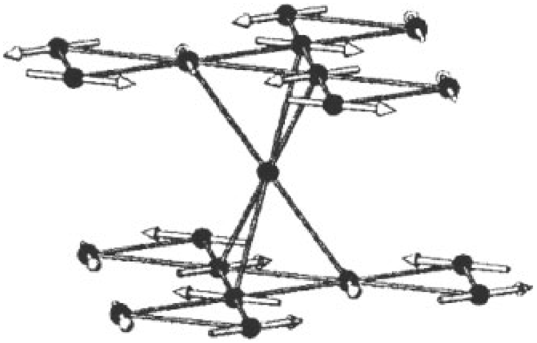

Figure 59 The magnetic structure of $Gd_2Ti_2O_7$ at 50 mK showing the Kagome type planes separated by paramagnetic Gd^{3+} ions on a planar triangular lattice. (Reprinted with permission from J.M.D. Champion, A.S. Wills, T. Fennell, S.T. Bramwell, J.S. Gardner, M.A. Green, *Phys.Rev.*, 2001, **B64**, R140407. © 2001 by the American Physical Society)

undiluted material. A phase transition occurs at 0.97 K and another at about 0.75 K, as detected by specific heat and susceptibility.[116,117] Thus, $|\Theta_c|/T_c \sim 10$ and one criterion for the presence of frustration is satisfied. Theoretical considerations suggest that Gd–Gd exchange makes the largest contribution to Θ_c with a secondary contribution from magnetic dipole–dipole interactions. The magnetic structure was determined using neutron diffraction on an isotopically substituted ^{160}Gd sample and the result is remarkable (Figure 59).[118] The experiment shows only partial order with the spins aligned in a noncollinear manner in the Kagome planes (the pyrochlore lattice can be constructed by stacking Kagome layers in an ...ABCABC... manner, see Ref. 110) but with uncoupled spins in alternating layers. Thus, $Gd_2Ti_2O_7$ finds a partially ordered ground state but with significant dynamics even at temperatures as low as 50 mK (well below the two-phase transitions seen in specific heat).

$Tb_2Ti_2O_7$ presents a sharp contrast to $Gd_2Ti_2O_7$. Tb^{3+} ($^7F_6$) will be strongly influenced by the crystal field. The Curie-Weiss law is also obeyed but with $\Theta_c = -18.9$ K. Experiments on a diluted sample with 2% Tb in $Y_2Ti_2O_7$ indicate a residual $\Theta_c = -6$ K, demonstrating a substantial 'crystal field' contribution. The effects of the crystal field have been investigated via calculations and neutron inelastic scattering with the result that the ground state is a doublet with the nearest excited state (doublet) at only 18 K above and other levels at 115 and 168 K.[119] Thus, $Tb_2Ti_2O_7$ can be regarded as an Ising system with a effective spin ground state, $S' = 1/2$. Extensive searches with neutron scattering, specific heat, muon spin relaxation and other probes have failed to find any evidence for long-range order down to 50 mK.[120] Yet, neutron scattering shows significant short range magnetic correlations even up to 50 K (Figure 60),[121] suggesting strongly that this material is an example of the rare and elusive spin liquid ground state. Finally, it has recently

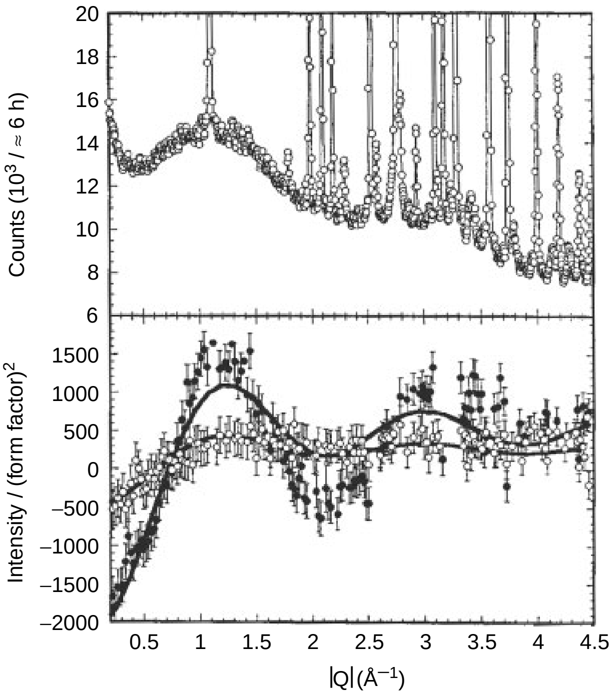

Figure 60 Short range magnetic correlations in $Tb_2Ti_2O_7$ at various temperatures up to 50 K. The x-axis is $Q = 4\pi \sin\theta/\lambda$. (Reprinted with permission from J.S. Gardner, S.R. Dunsiger, B.D. Gaulin, M.J.P. Gingras, J.E. Greedan, R.F. Kiefl, M.D. Lumsden, W.A. MacFarlane, N.P. Raju, J.E. Sonier, I. Swainson, Z. Tun, *Phys.Rev.Lett.*, 1999, **82**, 1012. © 1999 by the American Physical Society)

been shown that long-range order can be induced in applied fields of ~9 GPa.[122]

$Dy_2Ti_2O_7$ and $Ho_2Ti_2O_7$ are widely regarded as examples of 'spin ice' ground-state materials and a very nice summary of this phenomenon is available.[115] The spin ice state depends on two conditions: one, that the magnetic moments be constrained by anisotropy to lie parallel to the ⟨111⟩ directions and two, that the correlations be ferromagnetic. The first condition results from the strong axial crystal field at the Ln^{3+} site which creates a well-isolated ground state Ising like doublet with a ground-state wave function composed primarily of components with +/− M_J(max) where $M_J(\max) >= J$, the total angular momentum ($J = 8$ for Ho and 15/2 for Dy). The unusual ferromagnetism in these two materials is traceable to long-range magnetic dipole–dipole interactions. With these constraints, the spin configuration in a given tetrahedron must be of the 'two in, two out' type as shown in Figure 61(b). Within a single tetrahedron, the ⟨111⟩ directions are vectors that point from the corners to the midpoint of the opposite face. The connection to water ice arises in considering the environment of any given oxygen atom. There must be two short bonds to hydrogen (covalent) and two long bonds (hydrogen bonds) (Figure 61(a)), and these are known as the 'ice rules'. As the ice rules are a local constraint, there are a macroscopic number of ways to satisfy them over the entire lattice, which leads to a degeneracy shown by Linus Pauling to be $\sim(3/2)^{N/2}$, where N is the number of oxygen atoms in the lattice, that is, a macroscopic degeneracy as $N \sim 10^{23}$.[123] There is, thus, a residual entropy due to this macroscopic disorder, which is $S = (R/2)\ln(3/2)$ where R is the gas constant. The observation of a residual entropy is the determining criterion of the spin ice state and such evidence is shown for $Dy_2Ti_2O_7$ (Figure 62).[115,124]

It is remarkable that the nature of the ground state in these pyrochlores can be modified so strongly from a mixed long-range/short-range order (Gd) to a completely dynamic spin liquid (Tb) to a spin ice (Dy,Ho) simply by substituting one rare earth ion for another.

Other Pyrochlores, $Y_2Mo_2O_7$ and $Tl_2Mn_2O_7$. $Y_2Mo_2O_7$ is one of the most extensively investigated GFM materials.[110] It behaves as a canonical spin glass with a very well defined $T_f = 22$ K but diffraction studies indicate a crystallographically well-ordered material. Normally, both positional disorder and frustration are requirements to stabilize the spin glass ground state. Some evidence for a type of short

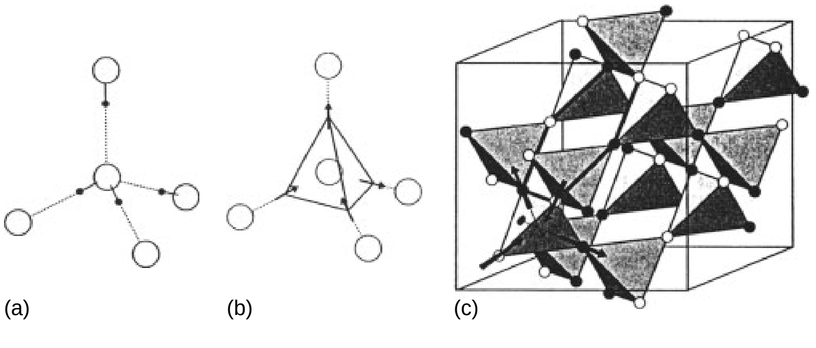

Figure 61 The connection between 'spin ice' and water ice. (a) The two short, two long O–H bonds about a single O atom in water ice. (b) The two in, two out configuration (obeying the 'ice rules') in any tetrahedron for a F Ising model. (c) One possible ground state of an infinitely degenerate set for a 'spin ice'. Figure 62 Heat capacity and entropy for $Dy_2Ti_2O_7$ showing the excess entropy, experimental evidence for the spin ice state.[115,124] (Reprinted by permission from Nature Ref. 124, © 1999 Macmillan Publishers Ltd. www.nature.com)

range disorder has been claimed from EXAFS studies.[125] Unfortunately, no attempt has been made to reconcile this observation with the diffraction studies and the disorder level is not easy to quantify but it appears to be inadequate to explain, quantitatively, such a large T_f.

$Tl_2Mn_2O_7$, while not a GFM, is remarkable in that it shows a transition from an insulating to a ferromagnetic, metallic state at 121 K.[126] Shortly after this report, CMR was discovered in this material, which was shown to contain only Mn^{4+} and, thus, the mechanism must be very different from that causing CMR in the perovskite manganates.[127,128] This mechanism is still not well understood.

Spinel Structure Oxides. Oxides with the spinel structure have composition AB_2O_4 and are also described in the cubic space group Fd3m. For a so-called 'normal' spinel, A^{2+} ions occupy tetrahedral sites but the B^{3+} ions occupy the 16d positions. Thus, the B ions form a pyrochlore sublattice and are potential GFM materials, a possibility noted as long ago as 1956![129] Several B-site magnetic spinels have been investigated recently but brief accounts will be given for two materials, $ZnCr_2O_4$ and the system $Li_{1+/-x}Mn_2O_4$.

$ZnCr_2O_4$ shows typical signs of GFM behavior with $\Theta_c = -330$ K but no sign of magnetic order until $T_N = 12.5$ K, a frustration index ~26.[130,131] The magnetic phase transition is remarkable in that it is first order rather than continuous as is usually found and there is a simultaneous crystallographic phase transition and a large dielectric anomaly. There is evidence for short range AF clustering at temperatures >100 K. These facts have led to speculation that the crystallographic phase transition is driven by a need to relieve the geometric frustration and arguments in terms of strain energies and magnetic energies.[130] Interestingly, as of yet the details of the low-temperature crystal and magnetic structure have not been determined. Arguments for both tetragonal and orthorhombic symmetry for the crystal structure have been advanced.[132] Finally, this material is extremely sensitive to positional disorder; only 3% substitution of Ga^{3+} for Cr^{3+} and 5% Cd^{2+} for Zn^{2+} can induce a spin glass ground state.[133]

For $Li_{1+/-x}Mn_2O_4$, x can vary from -1 to $+1$ and three compositions have been studied in detail, $x = -1$ (λ-MnO_2), $x = 0$ ($LiMn_2O_4$), and $x = +1$ ($Li_2Mn_2O_4$). The crystal structures are shown in Figure 63.[110]

$LiMn_2O_4$ is a normal spinel, with mixed Mn^{3+}/Mn^{4+} valence. There is a structural CO phase transition near 280 K to an orthorhombic form, Fddd, with a unit cell of nine times the volume of the Fd3m cell, but the CO appears to be partial.[134] Magnetic order does not occur until $T_c = 60$ K and the ground state is remarkable.[135] Approximately half of the magnetic scattering, measured by polarized neutron methods, is involved in long-range order of a very complex structure yet to be determined (the magnetic cell may involve 1152 spins!) and half is involved in a very short range order with correlation length of about 2 Mn nearest neighbors.

λ-MnO_2 is a spinel with empty A-sites and only Mn^{4+}. This compound orders with $T_N = 32$ K in a very complex magnetic structure with 128 spins per cell, indicative of a high level of frustration. A possible magnetic structure is shown in Figure 64.[136]

The all Mn^{3+} phase, $Li_2Mn_2O_4$, which is tetragonal ($I4_1$/amd) due to a static Jahn–Teller distortion, is perhaps the most remarkable of all. Θ_c is at least -600 K and yet no long-range order occurs down to 1.5 K. Instead a strange two dimensional order sets in at ~60 K, which can be understood as ordering in completely uncoupled Kagome planes, related to the situation in $Gd_2Ti_2O_7$.[137]

Other Pyrochlore Related Materials, Kagome Lattices, Jarosites, and SCGO. In contrast to the three-dimensional GFM pyrochlores and spinels, real examples of the Kagome lattice are very rare. The best examples are the Fe^{3+} based jarosite structure materials of composition $AFe_3(SO_4)_2(OH)_6$, where A is a group I ion or H_3O^+. The Kagome nets (see Figure 53) are stacked ...ABCABC... and are well separated. The case of $A = H_3O^+$ is the most unusual. Θ_c for this material is ~ -700 K but no long-range order occurs down to 1.5 K; instead, evidence for two dimensional correlations in the form

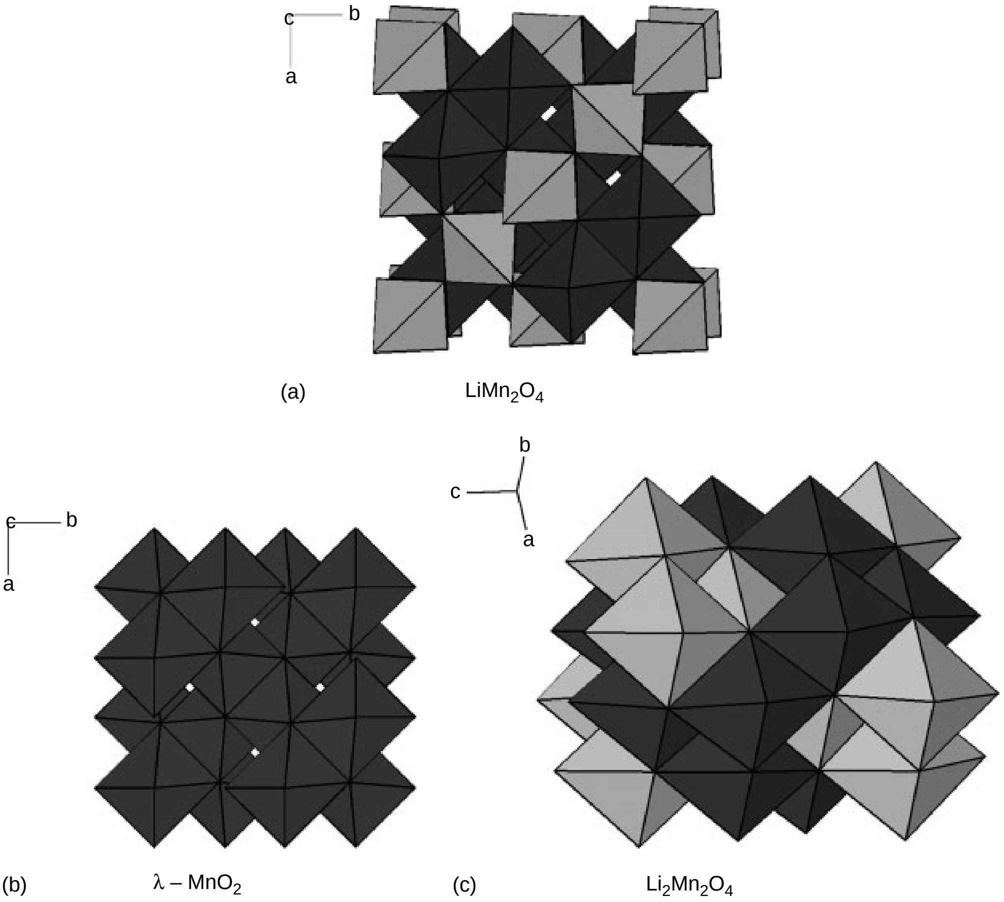

Figure 63 Crystal structures of the spinel structure materials, λ-MnO_2, $LiMn_2O_4$, and $Li_2Mn_2O_4$, in a polyhedral representation. The light colored polyhedra are the Li ions and the dark polyhedra the Mn ions. (Ref. 110. Reproduced by permission of Royal Society of Chemistry)

of an asymmetric Warren peak is seen Figure 65.[138] A phase transition at 13.8 K is thus ascribed to a spin glass freezing.

SCGO, $SrCr_{12-x}Ga_xO_{19}$, has been studied extensively and is covered in many of the earlier reviews.[93] Although often

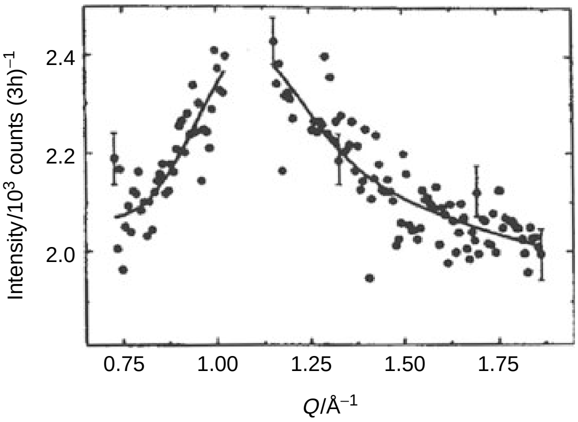

Figure 65 Evidence for short range, two dimensional order from neutron scattering for the jarosite, $D_3OFe_3(SO_4)_2(OH)_6$. Note the asymmetric 'Warren' line shape. (Ref. 138. Reproduced by permission from EDP Sciences)

labeled a Kagome system, in fact the structure is better described in terms of a 'pyrochlore slab' motif (Figure 66).[139]

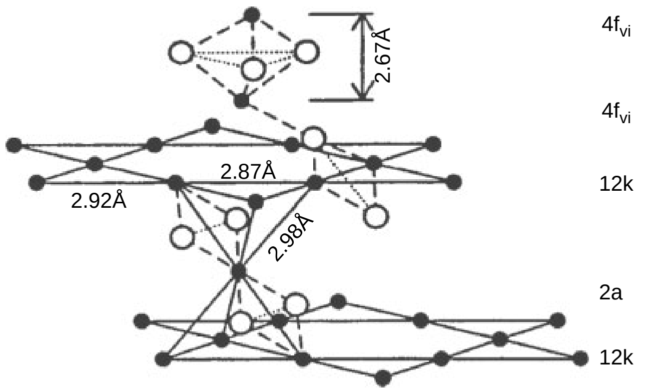

Figure 66 A 'pyrochlore slab' in $SrCr_{12-x}Ga_xO_{19}$. (Reprinted with permission from S.-H Lee, C. Broholm, G. Aeppli, T.G. Perring, B. Hessen, A. Taylor, *Phys. Rev .Lett.*, 1996, **76**, 4424. © 1996 by the American Physical Society)

It shows a huge frustration index of ∼150 with a spin freezing $T_f = 3.4$ K for a sample with 90% coverage of the pyrochlore slabs by Cr^{3+}. Several anomalous properties appear in the specific heat that are still not understood in detail but point to the possible involvement of spin singlets in the ground state.

B-site Ordered Double Perovskites. As mentioned in a preceding section, the B and B′ sites of B-site ordered double perovskites each form a f.c.c. lattice and are therefore potentially frustrated. This connection had not always been realized in earlier work and, indeed, there was often little experimental evidence for frustration. For compounds involving the first-row elements $A_2B'B''O_6$ where A = Ca, Sr, and Ba and B″ = Mo or W, the frustration indices were often in the range of 2–3 with only a few notable exceptions, in particular Ba_2FeBiO_6, f = 17 or Ba_2FeSbO_6, f = 18.[140] With 4d elements, for example, Ba_2LaRuO_6, which contains Ru^{5+} ($4d^3$, S = 3/2), a large f = 10 was noted.[141] Nonetheless, all of these materials with well established B-site order (materials with significant B′ – B″ site mixing are spin glasses) and magnetic B' sites having $S \geq 3/2$ with nonmagnetic B″ ions show long range magnetic order at low temperatures and not the more exotic ground states found for the pyrochlores and spinels.[142] This situation changes when S = 1/2 and possibly S = 1. For the first-row double perovskites, none of the $B' = Cu^{2+}$ materials, such as Sr_2CuWO_6 and Ba_2CuWO_6, show long-range order in spite of very large, negative Θ_c's, −230 K and −180 K, respectively. The absence of LRO in these cases has been discussed in terms of orbital ordering and low dimensionality, as the local symmetry at the Cu^{2+} site is highly distorted from octahedral, but geometric frustration may also play a major role.[143] The role of the spin quantum number is perhaps clearer in another set of perovskites, Sr_2CaReO_6 and Sr_2MgReO_6, both involving Re^{6+} ($5d^1$, S = 1/2), where no strong Jahn–Teller distortion is present to cloud the issue.[144,145] The Ca phase is $P2_1/n$ and the Mg compound I4/m. Despite what is nearly complete B-site ordering, both materials behave as spin-glass like, although the Ca phase shows many anomalous properties, especially in the heat capacity, including an unprecedented T^3 dependence at low temperatures and a robustness of the heat capacity anomaly to fields as large as 6T. It is not yet clear whether the absence of LRO in these materials is related to quantum spin fluctuations, orbital ordering within the t_{2g} manifold, both, or neither.

6 CONCLUDING REMARKS

Magnetic oxides have continued to provide a focus for intensive research over the past 10 years or so and this is unlikely to change for the foreseeable future as many interesting challenges clearly remain. The contents of this article represent a very selective and necessarily somewhat superficial overview of the major themes. The interested reader is urged to consult the numerous references provided for more details. As well, owing to limitations of time and space, topics that have received much attention have been omitted. Such areas include oxides that exhibit low-dimensional phenomena such as the spin-Peierls, spin ladder, and related effects, seen in certain Cu^{2+} and V^{4+} oxides. There is also no mention of the increasing use of ab initio computational methods in the understanding of magnetic structures.

Glossary

Anisotropic exchange: exchange coupling between electrons that is dependent on direction; that is, exchange along the x coordinate, for example, differs from exchange along the y or z coordinates
Antiferromagnet: an ordered magnet in which the individual moments point antiparallel to their neighbors owing to antiferromagnetic exchange
Antiferromagnetic exchange: an exchange interaction that couples adjacent moments antiparallel
Antisymmetric exchange: an exchange coupling process that tends to align the electrons perpendicular to one another; there cannot be a center of inversion between the two sites on which the electrons reside, and the g values must be different
Direct exchange: exchange coupling between electrons on centers that are close enough to one another that there can be direct overlap of the atomic wavefunctions
Dzialoshinski-Moriya exchange: an exchange coupling mechanism that is antisymmetric in nature and tends to align moments perpendicular to each other
Exchange interaction: a process that is responsible for short-range magnetic interactions; it may be thought of as the exchange of coordinates of pairs of electrons
Ferrimagnet: an ordered antiferromagnet formed by antiferromagnetic exchange between inequivalent moments
Ferromagnet: an ordered magnet in which all moments are parallel
Ferromagnetic exchange: an exchange interaction that couples adjacent moments parallel
Indirect exchange: exchange coupling between electrons on centers that require the orbitals of an intermediate group or groups for the process to occur
Ordered Magnet: a magnetic state in which moments have spontaneously aligned themselves owing to the action of short-range or long-range interactions; can be destroyed by sufficient thermal energy
Superexchange: see Indirect Exchange

Abbreviations

C = Curie constant; T_C = Curie temperature; T_N = Néel temperature; Θ = Weiss constant; χ_v = Magnetic susceptibility per unit volume; χ_M = Magnetic susceptibility per mole.

1 INTRODUCTION

The magnetic properties of extended array systems have received considerable attention from both chemists and physicists over the past decades.[1–8] The novel magnetic properties of these materials arise from interactions between paramagnetic sites. The origin of these interactions, known as exchange, is electrostatic and quantum mechanical in nature, as first realized by Heisenberg and Dirac in 1926.[1,2] As described in Section 2, it is possible to interpret exchange as formally equivalent to the vector coupling of spins. This equivalence permits the use of a vector-coupling scheme to model the quantitative behavior of coupled spins with the Heisenberg-Dirac-Van Vleck (HDVV) Hamiltonian[3]

$$H = -2JS_i \cdot S_j \quad (1)$$

where the subscripts i and j correspond to the two different spins and J is the exchange coupling constant. This Hamiltonian may be expanded to encompass many different geometries and to account for anisotropic properties, the latter being especially useful in the application of these materials. In the scientific literature, the HDVV Hamiltonian is used in a variety of forms (with or without the factor of 2, with or without the minus sign) and care must be used to avoid the misinterpretation of a given exchange strength. The exchange constant has units of energy, but is frequently reported in units of temperature (K), or in cm^{-1} where $J = k_B T$ and $1\,cm^{-1} = 1.431\,K$. In this article, a negative exchange coupling constant corresponds to antiparallel alignment of the electron spins, or an antiferromagnetic exchange interaction, while a positive exchange coupling constant denotes parallel alignment of the electrons, or a ferromagnetic exchange interaction.

Basic theoretical concepts of exchange will be developed in this article. Useful theoretical models invented for the rationalization of the results will be described and their use illustrated by descriptions of extended arrays, principally one-dimensional for simplicity. The development of molecular-based magnetism over the past 15 years has been particularly rapid,[9] so emphasis is given to the use of molecular units in

connecting the paramagnetic centers in this article. Surveys of the magnetic properties of extended arrays of a variety of geometries, metal oxidation states, and other diverse chemical features are available.[10–15,]

2 FUNDAMENTALS

It is convenient to classify extended arrays in terms of a scheme based on the specific nature of the exchange coupling between the magnetic units plus the structural dimensionality of the array. (This article will only concern interactions between nearest neighbors.) In this scheme, the magnetic units in the arrays may be either radicals or transition metal ions; the ions themselves may be of mixed valence and there may be more than one type of metal ion.

The magnetic properties of individual transition metal ions in compounds and complexes are considered in (*see* ***Magnetism of Transition Metal Ions***). There, the properties of a given ion are assumed to be independent of the presence of any other ions. However, the possibility of *minor* interactions between ions is taken into account in those cases in which the temperature dependence of the inverse magnetic susceptibility deviates from the Curie law.[11] This was accomplished by inclusion of the Weiss constant Θ and the generation of the Curie–Weiss law. The properties of extended arrays of this type may be primarily understood in terms of single ions, and they will not be discussed here.

Many interesting problems arise when significant interactions between magnetic moments exist in extended arrays of magnetic moments. When the array consists of two dimensions or more, transitions to a state of long-range magnetic order can occur, giving rise to a host of theoretically and technologically important properties. (If the magnetic system contains a finite number of interacting moments, no long-range order is possible but the magnetic behavior can nevertheless be complex (*see* ***Electronic Structure of Clusters***).)

2.1 Origins of Magnetic Exchange

As mentioned in the Introduction, magnetic exchange is both electrostatic and quantum mechanical in nature. It is electrostatic because the relevant energies are related to the energy costs of overlapping electron densities. It is quantum mechanical because of the fundamental requirement that the total wavefunction Ψ of two electrons must be antisymmetric to the exchange of both the spin and spatial coordinates of the two electrons. The wavefunction Ψ is separable into a product of spatial wavefunction $\psi(r_1, r_2)$ that is a function of the positions r_1 and r_2 of the two electrons, and a spin coordinate wavefunction $\chi(\sigma_1, \sigma_2)$, where σ_i is the Pauli matrix for the spin operator: $S_i = \hbar\sigma_i/2$. Both $\psi(r_1, r_2)$ and $\chi(\sigma_1, \sigma_2)$ can be symmetric or antisymmetric individually but the fundamental requirement permits only two combinations, that is,

$$\Psi_T = \psi_A(r_1, r_2)\chi_S(\sigma_1, \sigma_2) \tag{2a}$$

$$\Psi_A = \psi_S(r_1, r_2)\chi_A(\sigma_1, \sigma_2) \tag{2b}$$

The state with the symmetric spin part is labeled the triplet state while the state with the antisymmetric spin part is the singlet state. As seen below in the context of the hydrogen molecule, there is an electrostatic energy difference $\Delta E_{S,T}$ between the singlet and triplet states. By definition this energy difference equals the exchange energy,

$$\Delta E_{S,T} \equiv 2J \tag{3}$$

Consider a two-electron system in which there are two hydrogen nuclei, a and b, each with a positive charge. The Schrödinger equation for this system may be written as

$$(T + V)\psi = E\psi \tag{4}$$

where the kinetic energy term is

$$T = -\frac{\hbar^2}{2m}(\nabla_1^2 + \nabla_2^2) \tag{5}$$

and the potential energy term is

$$V = e^2\left(\frac{1}{r_{1,2}} - \left(\frac{1}{r_{a,1}} + \frac{1}{r_{b,1}}\right) - \left(\frac{1}{r_{a,2}} + \frac{1}{r_{b,2}}\right)\right) \tag{6}$$

The solution to the full Hamiltonian is rendered difficult by the electron–electron repulsion term that depends on $r_{1,2}$. The full solution can be approximated by initially ignoring this term, solving the remaining simplified Hamiltonian, and then reintroducing the term as a perturbation.

In the Heitler-London approach, the full Hamiltonian of equation (4) can be subdivided as follows

$$H = H_1 + H_2 + H_{1,2} \tag{7}$$

$$H_1 = -\frac{\hbar^2}{2m}\nabla_1^2 - \frac{e^2}{r_{a,1}},\ H_2 = -\frac{\hbar^2}{2m}\nabla_2^2 - \frac{e^2}{r_{b,2}},$$

$$H_{1,2} = \frac{e^2}{r_{1,2}} - \left(\frac{e^2}{r_{a,2}} + \frac{e^2}{r_{b,1}}\right)$$

with H_1 depending only on the coordinates of the first electron and H_2 depending only on the coordinates of the second. The Schrödinger equations involving only H_1 or H_2 correspond to that of the isolated hydrogen atom, yielding atomic wavefunctions $U_n(r_1)$, $U_m(r_2)$, and corresponding energies E_n, E_m.

The first approximation to the two-electron solution for the hydrogen molecule can be formed as a linear combination of the two atomic wavefunctions. The combination wavefunction $\psi(r_1,r_2)$ must be indistinguishable under interchange of the

labels of the two electrons so $\psi(r_1,r_2)$ must be either the symmetric or antisymmetric linear combination

$$\Psi_+(r_1, r_2) = N_+ [U_n(r_1)U_m(r_2) + U_m(r_1)U_n(r_2)] \quad (7a)$$

$$\Psi_-(r_1, r_2) = N_- [U_n(r_1)U_m(r_2) - U_m(r_1)U_n(r_2)] \quad (7b)$$

as solutions to the approximate two-electron Schrödinger equation

$$(H_1 + H_2)\psi = E\psi \quad (8)$$

($N+$ and $N-$ are the normalization constants for the symmetric and antisymmetric wavefunctions.) The energies for the molecule can now be calculated to the first order in the perturbation by evaluating the following integral using the approximate wavefunctions of equation (7) and the full Hamiltonian of equation (9).

$$E = \iint \psi^* H \psi dv_1 dv_2 \quad (9)$$

Four separate integrals result from the above equation with the result

$$E_\pm = E_n + E_m + 2N_\pm^2(Q \pm J) \quad (10)$$

where

$$E_n = \int U_n^*(r_1)H_1U_n(r_1)dv_1,\ E_m = \int U_m^*(r_2)H_2U_m(r_2)dv_2$$
$$Q = \iint U_n^*(r_1)U_m^*(r_2)H_{1,2}U_n(r_1)U_m(r_2)dv_1dv_2 \quad (11)$$
$$J = \iint U_n^*(r_1)U_m^*(r_2)H_{1,2}U_m(r_1)U_n(r_2)dv_1dv_2$$

The plus and minus signs for the energies in equation (10) correspond to the energy of the triplet and singlet states, respectively. The difference between these two energies follows from equation (9) as

$$\Delta E_{S,T} = E_+ - E_- = 2N_+^2(Q + J) - 2N_-^2(Q - J)$$
$$= 2Q(N_+^2 - N_-^2) + 2J(N_+^2 + N_-^2) \quad (12)$$

When the one-electron wavefunctions are orthogonal, both $N+$ and $N-$ equal $1/\sqrt{2}$, and we have regained the equivalence of the singlet-triplet energy gap with twice the exchange integral, as described in equation (3). The difference in energy between the symmetric and antisymmetric states is due to the difference in the correlation of the two electrons in their orbits.[7] In one wavefunction, they are more likely to be found close together and in the other, more likely to be further apart. This energy difference has nothing to do with the relative orientation of the electron's moments. However, the fundamental requirement that the total wavefunction be antisymmetric means that the antisymmetric spatial wavefunction is partnered with the symmetric two-electron spin function and visa versa. The spin singlet and triplet state therefore correspond to different energy levels.

Use of the Heisenberg spin Hamiltonian (equation 1) to represent the energy difference of the singlet and triplet spin states is easily demonstrated. Two spins, S_i and S_j, can be added to produce a maximum spin of $S_{\max} = S_i + S_j$, and lower values $S_{\max} - 1$, $S_{\max} - 2$ down to a minimum of $S_i - S_j$. When the two spins are both one-half, the two possible values for the total spin are $S_{\text{tot}} = 1$ and $S_{\text{tot}} = 0$, the spin triplet and singlet, respectively. To evaluate the energies of these states from equation 1, it is necessary to know the value of $S_i \cdot S_j$ for the two states. This can be found by evaluating the vector sum of the spins and employing the basic quantum rule

$$S^2 = S(S + 1) \quad (13)$$

$$S_{\text{tot}}^2 = S_{\text{tot}}(S_{\text{tot}} + 1) = (S_i + S_J)^2 = S_i^2 + S_j^2 + 2S_i \cdot S_j \quad (14)$$

Therefore

$$2S_i \cdot S_j = S_{\text{tot}}(S_{\text{tot}} + 1) - S_i^2 + S_j^2 = S_{\text{tot}}(S_{\text{tot}} + 1) - \frac{3}{4} - \frac{3}{4}$$
$$= S_{\text{tot}}(S_{\text{tot}} + 1) - \frac{3}{2} \quad (15)$$

where we have used $S^2 = (1/2)(3/2) = 3/4$ for a spin one-half.

$$S_{\text{tot}} = 1 : 2S_i \cdot S_j = 1(1 + 1) - \frac{3}{2} = \frac{1}{2}$$
$$S_{\text{tot}} = 0 : 2S_i \cdot S_j = 0(0 + 1) - \frac{3}{2} = -\frac{3}{2} \quad (16)$$

From equation (1), the energy eigenvalues for the two spin states can be evaluated as

$$E_{S=1} = -J_{i,j}\left(\frac{1}{2}\right) = -\frac{J_{i,j}}{2}$$
$$E_{S=0} = -J_{i,j}\left(-\frac{3}{2}\right) = +\frac{3J_{i,j}}{2} \quad (17)$$

leading to the expected result for the singlet-triplet energy gap

$$\Delta E_{S,T} = E_{S=0} - E_{S=1} = +\frac{3J_{i,j}}{2} - \left(-\frac{J_{i,j}}{2}\right) = 2J_{i,j} \quad (18)$$

In the antiferromagnetic case in which the exchange constant is negative, the singlet state lies an energy $2J$ below the triplet state.

The argument above establishes the formal equivalence between the HDVV Hamiltonian and the singlet-triplet energy gap, but such a formal definition is of little use. Calculating energy levels from first principles requires extensive basis sets and much computing effort. The uncertainties in any energy

level can easily be as large as the small differences between adjacent singlet and triplets states, typically a few hundreds of wavenumbers or less. What is needed in practice is an approach that can describe trends in exchange strength as a function of observable parameters such as bond distances or angles. This approach permits a conversation between the theoretical modeling and experimental discoveries, as described in the following section.

2.2 Superexchange Models and Magnetostructural Correlations

An important advance in magnetochemistry was the discovery by Hatfield and coworkers[16] that the exchange strength in a family of planar hydroxo-bridged copper dimers (Figure 1) varied linearly with the Cu–O–Cu bridging angle Φ over a range of $2J$ from $+170\,\mathrm{cm}^{-1}$ ($\Phi = 95.5°$) to $-510\,\mathrm{cm}^{-1}$ ($\Phi = 104.1°$) with ferromagnetic exchange occurring for bridging angles of less than 98°. Their data were well described by the empirical equation

$$2J(cm^{-1}) = 7270\,\mathrm{cm}^{-1} - 74(\mathrm{cm}^{-1}/°)\Phi \tag{19}$$

This correlation demonstrated that exchange strength was not strictly bipolar, strictly ferro- or antiferromagnetic in sign, but was rather a *tunable* quantity subject to modification by chemical/structural means. Its discovery led to a renewed interest[17–19] in superexchange theory with emphasis on the use of molecular orbital models (see Ref. 11 for a lucid description). A similar correlation was found[20] for dichlorobridged copper dimers with ferromagnetic exchange occurring for angles less than 90°.

Kahn and coworkers introduced the useful concept of natural magnetic orbitals.[18] For two paramagnetic centers A, B bridged by a ligand X, the natural magnetic orbital a in AXB is defined as the singly occupied molecular orbital for the AX fragment in its local ground state, while b is defined the same way for the XB fragment. The interaction between A and B leads to two molecular states, a singlet and triplet separated by $2J$. If the interaction is weak enough for the spin states to be described by Heitler-London wave functions built up of a and b, and if the metal–metal charge-transfer configuration is too high in energy to couple significantly with the ground-state configuration, then it is possible to express the exchange as the sum of two components: a positive ferromagnetic component J_F and a negative antiferromagnetic component J_{AF}:

$$2J = 2J_F + 2J_{AF} \tag{20}$$

where

$$J_F = 2j \tag{21}$$

$$J_{AF} = -2S(\Delta^2 - \delta^2)^{1/2} \tag{22}$$

S is the overlap integral between the magnetic orbitals, and j is the two-electron exchange integral.

$$S = \int \Phi_A^*(1)\Phi_B(2)\,\mathrm{d}v_1 \tag{23}$$

$$j = \int \Phi_A^*(1)\Phi_B^*(2)\frac{1}{r_{1,2}}\Phi_A(2)\Phi_B(1)\,\mathrm{d}v_1\,\mathrm{d}v_2 \tag{24}$$

Δ is the energy gap between the two molecular orbitals in the A–B dimer constructed from the magnetic orbitals for the triplet state and δ is the energy gap between Φ_A and Φ_B (Figure 2). When the two paramagnetic centers are identical, $\delta = 0$ and J_{AF} is simplified to

$$J_{AF} = -2S\Delta \tag{25}$$

The net interaction then depends on two distinct and competing terms: the two-electron exchange integral that favors the triplet state, and the product of the overlap integral and the energy gap that favors the singlet state. To first order the energy gap is proportional to the overlap integral so J_{AF} varies as $-S^2$. The smooth variation in exchange strength with bridging angle observed by Hatfield for the hydroxy-bridged copper dimers can now be understood in terms of different angular dependencies for the exchange integral j and the overlap integral S. (Including the interaction between the ground-state configuration and the charge-transfer configuration adds additional terms to J_{AF} that are also

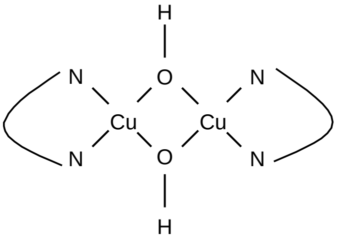

Figure 1 Model of a hydroxide bridged copper dimer

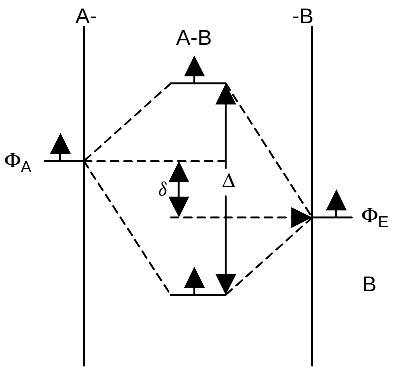

Figure 2 The orbital interaction in a dimer, AB

proportional to the overlap integral so the qualitative picture is not affected by ignoring it. See Reference 11, Chapter 8.)

A similar molecular orbital analysis on the copper dimer system (Figure 1) was performed by Hay *et al.*,[19] leading to the following formula for the singlet-triplet gap,

$$E_S - E_T = 2K_{ab} - \frac{(\varepsilon_S - \varepsilon_A)^2}{J_{aa} - J_{ab}} \qquad (26)$$

where K_{ab} is the two-electron exchange integral (equation 24), $\varepsilon_1 - \varepsilon_2$ is the difference between the two orbital energies, and J_{aa} and J_{ab} are the one-center and two-center Coulomb repulsion integrals. These authors focused on the quantity $(\varepsilon_S - \varepsilon_A)$ since the denominator was assumed to vary slowly as a function of distortion for closely related compounds.

The relative order of ε_1 and ε_2, or equivalently ε_S and ε_A, is determined by the metal-bridging ligand overlap. The metal orbitals for Φ_A and Φ_S are required by symmetry to remain *xy* for all M–L–M angles (see Figure 3). On the bridging atoms, there is one symmetry adapted combination of p orbitals $(y_1 + y_2)$ that interacts with Φ_S and another combination $(x1 + x2)$ that interacts with Φ_A. The oxygen 2s orbitals can interact with Φ_S but not with Φ_A.

The relative order of ε_S and ε_A as a function of bridging angle θ will be determined by the metal-bridging ligand overlap. At $\theta = 90°$, the overlaps are equal, the energies of ε_S and ε_A will be equal and one expects ferromagnetic exchange. As θ increases (Figure 4a), the overlap between ⟨xy|x⟩ will increase while the overlap between ⟨xy|y⟩ decreases. This leads to an increase in ε_A and a decrease in ε_S. One then expects to see an increased antiferromagnetic interaction as $(\varepsilon_A - \varepsilon_S)^2$ grows. In Figure 4(b), the energies of the two highest metal orbitals in $Cu_2(OH)_2Cl_4{}^{2-}$ are plotted as a function of bridge angle θ. If the effect of the 2s bridge orbitals are ignored, the energies cross near 107°. Including the ⟨xy|2s⟩ effect lowers ε_S and brings the crossing point to $\theta = 96°$, close to the observed angle for the Hatfield dimers. It is interesting to note the smallest bridge angles structurally accessible closely correspond to the crossover point. The results from Figure 4 predict that the exchange would once again turn antiferromagnetic for angles significantly smaller than 96°, but such compounds have not been discovered.

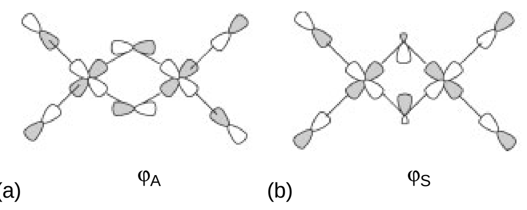

Figure 3 Orbital overlap in copper dimers

The dependence of J_{AF} upon S also provides insight into constructing A–B interactions that are predominately ferromagnetic in character. When the overlap integral is small enough for $J_F > |J_{AF}|$, the triplet state will be stabilized. The overlap orbital can sometimes be sufficiently tuned by geometrical parameters for this to occur, as illustrated above for Hatfield's dimers. When S vanishes at some special angle, the magnetic orbitals are said to be *accidentally* orthogonal.

A more systematic approach for obtaining ferromagnetic exchange is to make use of magnetic orbitals that are *strictly* orthogonal to one another by symmetry requirements. This will occur when the *a* and *b* orbitals transform as different irreducible presentations of the symmetry group of the system. As was pointed out by Kahn,[11] strict orthogonality is more easily achieved when the two interacting paramagnetic centers are not identical.

An elegant illustration of this principle is found in the binuclear metal complex MM(fsa)$_2$en·MeOH, where

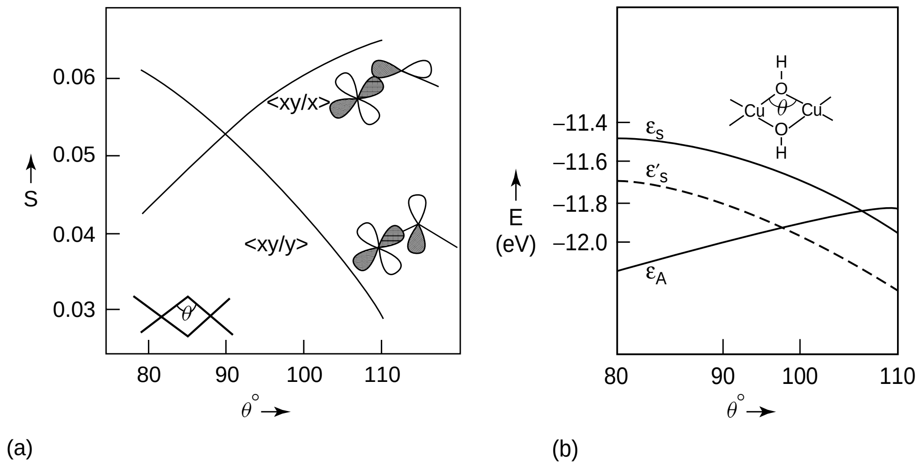

Figure 4 (a) Variation of metal–ligand overlap S in a bibridged dimer geometry as a function of bridging angle. (b) Energies of the highest metal orbitals in $Cu_2(OH)_2Cl_4{}^{2-}$ as a function of bridge angle. The solid line ε_S ignores the 2s bridge orbital effect, the dashed line considers it. The ε_A line does not depend on the oxygen 2s contribution. (Reprinted with permission from Ref. 19 © 1975 American Chemical Society)

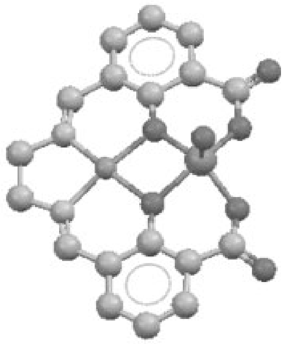

Figure 5 Perspective view of CuVO(fsa)2en·MeOH. The copper site is on the left side of the cage, the vanadyl to the right. The methanol molecule is not shown for clarity[21]

H_4(fsa)2(en)=N,N'-(2-hydroxy-3-carboxybenzilidene) ethylenediamine (see Figure 5).[21] The copper (II) and vanadium(IV) sites, the oxygen atom of the vanadyl group and the methanol oxygen atom weakly bonded to the copper atom (not shown) are very close to forming a mirror plane perpendicular to the plane of the macrocycle. The unpaired copper electron therefore has close to a pure *xy*-type wavefunction transforming as a'' while the unpaired electron around the vanadium is described by a $x^2 - y^2$ magnetic orbital transforming as a'. Strict orthogonality of the two orbitals is obtained and, as expected the triplet state is stabilized by 118 cm^{-1} below the singlet state. Replacing the vanadyl group with a second copper atom creates a strong overlap of orbitals, with a commensurate antiferromagnetic interaction $2J = -650\,cm^{-1}$.

The importance of symmetry in determining the sign of the superexchange interaction was first recognized in the late 1950s by Goodenough[22] and Kanamori.[23] Building on Anderson's original theory of superexchange[24] these authors derived qualitative guidelines (known collectively as the 'Goodenough-Kanamori Rules') for predicting the sign of the exchange for different d orbitals bridged by atomic anions though high symmetry bridging angles of 90° or 180°. These rules have more recently been generalized and extended by application of the concepts of natural orbitals to consider molecular bridging units.[11] These results have been particularly useful in the design of bimetallic cyanide compounds with high ordering temperatures (*see* ***Cyanide Complexes of the Transition Metals***).

2.3 The Heisenberg Hamiltonian

The origin of these interactions, called exchange, was first realized by Heisenberg and Dirac in 1926.[1,2] The interpretation of the exchange effect as formally equivalent to the coupling between spins permits the use of a vector-coupling scheme to model the quantitative behavior of coupled spins with the HDVV Hamiltonian[3]

$$H = -2JS_i \cdot S_j = -2J(S_i^x S_j^x + S_i^y S_j^y + S_i^z S_j^z) \qquad (27)$$

where the subscripts i and j correspond to the two different spins and J is the exchange coupling constant (the factor of two preceding the exchange strength J is traditional, dating back to Heisenberg's original paper.) The Hamiltonian states that the energy of the interacting spin pair depends only on the *relative* orientation of adjacent spins. No spatial direction is contained in this term so the spins are free to orient themselves along any crystallographic direction, so long as their relative orientation remains the same. An important consequence of this fact is the tendency of antiferromagnetically coupled moments to orient perpendicular to small external fields (see Section 2.8). With the negative sign preceding the dot product, a positive J indicates that a minimum energy is achieved with adjacent spins parallel, that is, in a ferromagnetic alignment.

2.4 Anisotropic Interactions & Spin Dimensionality

The spin angular momentum of an electron is properly described by a three-component vector and an isolated spin is free to orient in any direction in space. Likewise, the magnetic moment of the electron, related to the vector spin through the relation

$$m_S = -g\mu_\beta S \qquad (28)$$

is free to point in any direction. However for an ion within a crystalline lattice, the situation is more complex. The total spin of the ion will depend on the number of d-electrons and the crystal field states in which the electrons reside. In addition, for ions with significant amounts of unquenched orbital angular momentum such as Fe^{2+} or Co^{2+}, the moment of the ion can have greatly different values along the different axes of the local coordination sphere. One technique of describing this behavior is to replace the simple scalar g-factor in equation (28) with a g-tensor. A more complete discussion is found in the contribution (*see* ***Magnetism of Transition Metal Ions***).

What is the connection between the HDVV exchange interaction of equation (27) and the complexities of an ion in a crystal field? The isotropic exchange Hamiltonian is always correct since it is a direct consequence of the Pauli Exclusion Principle. However, a modified form of the exchange interaction is frequently used to describe those cases in which the individual moments are no longer isotropic.

$$H = -2J\left[\alpha(S_i^x S_j^x + S_i^y S_j^y) + \beta S_i^z S_j^z\right] \qquad (29)$$

The anisotropic exchange Hamiltonian appears as equation (29). It retains the form of a product of spins S_i and S_j but the spin components are given different weights. The x- and

y-components are multiplied by the dimensionless factor α while the z-components are multiplied by β. It is convenient to discuss three limiting classes of spin anisotropy in which one, two, or all three spin components have significant weight. For historical reasons, these classes are known as the one-dimensional Ising case ($\alpha = 0$, $\beta = 1$), the two-dimensional XY case ($\alpha = 1$, $\beta = 0$), and the three-dimensional, or fully isotropic Heisenberg case ($\alpha = \beta = 1$). The dimensionality refers to the number of spin components that have important weight in the Hamiltonian and is known both as the *spin dimensionality* and as the number of spin degrees of freedom. It is determined by the local environment of each ion and is independent of the exchange pathways that can connect any given moment to a one-, two-, or three-dimensional magnetic lattice.

In general, the spin dimensionality classes arise from structural features of materials that govern interactions between paramagnetic ions or from the electronic structure of the single ions.

The physical origins of the α/β ratio are due to the presence of strong internal fields on the ions themselves. Unquenched orbital angular momentum in a ferrous ion can create internal fields greater than 50 tesla along an internal axis. The exchange is always Heisenberg, but the effect of the internal fields can be modeled as $\beta \gg \alpha$, or the Ising interaction. Likewise, cases in which the spins are constrained to lie in a plane can be modeled as $\alpha \gg \beta$, the XY interaction.

2.5 Nonexchange Interactions: Dzialoshinski-Moriya Coupling

If two paramagnetic centers are related to each other by low symmetry, they are subject to an antisymmetric interaction known as Dzialoshinski-Moriya exchange.[25] The strength of the interaction D_{D-M} was shown by Moriya[25b] to be proportional to the exchange constant as follows:

$$H_{anti} = D_{D-M} \cdot S_A \times S_B \qquad (30a)$$

$$\text{where} \quad D_{D-M} \propto \frac{\Delta g}{g} J \qquad (30b)$$

Δg is the variation of the g-tensor components from 2.0023. This interaction arises from the coupling of the paramagnetic moment to the lattice through spin-orbit coupling as was derived by Moriya by extending Anderson's superexchange model[24] to include the spin-orbit effect.

D_{D-M} equals zero exactly if the two magnetic centers are centrosymmetric or lie on an n-fold axis of C_{nv} symmetry with $n \geq 2$, so many compounds are unaffected by this term. It is most commonly observed when adjacent magnetic sites are related by a screw axis. The effect of this term is to align adjacent spins at right angles to each other, but it only occurs when the exchange interaction is also present and rendering the spins either parallel or antiparallel. The result is for the spins to be canted alternately to either side of their mean axis by an angle Φ whose tangent is proportional to the ratio of the interaction strengths

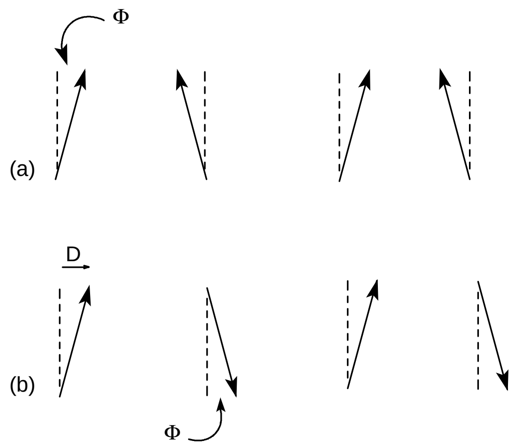

Figure 6 Spin canting in (a) a linear ferromagnet and (b) in a linear antiferromagnet

$$\tan(\Phi) \propto \frac{D_{D-M}}{J} \qquad (31)$$

The effect of the canting on ferromagnets is usually minor (Figure 6a) but it can change the behavior of antiferromagnets dramatically. As seen in Figure 6(b), spin canting in an antiferromagnet can lead to the formation of a spontaneous moment along one axis for temperatures below the Néel temperature. This phenomena is know as 'weak ferromagnetism' because the canted moment is much smaller than the full saturated moment.

2.6 Magnetic Correlations and Magnetic Ordering

Magnetic ordering is a cooperative process in which, at some critical temperature, every moment assumes a specific orientation relative to the entire lattice of interacting moments. (The critical temperature for a ferromagnetic transition is historically called the Curie temperature, T_C, while antiferromagnetic transitions occur at the Néel temperature, T_N.) Below T_C, the expectation value of the dot product of a pair of spins, $\langle S_i \cdot S_j \rangle$, will be nonzero for any spin pair, no matter how distant they may be from each other. Above T_C, the expectation value is finite for nearby spins but decreases to zero as the spins become further separated. The *correlation length* is defined as the distance between spins at which the expectation value of the spin pair drops to some stated fraction of its maximum possible value. Using this definition, a magnetic transition to an ordered state can be said to occur when the system's correlation length grows to infinity.

Magnetic correlations are caused by magnetic interactions. The interacting system has a ground state and excited states,

with the population of the states determined by the Boltzmann distribution, or a quantum statistical distribution function. The width of the energy spectrum will be proportional to the interaction strength J. When the temperature is reduced, the population of the ground state increases and the correlation length expands. Significant deviations from the behavior of a noninteracting system occur for temperatures $T \approx J$.

Low relative temperatures (T/J) are a necessary, *but not sufficient*, condition for the occurrence of magnetic ordering. As the temperature approaches zero, the correlation length will grow, but if there exist natural limits to the size of the correlation length, it cannot diverge, and magnetic ordering will not occur. The most fundamental limit is the dimensionality of the magnetic lattice itself. As described in the following section, no cluster with a finite number of moments can sustain long-range order, while every three-dimensional lattice can. All one-dimensional systems are prevented from ordering by entropic effects, while the ability of two-dimensional lattices to undergo a magnetic transition depends on the spin dimensionality.

2.7 Lattice Dimensionality

The *lattice dimensionality* of the interacting spin system describes the number of directions in which there are extended interaction pathways. Along with the spin dimensionality, the lattice dimensionality determines if a magnetic system can spontaneously undergo a transition to a magnetically ordered state at a finite temperature (see Section 2.6). Spin and lattice dimensionalities are independent parameters so within each class of lattice dimensionality, the spins can be described by Ising-like, XY-like, or Heisenberg Hamiltonians.

There are four classes of structural dimensionality. The simplest class is that in which the structure is made up of isolated clusters containing a finite number of exchange-coupled paramagnetic ions. Such systems are defined to be zero dimensional, 0D, because of the absence of any direction of extended interactions. If the number of paramagnetic ions in the cluster is small, exact expressions for the thermomagnetic properties of the cluster can be derived for any of the three spin dimensionalities. Small clusters of exchange-coupled paramagnetic ions are frequently used as models for more complicated extended systems. In every cluster, the correlation length is restricted to the size of the cluster; no magnetically ordered state is possible. Clusters with a magnetic ground state are known both as 'high-spin molecules' and 'nanomagnets' and display many interesting features, including quantum tunneling.[26]

The second structural class is that of infinite chains of exchange-coupled ions (Figure 7). In the simplest example of a one-dimensional (1-D) system, each paramagnetic ion has two nearest neighbors linked by suitable ligand bridges, with the next-nearest neighbors much farther away and not directly bridged to the chain. As always the exchange interactions may have spin dimensionalities of one, two, or three. The study of linear quantum magnets has played an important part in the study of phase transitions with such seminal names as Ising[27] and Bethe[28] being the first scientists to study the 1D $S = 1/2$ Ising and Heisenberg chains, respectively. While it is energetically possible for the correlation of a 1-D system to diverge at low temperatures, entropic effects will induce disorder in the chain and keep the correlation length finite for all nonzero temperatures. No long-range order is possible in purely 1D systems although weak secondary interactions in 2D or 3D may induce order at low temperatures.

The last structural class of *low-dimensional* magnetic systems is an isolated layer or sheet containing exchange-coupled paramagnetic ions (Figure 8). Spin dimensionality plays an important role in determining the nature of long-range cooperative behavior in two-dimensional (2-D) arrays[12,13] with 2D Heisenberg systems unable to sustain an ordered state at any finite temperature owing to the strong effects of their quantum fluctuations. (They are ordered in the absence of all thermal fluctuations at $T = 0$.) 2D Ising magnets spontaneously order as either ferro- or antiferromagnets[29] while 2D XY magnets are predicted to have a special kind of behavior in which the moments align in vortices within

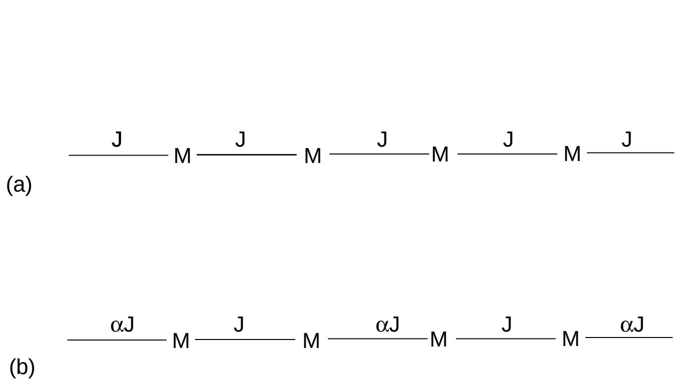

Figure 7 Some low-dimensional magnetic lattices: (a) uniform chain, (b) alternating chain, (c) two-leg ladder, and (d) three-leg ladder

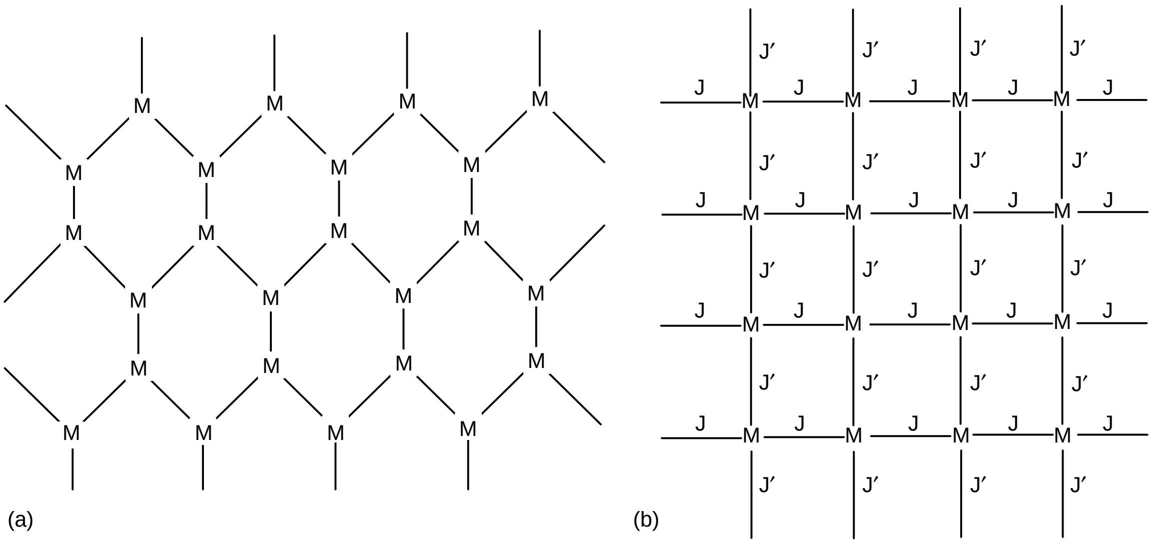

Figure 8 Some two-dimensional magnetic lattices: (a) honeycomb and (b) square (if $J = J'$) or rectangular (if $J > J'$)

the planes.[30] The correlation length is predicted to diverge at the critical temperature but no spontaneous moments appear.

Three-dimensional (3-D) magnetic systems are those in which exchange interactions occur in all directions. These may range from simple cubic systems to very complex arrays that reflect structural details of superexchange pathways and the electronic structures of the paramagnetic ions. A number of fascinating phenomena are exhibited by many of these systems, and a wide range of models for the nature of these interactions has been generated. Theoretical and experimental efforts are synergistic with advances in one area stimulating additional efforts in the other.

2.8 Magnetic Susceptibilities of Exchange-coupled Systems

The essential measurement to characterize a magnetic material is the determination of the temperature dependence of the magnetic susceptibility, χ. Many other experimental techniques will be necessary to understand fully the static and dynamic properties of a magnetic material (isothermal magnetization, specific heat in zero and applied fields, EPR and NMR spectroscopies, and elastic and inelastic neutron scattering) but, following a determination of the structure, no other experiment can yield as much information with as little effort. Analysis of the magnetic susceptibility can reveal the spatial and spin dimensionalities of the magnetic lattice, the sign and magnitude of the exchange strength, the absence or presence of an ordering transition, and even estimates of the internal anisotropies.

By definition, the susceptibility is the ratio of the sample's magnetization per unit volume M_V to the applied field H, in the limit of the field going to zero.

$$\chi_V = \lim_{H \to o} \frac{M_V}{H} \text{ (dimensionless)} \tag{32}$$

The magnetization per unit volume has the same units as the H-field for both cgs and SI units so the volume susceptibility is dimensionless. In practice, it is much more common to work with the molar magnetization $M_{mol} = M_V \times (MW/\rho)$ where MW is the molecular weight and ρ is the density of the material.

$$\chi_{mol} = \lim_{H \to o} \frac{M_{mol}}{H} \left(\frac{\text{vol}}{\text{mol}}\right) \tag{33}$$

The molar susceptibility thus has units of volume per mole for all unit systems. In practice, the molar susceptibility is frequently reported in cgs units as 'emu Oe^{-1} mol^{-1}'. (Scientists studying magnetism continue to utilize an eccentric mix of mostly cgs units in which the unit of magnetic moment, properly 'erg Oe^{-1}' is given the name of 'emu'. The volume susceptibility remains dimensionless but is said to have units of 'emu cm^{-3} Oe^{-1}' and the molar susceptibility can be expressed as 'emu Oe^{-1} mol^{-1}', which is equivalent to 'cm^3 mol^{-1}'. See Reference 31 for a lucid discussion of SI units.)[31]

2.8.1 *Heisenberg 1D Chains: Uniform $S = 1/2$ Antiferromagnets*

The uniform Heisenberg magnetic chain has been an object of study for three quarters of a century, dating back to the initial work of Bethe.[28] Unlike the equivalent Ising and XY-chains, the Heisenberg model cannot be solved analytically. The first calculations of the susceptibility and specific heat

were reported in a now-celebrated 1964 paper by Bonner and Fisher[32] who used extrapolated results based on computer calculations for finite chains. The revolution in computer technology and numerical methods over the past forty years has led to detailed understanding of the energy spectrum of the 1D quantum Heisenberg antiferromagnet (QHAF) in both zero- and applied fields.

A rigorous examination of the susceptibility and specific heats of the uniform and alternating Heisenberg antiferromagnets was reported by Johnston.[33] As shown in Figure 9, the susceptibility at low relative temperatures shows a rounded maximum, and then decreases to a finite value as the temperature approaches zero. The temperature ($T^{\max}$) at which the maximum susceptibility ($\chi^{\max}$) occurs is proportional to the exchange strength while the value of $\chi^{\max}$ is inversely proportional to the exchange.

The $T^{\max}\chi^{\max}$ product, is a constant now known to nine decimal places. (It is important to note that Figure 9 was prepared using the single J format for the Hamiltonian.)

$$T^{\max} = \frac{0.640\,851\,0(2J)}{k_B} \tag{34}$$

$$\frac{\chi^{\max}(2J)}{Ng^2\mu_\beta^2} = 0.146\,926\,279 \tag{35}$$

Exchange constants for low-dimensional magnets are most commonly obtained via comparison of experimental data to the predicted behavior of a thermodynamic property for a given model, usually the magnetic susceptibility. Johnston *et al.*[33] showed that the molar susceptibility χ_M of the uniform chain can be expressed as a ratio of polynomials in powers of the reduced temperature t ($t \equiv k_B T/|2J|$). The coefficients N_n and D_n are listed in Table 1.

$$\chi_M = \frac{C}{T} P_r^q(t) \text{where} P_r^q(t) = \frac{1 + \sum_{n=1}^{q} N_n/t^n}{1 + \sum_{n=1}^{r} D_n/t^n} \tag{36}$$

In the limit of high temperature, $P_r^q(t) \rightarrow 1$, and the molar susceptibility $\chi_{\text{mol}} \rightarrow C/T$, where $C = (N_A g^2 \mu_\beta^2 / 4k_B)$ for the $S = 1/2$ system. When equation (35) is used to determine the exchange strength from comparison to an experimental data set the fitting parameter will be the absolute value $|J|$.

2.8.2 Heisenberg 1D Chains: Alternating Exchange Linear Chains

Inspection of the low-temperature region of Figure 10 shows two distinct types of behavior. If the lattice is uniform, either 1D or 2D, the susceptibility remains finite as the temperature approaches zero. If the lattice consists of a network of dimers, such as an alternating chain or a spin ladder, the ground state is a nonmagnetic singlet separated from the lowest excited state by an energy gap Δ. As the temperature is reduced, the system drops into the ground state and the susceptibility decreases to zero exponentially $\chi \propto 1/\sqrt{T}\exp(-T/\Delta)$

The alternating chain consists of $S = 1/2$ units linked alternately by an exchange strength J and a strength αJ,

where $\alpha < 1$ (Figure 7b). In the limit of $\alpha \rightarrow 0$, the chain is reduced to a collection of isolated dimers, while it approaches the uniform chain as $\alpha \rightarrow 1$. The singlet-triplet gap is also a function of the alternation parameter being equal to $2|J|$ for the dimer and zero for the uniform chain. The variation of the susceptibility of the alternating chain as a function of α and temperature is seen in Figure 9. Expressions for the alternating chain susceptibility are considerably more complex than the expression (equation 36) for the uniform chain.[33]

2.8.3 Heisenberg Antiferromagnetic Spin Ladders

Spin ladders consist of two uniform chains, exchange strength $2J_{\text{rail}}$, coupled together by a second interaction $2J_{\text{rung}}$ (Figure 7c). When $|J_{\text{rung}}| \gg |J_{\text{rail}}|$, the system can be approximated as nearly independent dimers with $\Delta E_{S-T} = 2|J_{\text{rung}}|$. Consequently the susceptibility will vanish exponentially as $T \rightarrow 0$ (Figure 11). Surprisingly, the gap remains finite even in the opposite limit of $|J_{\text{rail}}| \gg |J_{\text{rung}}|$ and the low-temperature susceptibility of all spin ladders vanishes. Figure 11 shows the variation of susceptibility as a function of temperature and the $|J_{\text{rail}}/J_{\text{rung}}|$ ratio.[34]

Comparison of Figures 9 and 11 shows the susceptibilities of alternating chains and spin ladders are very similar. It is not possible to distinguish between the two models when examining an experimental data set. Additional experiment evidence is required.

2.8.4 Heisenberg Ferromagnetic $S = 1/2$ Heisenberg Chains

Ferromagnetic chains become increasingly easier to magnetize as the temperature is lowered and their correlation length expands. Their susceptibilities increase considerably faster than the Curie-like T^{-1} behavior; Heisenberg $S = 1/2$ ferromagnetic chains have been approximated[32] as diverging as $T^{-1.7}$. This property means the applied external field must be carefully checked to insure that the moment remains linear in field at low temperatures.

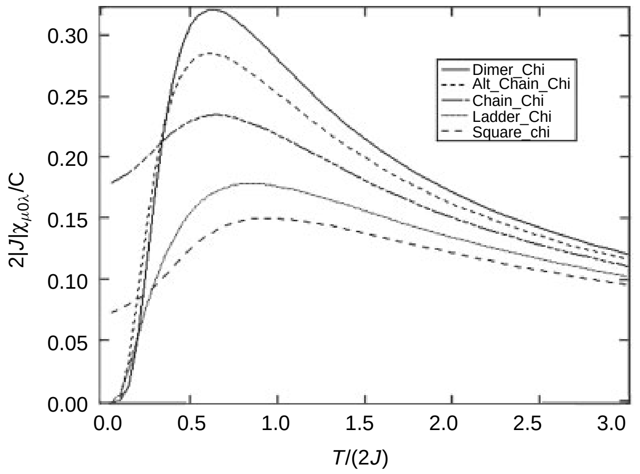

Figure 10 Comparison of the relative molar susceptibilities as a function of relative temperature $(T/2|J|)$ for five $S = 1/2$ Heisenberg antiferromagnet lattices: a dimer, an alternating chain with an alternation parameter $\alpha = 0.5$, a uniform chain, a spin ladder with $J_{\text{rung}}/J_{\text{rail}} = 2$, and a square lattice. The value of J is the same for all curves

For comparison to experimental data, the susceptibility of the Heisenberg $S = 1/2$ ferromagnetic chain in zero field can be expressed as a power series expansion in powers of $J/(2T)$ with the coefficients β known for the first one hundred terms.[35]

$$\chi_{\text{mol}} = \frac{C}{T} \sum \frac{\beta_n}{(n+1)!} \left(\frac{J}{2T}\right)^n \tag{37}$$

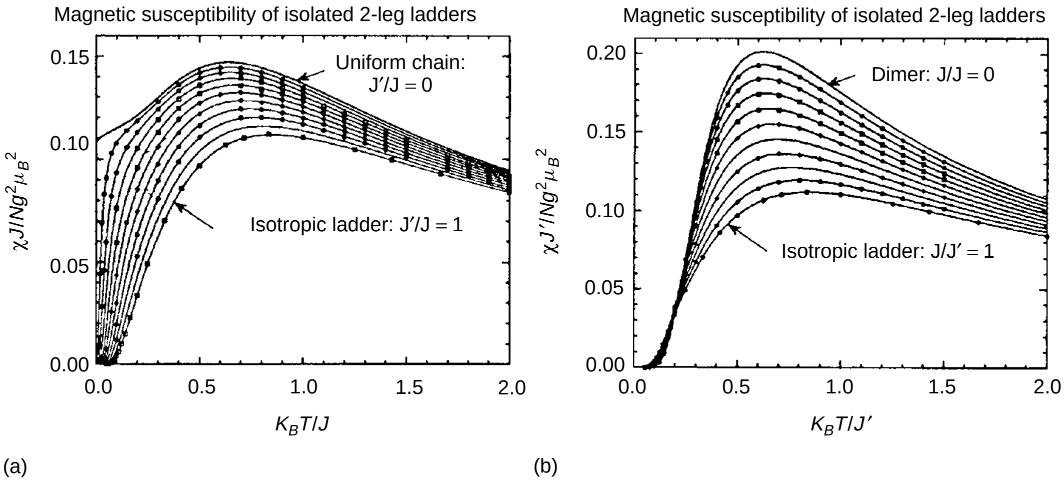

Figure 11 Magnetic susceptibility for two-leg Heisenberg ladders in the (a) weak exchange and (b) strong exchange models. (Ref. 34. Reproduced by permission of Author Matthias Troyer)

where $\beta_0 = 1$, $\beta_1 = 4$, $\beta_2 = 0$, $\beta_3 = -64$, $\beta_4 = 400$, and so on. This J is based on the $2J$ form of the Heisenberg Hamiltonian and is positive.

2.8.5 Heisenberg Chains with S ≥ 1

Understanding of the susceptibility of chains of spins with $S = 1$ or higher underwent dramatic change in 1983. Prior to that year, only the susceptibility of the classical ($S = \infty$) chain was known[36] and, like the $S = 1/2$ susceptibility, it showed a rounded maximum and remained finite at low temperature. Susceptibilities calculated for $S = 1$ and higher values using variations of the Bonner–Fisher technique,[32] or by using high-temperature series expansion techniques also showed the presence of rounded maxima but these techniques were unable to obtain values for lower relative temperature. It was assumed that the antiferromagnetic susceptibilities for all values of S remained finite as temperature declined to zero.

In 1983, Haldane[37] predicted that the ground states for all Heisenberg chains with integer spins were nonmagnetic singlet ground states, with energy gaps Δ to the first excited triplet. These predictions were confirmed by finite-chain calculations[38] that showed the gap was also affected by the presence of single-ion anisotropy D. For the $S = 1$ chain with $D = 0$, $\Delta \approx 0.4(J)$ and decreases as D increases (where J is from the $2J$ format). The presence of the singlet ground state means that for temperatures at or below Δ, the susceptibility will vanish exponentially and will resemble the curves for the alternating chain or spin ladder in Figures 9 and 11.

2.8.6 Bimetallic Spin Chains – 1D Ferrimagnets

Since the 1980s, it has been possible to synthesize site-ordered bimetallic chains in which metal ions of type A and B alternate. A and B are generally coupled antiferromagnetically and will have different moments that will tend to cancel at low temperatures, leaving a net moment within each unit cell. The net moments all have the same orientation, similar to the case of a monometallic ferromagnetic chain, so at low temperature the bimetallic chain has a diverging susceptibility. Materials that contain antiferromagnetically coupled inequivalent moments are known as ferrimagnets.

The susceptibility of a ferrimagnetic chain increases continuously upon cooling, with no obvious features. Their behavior can be identified more clearly by observing the $\chi_M T$ product, which shows a characteristic minimum at low temperatures. The $\chi_M T$ product of noninteracting spins is simply the sum of the Curie constants, C_A and C_B.; this value will be the high-temperature limit for interacting spins. Figure 12 shows that upon cooling the $\chi_M T$ product for each chain first decreases in response to the antiferromagnetic interaction. Upon further cooling, the moments of each unit cell become aligned parallel, leading to a diverging susceptibility. It is noted that the depth of the minimum

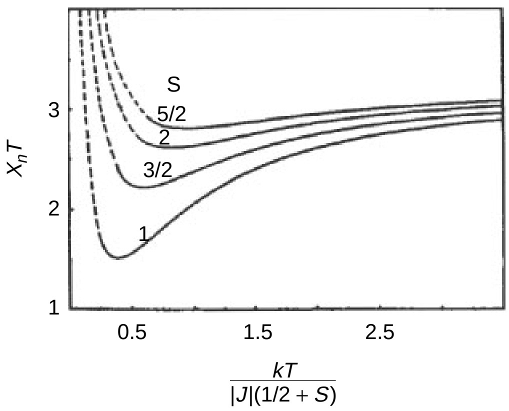

Figure 12 The product of susceptibility time temperature is shown as a function of temperature for four ferrimagnetic spin chains.[39] Each chain alternates a $S = 1/2$ spin and a second, larger spin S. The dashed lines at low temperatures correspond to the $\chi_M T$ values for ferromagnetic spins of S-1/2[39]

is largest for the [1/2–1] chain and decreases rapidly with increasing S.

2.8.7 Chains with Anisotropic Exchange

When the exchange Hamiltonian is no longer isotropic, that is, when $\alpha \neq \beta$ in the exchange Hamiltonian, the susceptibility is no longer isotropic. The anisotropic Hamiltonian describes a system in which there is a preferred direction (Ising-like, $\alpha < \beta$) or preferred plane (XY-like, $\alpha > \beta$) in space. The magnetic response will be different depending on whether the external field is applied parallel to or perpendicular to the preferred direction(s). These responses correspond to the parallel ($\chi_\parallel$) and perpendicular susceptibilities ($\chi_\perp$).

Anisotropic Antiferromagnetic Exchange. For the isotropic Heisenberg case, the spins are free to rotate in space to remain antiferromagnetic to each other and essentially perpendicular to the field. For a Heisenberg system, there is only a perpendicular susceptibility with its characteristic rounded maximum (Figure 10). The g-factors for the Heisenberg ions can be slightly different in different directions but this difference only affects the magnitudes of the susceptibilities. The temperature dependences of the susceptibility are identical in all directions.

The zero-field susceptibilities for the $S = 1/2$ Ising chain have been derived by Fisher.[40] They have the same form for both antiferromagnetic and ferromagnetic exchange, only the sign of J is different.

$$\chi_\parallel = \frac{Ng_\parallel^2\mu_B^2}{2J}\left(\frac{J}{2kT}\right)\exp\left(\frac{J}{kT}\right) \tag{38}$$

$$\chi_\perp = \frac{Ng_\perp^2\mu_B^2}{4J}\left[\tanh\left(\frac{J}{kT}\right) + \left(\frac{J}{kT}\right)\sec h^2\left(\frac{J}{kT}\right)\right] \tag{39}$$

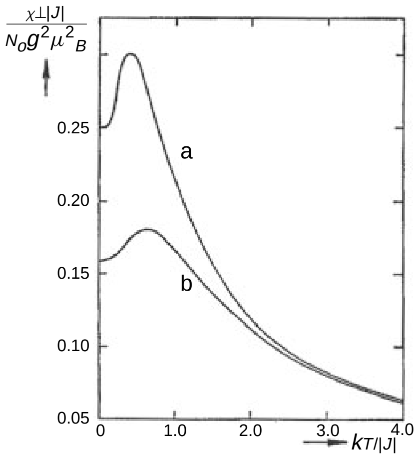

Figure 13 The perpendicular susceptibility as a function of temperature for (a) an Ising antiferromagnet and (b) an XY-antiferromagnet. (Ref. 12. Reproduced by permission of Taylor & Francis)

The perpendicular susceptibilities of the Ising ($\alpha = 0$) antiferromagnetic chain and XY($\beta = 0$) chain likewise have rounded maxima and remain finite as the temperature descends to zero (Figure 13). The parallel susceptibility of the Ising antiferromagnet decreases exponentially to zero as the temperature drops, in response to the energy gap in the Ising spectrum.

The XY magnet ($\beta = 0$) retains isotropic symmetry in the plane, so the spins are free to rotate and align themselves perpendicular to any field lying in the plane, similar to the Heisenberg susceptibility. There is a thus a perpendicular susceptibility[41] (see Figure 13), which has a similar shape to that of the Ising $\chi_\perp$. There is no easy axis in the XY system so there does not exist a true $\chi_\parallel$. A field applied normal to the easy-plane induces a magnetic response at finite temperature, which vanishes at zero temperature, in a manner similar to $\chi_\parallel$ of the Ising magnet.[42] This response is, unfortunately, called the XY parallel susceptibility.

3 EXCHANGE COUPLING IN ONE-DIMENSIONAL LATTICES

The fundamental idea of exchange leads directly to the simple Heisenberg Hamiltonian (equation 1), but numerous variations in magnetic behavior arise as a result of exchange anisotropy, lattice dimensionality, or the presence of more than one exchange constant. The onset of long-range order can obscure some of these variations but low-dimensional magnets that do not spontaneously order (Table 2) permit the development of the characteristic behavior over broad temperature ranges. Since order is most difficult to achieve in one-dimensional systems, the examples below have been selected to illustrate variations of magnetic behavior in one-dimension.

Table 2 Existence (Yes) or absence (No) of spontaneous magnetic order at finite temperature as a function of spin- and lattice dimensionality

	Lattice dimension			
Spin dimension	0D	1D	2D	3D
Ising	No	No	Yes	Yes
XY	No	No	Unusual	Yes
Heisenberg	No	No	At $T = 0$	Yes

Experimental progress in low-dimensional magnetism became possible when what constituted a low-dimensional *magnetic* lattice in a 3D *crystalline* environment was recognized. The key is the existence of moments joined by significant low-dimensional (1D or 2D) superexchange pathways while in the orthogonal direction(s), the interaction strengths are much weaker. Superexchange pathways are commonly provided by bridging anions or coordinating organic groups while the magnetic isolation arises from the presence of large counterions or neutral organic groups. While the crystalline host of the magnetic lattice will always remain three dimensional, the magnetic behavior remains essentially 1D down to low temperatures if the ratio of the 1D exchange J to that of the 3D exchange J_{3D} exceeds $\approx 10^2$.[12]

3.1 Heisenberg 1D Chains: Uniform $S = 1/2$ Antiferromagnets

One of the earliest examples of a 1D antiferromagnet is copper bispyridine dichloride (CPC). Its structure (Figure 14)[43] consists of bichloride-bridged chains of Cu^{II} ions extended along the c-axis, with the two pyridine ligands coordinated to the metal site through the nitrogens. The magnetic interaction is due to the superexchange along the copper chloride spine (intrachain Cu–Cu distance = 3.87 Å). The bridging Cu–Cl–Cu angle (91.1°) is large enough to induce significant antiferromagnetic exchange. The bulk of the pyridine rings forces adjacent chains far apart (interchain Cu–Cu separation = 8.59 Å) and prevents the formation of any interchain superexchange pathway. Susceptibility studies[44] found a rounded maximum in the susceptibility near 18 K; comparison to the Bonner–Fisher calculation for the susceptibility yielded an exchange strength $2J/k_B = -26.8$ K. The experimental susceptibility dropped below the Bonner–Fisher (BF) results below 2 K, an effect attributed to the 3D antiferromagnetic ordering transition found at 1.13 K by specific heat measurements.[44b]

The ideal 1D Heisenberg antiferromagnet becomes increasingly correlated within the chain as the temperature cools but will remain disordered even at $T = 0$ (see Section 2.8). Long-range order arises from the presence of weaker interactions J' between the chains. The ratio of the Néel temperature T_N to the exchange strength ($T_N/|2J|$) is a

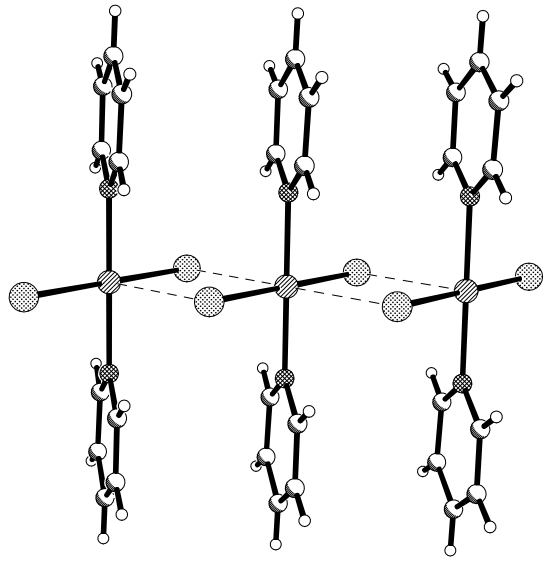

Figure 14 The structure of $Cu(py)_2Cl_2$

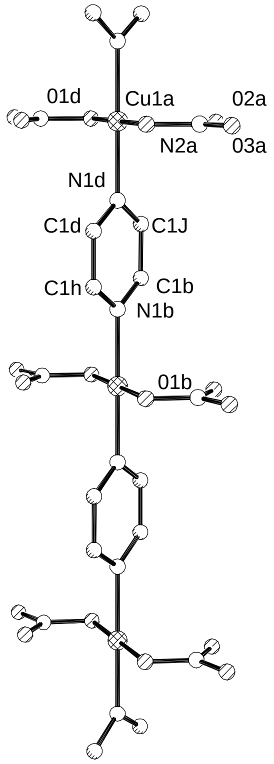

Figure 15 The structure of $Cu(pz)(NO_3)_2$[50]

sensitive measure of the degree of one-dimensional isolation, decreasingly approximately a factor of 3 for every decade of reduction of the J'/J ratio.[45] The value $T_N/|2J| = 0.042$ for CPC corresponds to a ratio of exchange strengths $J'/J = 7 \times 10^{-3}$ and is sufficiently low for the characteristic behavior of the 1D QHAF to be examined over a wide relative temperature range $(T/|2J|)$ without interference from 3D correlations. Neutron scattering studies on CPC were among the earliest and most influential studies of low-dimensional spin dynamics.[46]

Even greater 1D isolation is found in copper pyrazine dinitrate,[47] CuPzN. It consists of chains of Cu^{II} ions bridged by the diazines along the a-axis (see Figure 15). Charge neutrality is achieved by having two nitrate groups chelate to each metal site. Early magnetic studies by Hatfield[48] showed the interaction strength to be $2J/k_B = -10.6(2)$ K and detected no evidence of 3D effects. The specific heat of CuPzN has been measured down to 0.05 K[49] and has been found to agree with the predictions for the 1D QHAF model with $2J/k_B = -10.4(1)$ K down to the lowest measured temperature. No evidence of magnetic ordering was observed so $T_N < 0.05$ K; consequently $T_N/|2J| < 0.005$, one of the lowest ratios found for a 1D QHAF.

Two other 1D QHAF are included in Table 3. They are the copper oxide Sr_2CuO_3, and $KCuF_3$. Copper oxide magnetic systems are renowned for the strength of their magnetic interactions and Sr_2CuO_3 is no exception; based on susceptibility studies[51] its exchange constant has been determined to be $2J/k_B = -2200 \pm 200$ K. While there is a separate section on magnetic oxides found elsewhere in the Encyclopedia (*see* ***Magnetic Oxides***), we mention Sr_2CuO_3 here because it has the lowest critical ratio $k_BT_N/|2J| = 0.0025$ of any linear magnet.

Table 3 Susceptibility and ordering parameters for a selection of 1D-antiferromagnets

Compound	$\|2J\|/k_B$ (K)	T_N (K)	$k_BT_N/\|2J\|$	Ref.
$Cu(py)_2Cl_2$	26.8	1.13	0.042	44
$Cu(pz)(NO_3)_2$	10.5	<0.05	$<5 \times 10^{-3}$	49
Sr_2CuO_3	2200	5.4	2.5×10^{-3}	51
$KCuF_3$	375	39	0.104	52
Copper Benzoate	18	0.76	0.042	53,54
$Cu(DMSO)_2Cl_2$	16.5	0.92	0.02	55

Potassium copper fluoride, $KCuF_3$, is a surprising 1D magnet because its structure is closely related to that of the cubic perovskite. The cooperative Jahn–Teller distortion causes the fluorides to move from their midpositions in the (001) plane and leads to a special alignment of the 3d orbitals of the Cu^{2+} ions, giving rise to strong superexchange interactions along the tetragonal c-axis ($2J/kB = -375$ K),[52] and much weaker interactions perpendicular to the chains. The critical ratio, $k_BT_N/|2J| = 0.104$, is higher than that of any other chain in Table 3, but is still a remarkably low value considering the copper–copper distance is very nearly the same in all directions. We find it notable that compounds such as $KCuF_3$ and $SrCuO_3$ can provide such a range of J'/J ratios without the need for organic blocking groups such as those found in CPC.

3.2 Heisenberg 1D Chains: Canted $S = 1/2$ Antiferromagnets

The uniform chain compounds discussed above contained magnetic centers related by unit-cell translations; consequently there is only one exchange constant. When adjacent centers are related by screw axes, there remains only one exchange interaction but the magnetic behavior becomes more complex. Owing to the presence of the screw axis, the local coordination spheres and g-tensors are canted with respect to each other, creating the conditions for the Dzialoshinski-Moriya antisymmetric interaction D_{D-M} (Section 2.5). The DM interaction tends to align adjacent moments perpendicular to each other, in competition with the exchange interaction's effort to align the moments (anti)parallel. The competition between the DM and exchange terms creates a net canted moment (see Figure 6b), whose magnitude depends on the D/J ratio. The canted g-tensors have a similar effect and create an environment in which any uniform field is unable to be parallel to every moment; the parallel susceptibility cannot be measured directly.

$$H = -2J\sum_i S_i \cdot S_{i+1} - \sum_{j,\alpha,\beta} H^\alpha[g^u_{\alpha,\beta} + (-1)^j g^s_{\alpha,\beta}]S^\beta_j + \sum_j (-1)^j D \cdot S_{j-1} x S_j \qquad (40)$$

Copper benzoate trihydrate is an example of a uniform chain with a 2_1 screw axes.[53] As seen in Figure 16, the chains are formed by the copper ions aligned along the c-axis. There are two copper sites that alternate along the chain with local symmetry axes that differ by 20°.[53a] The antiferromagnetic interaction along the chain has a strength of $2J/k = -18.2$ K but the characteristic susceptibility maximum is only observed in large fields. Owing to the canting of the moments parallel to the c-axis, in small fields ($H < 50$ Oe) χ_c is as much as 10 times bigger than χ_a and one hundred times bigger than χ_b.[53b] Anomalies are observed near 0.8 K for the susceptibility, but specific heat studies at low temperature[54] show no unusual behavior near that temperature.

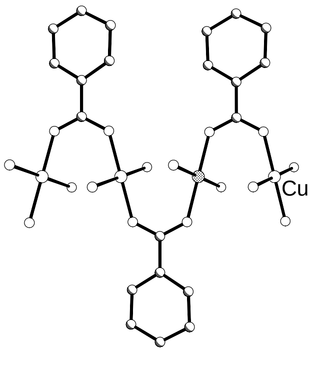

Figure 16 The structure of copper(II) benzoate

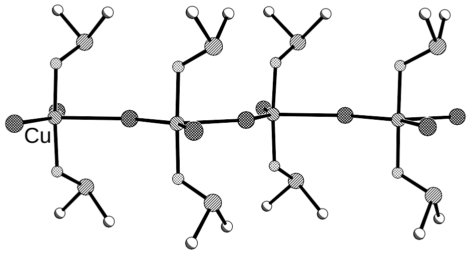

Figure 17 The structure of $CuCl_2(DMSO)_2$

Copper dichloride bisDMSO $Cu(DMSO)_2Cl_2$ (DMSO = dimethylsulfoxide) consists of chains of roughly square planar coordinated copper with the two chloride ions and the two organic molecules in trans positions, and the chloride from an adjacent molecule semicoordinated in an axial site (see Figure 17).[56] Adjacent copper sites are related by a 2_1 axis.

The exchange strength is $2J/k = -16.5$ K for the chloride. While there is no overt canting observed in the data, the presence of the spin-canting terms in the Hamiltonian creates different temperature dependences for each of the three principle susceptibilities.[55]

3.3 Heisenberg 1D Chains: Ferromagnetic $S = 1/2$ Heisenberg Chains

Copper halide chains exhibit ferromagnetic interactions when the coppers are tribridged along the chain axis (see Figure 18). This contrasts with the antiferromagnetic interactions observed when the coppers are distinctly bibridged, as in $Cu(py)_2Cl_2$ (Figure 14). The sensitivity of the ferromagnetic susceptibility to small anisotropic contributions to the exchange Hamiltonian makes ferromagnetic chains particularly good subjects for the study of local coordination upon exchange anisotropy.

Copper(II) chloride tetramethylenesulfoxide[57] consists of the formula units tied together by two chlorine interactions and one oxygen interaction to form chains parallel to the b-axis. The copper coordination sphere has an elongated tetragonal distortion giving the common '4 + 2' coordination geometry. The chains are formed by the action of the 2_1 screw axis parallel to b, leading to a structure with three Cu–ligand–Cu bridges between adjacent Cu ions. The most important is the symmetrical Cu–Cl(1)Cu' bridge with Cu–Cl distances of 2.325 and 2.358 Å and a bridging angle of 86.5° (there are also two asymmetrical bridges with bridging angles of 80.95° and 79.63°). Hatfield had demonstrated that superexchange interactions through symmetrical Cu–Cl–Cu bridges with an angle near 90° gave ferromagnetic interactions[58] and a ferromagnetic interaction was found for $CuCl_2$(TMSO) with a strength of $2J/k = 78$ K. Interactions between the chains lead to a 3D ordered state near 3.9 K. When plotted on a log–log plot, the susceptibility of a Heisenberg ferromagnetic chain is linear, corresponding to a divergence as $T^{-1.7}$. This

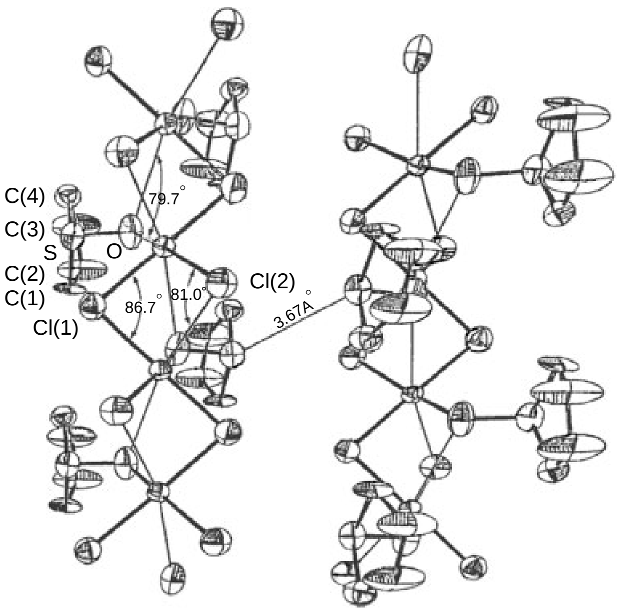

Figure 18 The structure of $CuCl_2$(TMSO)[57]

behavior is seen for $CuCl_2$(TMSO) and the analogous DMSO in Figure 19,[57] as well as for two other tribridged copper chains, tetramethylammonium copper trichloride (TMCuC) and tris(trimethylammonium)Cu_2Cl_7 (TTMCuC).[59]

Two excellent examples of ferromagnetic chains with measurable exchange anisotropy are the isotropic cyclohexylammonium copper trichloride and tribromide, CHAC and CHAB respectively.[60] The structure of CHAC consist of bibridged linear chains of $CuCl_3^-$ ions parallel to the c-axis, hydrogen bonded together in the b-c plane by the $-NH3^+$ moiety of the organic group, (see Figure 20). The coordination sphere around the copper atom assumes nearly perfect square pyramidal (C_{4V}) geometry. The apical chlorides, related by the 2_1 axis parallel to c are rotated by $\pm 17°$ out of the b-c plane. Two symmetrical Cu–Cl–Cu bridges are formed, each with a bridging angle of 86.0°, leading to the presence of ferromagnetic interactions.

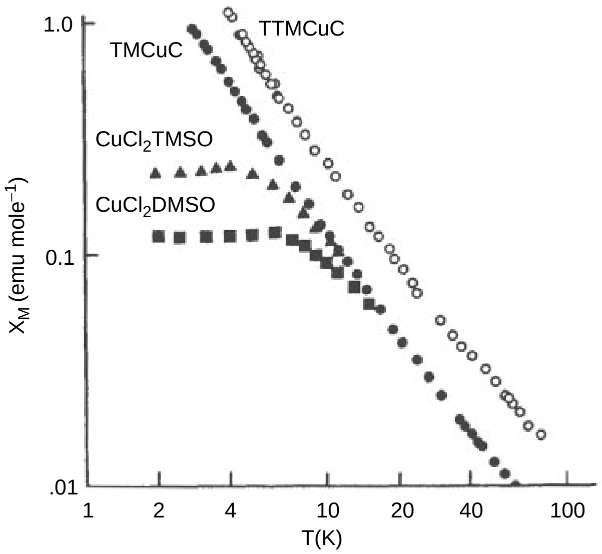

Figure 19 Log–log plot of susceptibility versus temperature for four Heisenberg ferromagnetic chains. Deviations from linearity are due to interchain interactions. (Reprinted with permission from C.P. Landee and R.D. Willett, *Phys. Rev. Lett.*, 1979, **43**, 463. © 1979 by the American Physical Society)

The susceptibility of CHAC above 30 K is well described by the prediction for a ferromagnetic Heisenberg chain with $J/k = 45(5)$ K (Figure 21a), but the single-crystal susceptibilities become increasingly anisotropic below that temperature, indicating the presence of non-Heisenberg behavior. The low-temperature ac-susceptibilities (Figure 21b) shows strong anisotropy in the vicinity of the Néel temperature of 2.18 K. The greatest susceptibility for all $T > T_N$ is found along the b-axis, defining b as the magnetic easy axis. The antiferromagnetic transition is due to the moments of adjacent ferromagnetic chains alternately aligning along the b-axis. Consistent with this assignment is the disappearance of χ_b at the lowest temperature. The susceptibility along c is small at all temperatures and remains finite as $T \rightarrow 0$, marking χ_c as a perpendicular susceptibility. The susceptibility along the a-axis is also small and characteristic of $\chi_\perp$ above 4 K, but it diverges at T_N and a spontaneous moment develops along the a-axis. This weak ferromagnetism is due to the spin canting of each ferromagnetic chain in the same direction along the a-axis. Further examinations of the magnetism and the magnetic specific heat led to a quantitative understanding of the exchange anisotropy in CHAC; it has a slight Ising-like behavior, consistent with a Hamiltonian (equation 29) with $\alpha = 0.98$, $\beta = 1$. In CHAC, the moments point along the local axes defined by the copper and apical chloride.

The isostructural bromide analog CHAB also consists of ferromagnetic chains along c ($J/k = 55(5)$ K), with the easy

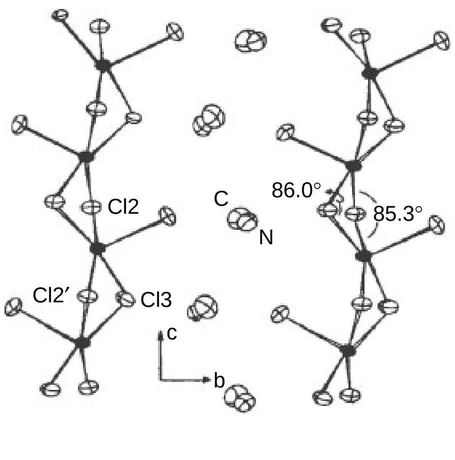

Figure 20 The chain structure of CHAC[60b]

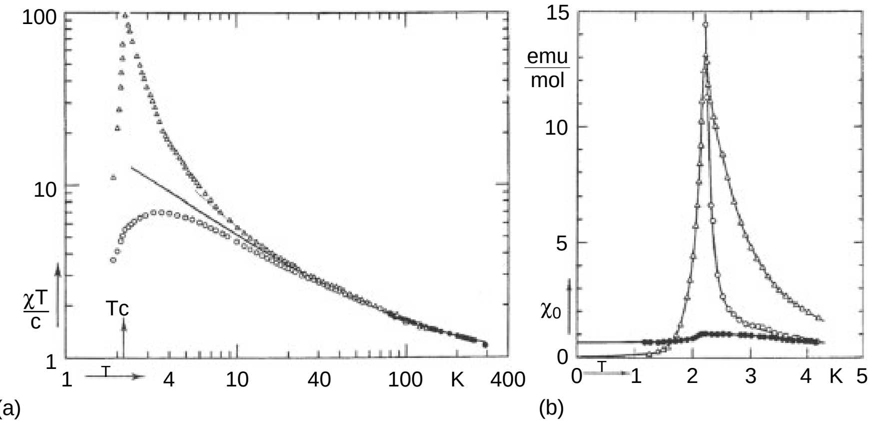

Figure 21 Single-crystal susceptibilities of CHAC. (a) log−log plot of the DC responses along the easy b-axis (Δ) and the hard c-axis ((0) and b) ac responses along the easy b-axis (Δ), the canted a-axis ((0), and the hard c-axis (•)). (Reprinted from Ref. 60a. © 1981, with permission from Elsevier)

axis along b, a canted moment along a, and a Néel temperature of 1.50 K. However, CHAB has an easy-plane anisotropy ($\alpha = 1$, $\beta = 0.95$) with the moments rotating most easily in the bc plane. Such reversals in anisotropy upon substitution of bromide for chloride ligands in copper complexes are common and have been explained[61] as arising from the reversal in sign in the effective spin-orbit coupling of the spins to the lattice upon change of the halide.

3.4 Heisenberg 1D Chains: Alternating Linear Chains

The moments in uniform chains are related by simple crystallographic symmetry such as a unit-cell translation or a screw axis. Consequently the exchange coupling between each pair of nearest neighbors is identical and only one exchange strength is present. For homometallic linear systems containing a basis with more than one magnetic site, there will be two (or more) exchange constants, one within the basis and the second connecting adjacent bases. Such systems are known as alternating chains with the stronger interaction labeled J and the weaker interaction labeled αJ, where $\alpha < 1$ (Section 2.8). When α is positive, the two interactions have the same sign; $\alpha = 0$ or 1 corresponds to the isolated dimer and uniform chain, respectively. Alternation commonly occurs when structural dimers are linked in an end-on fashion to their neighbors, forming a chain of dimers. It is also found when moments are linked by alternating ligands as in . . .M–L–M–L′ – M–L–M–L′. . ..

The temperature dependence of the alternating chain susceptibility as a function of alternation parameter α is shown in Figure 9. The susceptibility for each α displays a rounded maximum at nearly the same relative temperature ($T^{max} \approx 0.6(2J)/kB$ in our notation), but the maximum susceptibility reached and the low-temperature behavior of the susceptibility are strongly dependent upon α. For all $\alpha < 1$, the ground state is a nonmagnetic singlet separated by an energy gap Δ from the lowest excited state with $\Delta = 0$ or $2|J|$ for $\alpha = 1$ or 0, respectively. Consequently, at low temperatures the susceptibilities for the alternating chains all decrease exponentially to zero with the fastest decrease occurring for small values of α.

Piperazinium hexachlordicuprate (PHCC) consists of trichlorocuprate anions and piperazinium cations.[62] Two contiguous copper atoms are bridged symmetrically by two Cl(1) chlorine atoms into Cu_2Cl_6 dimers, which in turn are linked through semicoordinate Cu–Cl(3) bonds to form chains running along the a-axis (Figure 22).

The symmetric Cu–Cl(1) bridges are 2.32 Å while the asymmetric Cu–Cl(3) bridge contains a long bond of 2.60 Å. The structural alternation is reflected in the magnetic susceptibility that shows a rounded maximum near 15 K and decreases rapidly to zero upon further cooling (see Figure 23).

The magnetic data are well described by an exchange constant $J/k = -12.5$ K and an alternation parameter $\alpha \approx 0.63(4)$. The relatively small exchange for the copper chloride dimeric units has been explained by a molecular overlap analysis of natural magnetic orbitals, similar to that used by Girerd *et al.*[18] The symmetric Cu–Cl(1)–Cu bridging angle $\theta = 96°$ produces an antiferromagnetic contribution

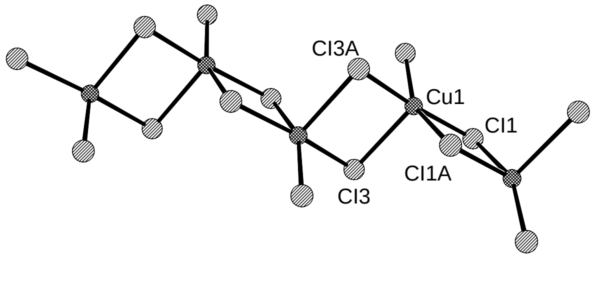

Figure 22 Schematic view of the chain structure of piperazinium hexachlorodicuprate

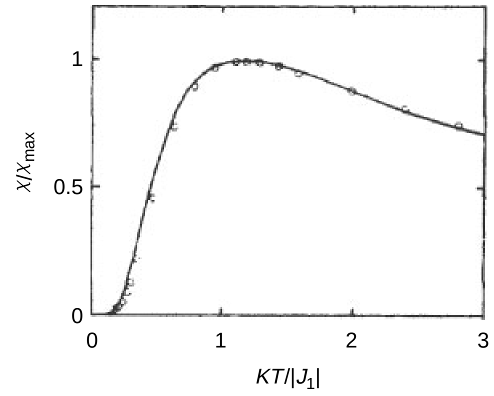

Figure 23 Reduced susceptibility (c/cmax) of piperazinium hexachlordicuprate as a function of the reduced temperature kT/J. The solid curve is the theoretical prediction for $J/k = -12.5\,K$ and $\alpha = 0.6$ (Reprinted with permission from A. Daoud, A.B. Salah, C. Chappert, J.P. Renard, A. Cheikhrouhou, T. Duc, and M. Verdaguer, *Phys. Rev. B*, 1986, **33**, 6253. © 1986 by the American Physical Society)

approximately equal to that of the ferromagnetic contribution, leading to a near cancellation of exchange. The dimer formed by the Cu–Cl(3)–Cu links is small owing to a poor overlap integral.

The 1980s saw rapid advances in the understanding of coordination compounds with more than one metal or more than one ligand. Techniques were developed by which two different metals M, M' could be inserted *site-specifically* into an extended lattice, forming molecular-based ferrimagnets (see Section 3.7). Concurrently, it was discovered how using *alternating ligands* to link a single type of magnetic moment into an alternating chain. The compound $[Cu_2(bpm)(H_2O)_2(OH)_2(NO_3)_2]2H_2O$ (bpm = 2, 2′-dipyrimidine) consists of discrete, centrosymmetric bis(μ-hydroxo) copper(II) dimers with bpm as terminal ligand, weakly coordinated water molecules, unidentate nitrate anions, and two waters of crystallization (Figure 24).[63]

The Cu(1)–OH–Cu(1a) bridging angle is 95.0°, within the ferromagnetic range for hydroxy-bridged copper dimers (Section 2.8). Each dimeric unit is linked to its neighbor by

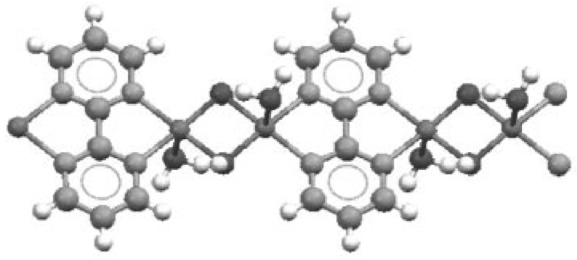

Figure 24 The alternating chain structure of $[Cu_2(bpm)(H_2O)_2(OH)_2(NO_3)_2]\cdot 2H_2O$[63]

the unused chelating site of the bpm, forming the alternating ligand exchange.

Bipyrimidine is known to transfer strong antiferromagnetic interactions while the hydroxo bridge produces ferromagnetic exchange; this compound is thus an alternating exchange alternating chain. Analysis of the magnetic data reveals the ferromagnetic interaction to be $2J/k = +160\ cm^{-1}$ while the antiferromagnetic interaction $\alpha(2J)/k = -145\ cm^{-1}$, that is, $\alpha = -0.91$.

Spin-Peierls Chains. The uniform one-dimensional exchange-coupled chain is inherently unstable at low temperatures toward distortion to an alternating exchange chain, because the electronic energy is lowered as the system drops into the nonmagnetic ground state of the distorted chain, separated from excited states by an energy gap Δ. The dimerization will occur if the reduction in magnetic energy is greater than the increase in lattice energy caused by the dimerization. This spontaneous structural transition, known as the spin-Peierls distortion is very rare because the energy requirement is difficult to meet. One of the few examples of a spin-Peierls transition occurs in $CuGeO_3$, with a transition temperature $T_{SP} \approx 14\,K$.[64] The magnetic susceptibility is dramatically affected at the transition as seen in Figure 25.

The data above T_{SP} cannot be described with a uniform chain model, but can be explained by including the existence of a next-nearest interaction $2J_{nnn}/k = -58\,K$ to the presence of a nearest neighbor exchange $2J/k = -160\,K$.[65]

3.5 Spin Ladder Linear Chains

Spin ladders consist of two or more uniform chains, exchange strength $2J_{rail}$, coupled together by a second

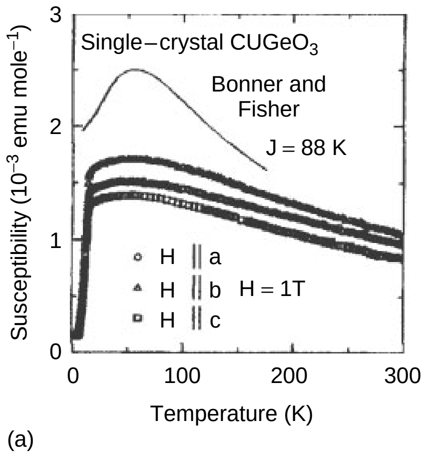

Figure 25 The magnetic susceptibility of single crystals of $CuGeO_3$ measured under $H = 1T$. Note the rapid decrease of the susceptibility towards zero along each axis below 14 K. (Reprinted with permission from M. Hase, I. Terasaki, and K. Uchinokura, *Phys. Rev. Lett.*, 1993, **70**, 3651. © 1993 by the American Physical Society)

interaction $2J_{\text{rung}}$. The ground state for ladders of an even number of rails is a nonmagnetic singlet, separated by an energy gap Δ from the lowest magnetic states. Recent strong interest in two-leg ladders is due to the prediction and discovery of superconductivity in such ladders doped with charge carriers.[66] Only two-leg ladders will be considered further.

A small number of spin ladders is known. An excellent example is $SrCu_2O_3$,[67] but it is characterized by very large exchange ($2J/k \approx -2000$ K) and an energy gap $\Delta = 420$ K but these large magnitudes make field-dependent studies, necessary to distinguish between a ladder or alternating chain, impossible to carry out. Molecular-based ladders are alternatives.

Bis(piperidinium)tetrabromocuprate, BPCB,[68] consists of $CuBr_4$ dianions and organic cations. Hydrogen bonding creates a structure where the $CuBr_4$ groups are packed together in pairs, with adjacent pairs aligned along the a-axis (Figure 26). The copper–copper interactions take place by double-halide superexchange through Cu–Br· · ·Br–Cu pathways.

Such contacts are known to create antiferromagnetic interactions on the order of 10 K, depending on the Br–Br distance and bond angles. The magnetic susceptibility of BPCB[69] has a rounded maximum near 8 K and decreases rapidly towards zero at lower temperatures, characteristic of a singlet ground state. Both the spin ladder and alternating chain models fit this data equally well (Figure 27).

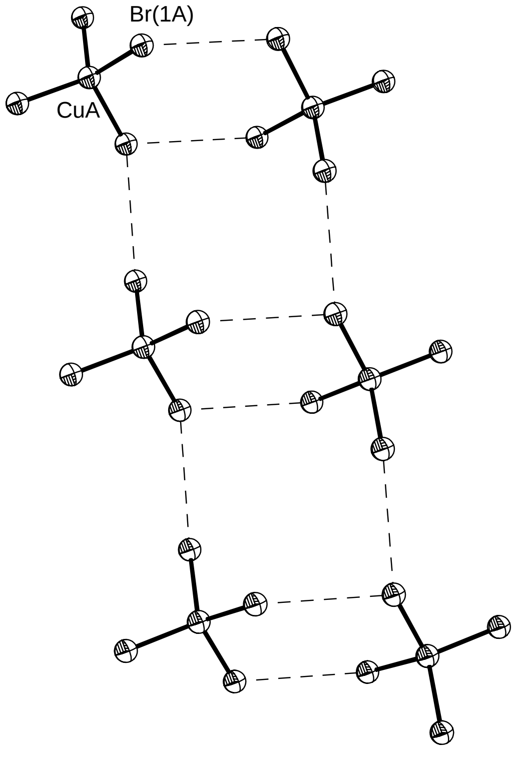

Figure 26 The $CuBr_4{}^{2-}$ packing structure of BPCB[68]

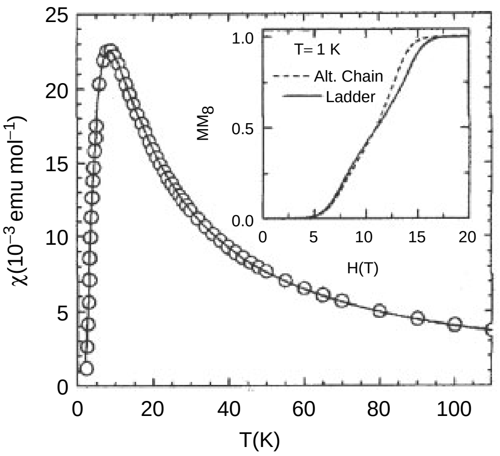

Figure 27 Susceptibility as a function of temperature for BPCB. (Reprinted with permission from B.C. Watson, V.N. Kotov, M.W. Meisel, D.W. Hall, G.E. Granroth, W.T. Monfrooij, S.E. Nagler, D.A. Jensen, R. Backov, M.A. Petruska, G.E. Fanucci, and D.R. Talham, *Phys. Rev. Lett.*, 2001, **86**, 5168. © 2001 by the American Physical Society)

The low-temperature magnetization (insert of previous figure) of BPCB is essentially zero until 5 tesla when the gap is closed by the Zeeman interaction. There is a rapid increase until 17 tesla when the field overcomes both the rung and rail exchanges. The ladder and alternating chain models make different predictions for M(H) leading to the conclusion that BPCB is a spin ladder with $2J_{\text{rung}}/k = -13.3$ K and $J_{\text{rail}}/k = -3.8$ K.

An alternative approach to spin ladders has been taken in the synthesis of Cu(quinoxaline)Br_2.[70] Here the rails are formed by the bridging bidentate quinoxaline with the rungs formed by bridging bromine atoms (Figure 28). The second ring of the quinoxaline projects into the coordination sphere of the copper atom and prevents the formation of an extended $(CuBr_2)_n$ chain orthogonal to the copper/quinoxaline axis. The exchange constants were found to be $2J_{\text{rung}}/k = -35.0$ K through the bromides and $J_{\text{rail}}/k = -30.3$ K through the quinoxalines.

3.6 Chains with $S > 1/2$

$S = 1$: The most well-studied chain compound is $[Ni(en)_2NO_2(ClO_4)]$, en = ethylenediamine, commonly known as NENP.[71] The structure of NENP consists of Ni(II) atoms bridged into chains by nitrite ion (Figure 29). The coordination sphere of the nickel is completed by the two chelating en ligands. The noncoordinating perchlorate groups (not shown) balance the charge and provide isolation between the chains. Adjacent nickel sites are related by a 2_1 screw axis, which creates the condition for spin canting.

When it was first reported, the susceptibility of NENP was a great mystery. While showing a rounded maximum near 50 K, the susceptibility along each of the crystallographic

Hori, T. Takeuchi, M. Date, A. Yamagishi, and J.-P. Renard, *Phys. Rev. Lett.*, 1989, **63**, 86. © 1989 by the American Physical Society). The left insert shows the low field behavior

axis decreased exponentially (Figure 30),[72] but to a small constant value rather than zero. It was soon realized that the existence of the Haldane gap Δ_H (Section 2.8) could account neither for the decrease at low temperatures nor for the finite values that remained nor for the anisotropy in the rate of decrease. Examination of the low-temperature magnetization for different crystal orientations showed the moment to be zero for fields less than 7 tesla along the b and c axes before increasing sharply at separate larger fields (Figure 31).[73] This behavior is characteristic of a spin singlet state, but with different gap energies for different directions. Inclusion of a single-ion anisotropy D into the Haldane theory led to the following field-dependent energy level diagram of NENP[74] consistent with parameters $2J/k = -45\,K$, $D/k = 9\,K$, and which can explain all the susceptibility and magnetization studies as well as the observed NMR T1 studies, plus EPR and inelastic neutron studies (Figure 32). The presence of the spin-canting interaction mixes different eigenstates and accounts for the observed anisotropies.

The great interest in NENP led to the development of many other antiferromagnetic nickel chains, as a way of exploring the effects of different D/J ratios and spin-canting effects. Because Haldane gap theory also predicts that the ratio of gap to exchange energy ($\Delta_H/2J$), approximately 0.4 for $S = 1$, should decrease exponentially with the value of the spin, there has been interest in $S = 2$ Heisenberg antiferromagnets. Only one is known, Mn(III)(bipy)$_2$Cl·2H_2O, for which $\Delta_H/2J = 0.07(2)$, consistent with numerical predictions.[75]

3.7 Bimetallic Spin Chains – 1D Ferrimagnets

Antiferromagnetic chains with alternating inequivalent moments will develop strongly diverging susceptibilities at low temperatures as the net moment of each unit cell aligns parallel to those in adjacent cells. The technique for insuring a site-ordered M, M' bimetallic is to encapsulate one of the metals inside a polydentate ligand, such that the M–L unit remains intact in solution. If the ligand has external binding sites that can (preferably) chelate to the second metal M', the system will self-assemble into the desired chain. This principle was demonstrated in 1981[76] using the unsymmetrical ligand dithiooxalate to bridge Ni(II) and Mn(II) ions in $[Ni(S_2C_2O_2)][Mn(H_2O)_3]{\cdot}4.5H_2O$.

An elegant example of this process is the compound $MnCu(pba)(H_2O)_3{\cdot}2H_2O$,[77] where pba = 1, 3-propylenebis(oxamate). This compound contains the mononuclear dianion $[Cu(pba)]^{2-}$ as an unbreakable copper containing unit, the 'brick' out of which the chain is assembled. Crystals are obtained by slow diffusion of aqueous solutions of $Na_2[Cu(pba)]{\cdot}2H_2O$ and manganese perchlorate. The Mn^{2+} cation is chelated by the external binding sites of two bricks to serve as the 'mortar' between the bricks, with water molecules filling in the coordination spheres of the two metal atoms (Figure 33).

The magnetic susceptibility of $MnCu(pba)(H_2O)_3{\cdot}2H_2O$ rises continuously upon cooling from room temperature until 2.4 K, where 3D ordering occurs (see Figure 34). Identification of the ferrimagnetic nature of the chain is observed in the characteristic minimum in the χT product near 115 K (insert).

An alternative approach to the formation of ferrimagnetic chains has been to combine transition ions and stable organic radicals in an alternating manner. One such example is the compound $Mn(hfac)_2(NIT)^iPr$, where hfac = hexafluoroacetylacetonate and $(NIT)^iPr$ is the nitronyl

nitroxide 2-isopropyl 4,4,5,5-tetramethylimidazoline-1-oxy 3-oxide.[78] An advantage of using the radicals is the very strong antiferromagnetic exchange that occurs between the radical and the transition metal ion. For the Mn(NIT) derivatives, the magnitudes of $2J$ range from 200 to 330 cm^{-1}. Such large exchange causes the ferrimagnetic minimum in χT to occur above 300 K. The excellent 1D isolation of these chains leads to χT values of several hundred before the chains order ferromagnetically between 5 and 10 K.

4 CONCLUDING REMARKS

Magnetic exchange, direct or via superexchange, arises from the overlap of wavefunctions of unpaired electrons and the quantum mechanical requirement that the two-electron wavefunction be antisymmetric. Although simple in concept, exchange is the basis of all useful magnets and magnetic technology. When combined with the diverse properties of transition metal ions and radicals, and the endless imagination of synthetic chemists, it leads to the wide variety of magnetic behavior illustrated above and more.

Glossary

Flux density: the number of lines of force per unit area
Lines of force: the free path that would be traced by a unit pole in a magnetic field owing to the forces acting upon it is called the line of force. Consider a unit pole enclosed in a sphere that has a radius of 1.0 cm. For the unit pole, one line of force passes through each square cm of area, and since there are 4π cm^2 of surface area on the sphere, there are 4π lines of force emanating from each unit pole
Magnetic dipole: a magnetic system composed of two poles that are equal in magnitude but opposite in nature, and that are separated by a short distance
Magnetic field: the region surrounding a magnetic body
Magnetic field strength: the force that acts upon a unit pole placed at a fixed point in a magnetic field in a vacuum is a measure of the magnetic field strength. The unit of magnetic field strength is the oersted, although frequently field strengths are given in gauss, an older term
Magnetic flux: the total number of lines of force emanating from the pole face of a magnet is called the total magnetic flux. Magnetic flux is measured in maxwells
Magnetic induction: magnetic induction along a specific direction, say i, is given by $B_i = H_i + 4\pi M_i$
Magnetic permeability: if two poles of strength m_1 and m_2 are placed at a distance r cm apart in a vacuum, the force between them is given by $F = km_1m_2/r^2$. If some material is placed between the poles, then the force will be given by $F = (k/\mu)m_1m_2/r^2$, where μ is the magnetic permeability of the material between the poles. Magnetic permeability is related to magnetic susceptibility by $\mu = 1 + 4\pi\chi$
Magnetic susceptibility: gram magnetic susceptibility is obtained by dividing the volume magnetic susceptibility (see below) by the density of the substance; molar magnetic susceptibility is obtained by multiplying the gram magnetic susceptibility by the molecular weight; when the magnetic induction along a specific direction i is divided by H_i, the result is $B_i/H_i = 1 + 4\pi M_i/H_i$, where the quantity M_i/H_i is the volume susceptibility. Volume magnetic susceptibility is almost always designated as κ_i
Pole strength: the pole strength of a magnet is measured by the number of unit poles to which each pole of the magnet is equivalent
Unit pole: a unit pole is one that will repel with a force of one dyne an equal and similar pole placed 1.0 cm away in a vacuum; the repulsion obeys Coulomb's law; a unit magnetic pole has not been isolated

1 INTRODUCTION

Much chemical information may be obtained from a determination of the response to magnetic fields of complexes or compounds of transition metal ions. This article is devoted to a development of the basis for a discussion of the magnetic susceptibility and magnetization studies of complexes or compounds in which short- or long-range order does not dictate the magnetic behavior. Magnetic susceptibility and magnetization studies are supplemented by electron paramagnetic resonance studies. Substances will be broadly classified as to their response to an inhomogeneous magnetic field. When placed in an inhomogeneous magnetic field, a diamagnetic substance will tend to move towards the weakest region of the inhomogeneous magnetic field, while a paramagnetic substance will tend to move to the strongest region of the magnetic field. These simple observations yield extremely important information about electronic structure, and ultimately bonding, in transition metal complexes and compounds.

Magnetic properties arise from the spin and orbital motions of electrons. If all of the electrons in a substance are paired, then the substance will usually be diamagnetic. However, if unpaired electrons are present, then the substance may be paramagnetic. Cooperative interionic interactions may lead to long-range magnetic ordering resulting in ferromagnetism, antiferromagnetism, or ferrimagnetism among other forms of cooperative magnetic ordering (*see* ***Magnetism of Extended Arrays in Inorganic Solids***).

Useful theory for the description of the properties of transition metal complexes and compounds has been developed in depth in a number of monographs (some classical ones are referenced here; *see* ***Ligand Field Theory & Spectra***).[1–6] Therefore, only a brief outline of theoretical developments will be presented along with some valuable results for the interpretation of magnetic data.

Table 1 Conversion factors for magnetic quantities

Multiply the number for			To obtain the number for	
Gaussian quantity	Unit	By	SI quantity	Unit
Flux density, B	G	10^{-4}	Flux density, B	T ($\equiv$ Wb m^{-2} $\equiv$ V s m^{-2})
Magnetic field strength, H	Oe	$10^3/4\pi$	Magnetic field strength, H	A m^{-1}
Volume magnetic susceptibility, κ	emu cm^{-3} (dimensionless)	4π	Rationalized volume susceptibility, κ	(dimensionless)
Gram magnetic susceptibility, χ_g	emu g^{-1} ($\equiv$ cm^3 g^{-1})	$4\pi \times 10^{-3}$	Rationalized gram susceptibility, κ_g	m^3 kg^{-1}
Molar magnetic susceptibility, χ_M	emu mol^{-1} ($\equiv$ cm^3 mol^{-1})	$4\pi \times 10^{-6}$	Rationalized molar susceptibility, κ_{mol}	m^3 mol^{-1}

There are two systems of units commonly used in publications dealing with magnetic properties. These are the cgs–emu system and the International System of Units (SI). A number of useful conversion factors are collected in Table 1.

1.1 Experimental Techniques

Magnetic susceptibility and magnetization measurements are made by a variety of techniques. These include the Gouy method, the Faraday method, and change in flux methods. Excellent descriptions of the methods as well as their advantages and limitations are available.[7–9]

Absolute values of magnetic susceptibilities are rarely measured in the laboratory. Instead, the apparatus for the measurement of magnetic susceptibilities are usually calibrated with standard substances that have well known values. It is generally advisable to use a standard that has a gram magnetic susceptibility comparable in magnitude to that of the unknown. Thus, for diamagnetic materials, water ($\chi_g = -0.720 \times 10^{-6}$ cgs units at 293 K)[7] is frequently used. The compound $HgCo(NCS)_4$ ($\chi_g = 16.44 \times 10^{-6}$ cgs units at 293 K) is widely used as a standard for paramagnetic substances, even though the gram magnetic susceptibility is rather large. $HgCo(NCS)_4$ can be used over a range of temperatures since the Curie–Weiss parameters are well known.[10,11] The manganese Tutton salt $(NH_4)_2Mn(SO_4)_2{\cdot}6H_2O$ is widely used since the magnetic susceptibility of this compound obeys the Curie law with $C = 4.375$.[12] The compound $(Me_2enH_2)CuC1_4$ ($Me_2enH_2 = [Me_2NHCH_2CH_2NHMe_2]^{2+}$) has been suggested[11] as a calibration standard for work with less paramagnetic materials since the gram magnetic susceptibility is significantly smaller than that of $HgCo(NCS)_4$ or the manganese Tutton salt. The magnetic susceptibility of $(Me_2enH_2)CuC1_4$ obeys the Curie–Weiss law with $C = 0.433$ and $\theta = -0.07$.[11]

2 ANALYSIS OF EXPERIMENTAL DATA

2.1 The Van Vleck Equation

Van Vleck[13] derived an equation for the calculation of magnetic susceptibilities of paramagnetic systems in which the magnetic susceptibility is independent of the magnetic field. The equation is applicable for moderate magnetic fields and temperatures. The system to be described by the theory consists of a series of n states, each of which is m-fold degenerate. The energy of the state $E_{n,m}$ in a magnetic field H is expanded in terms of a power series in H:

$$E_{n,m} = E^{(0)}_{n\cdot m} + HE^{(1)}_{n\cdot m} + H^2E^{(2)}_{n\cdot m} + \mathrm{K} \qquad (1)$$

The magnetic moment of the level $E_{n,m}$ in the magnetic field direction ($i = x, y, z$) is given by

$$\begin{aligned}\mu_{n,m} &= \frac{-\mathrm{d}E_{n,m}}{\mathrm{d}H_i} \\ &= \left(\frac{-\mathrm{d}}{\mathrm{d}H_i}\right)(E^{(0)}_{n\cdot m} + HE^{(1)}_{n,m} + H^2E^{(2)}_{n,m} + \mathrm{K}) \\ &= -E^{(1)}_{n,m} - 2HE^{(2)}_{n,m} - \mathrm{K} \end{aligned} \qquad (2)$$

The magnetic moment per gram atom for the array of states is obtained by taking a statistical mean over the populated states weighted by a Boltzmann distribution, yielding

$$M_i = \frac{N_A \sum_{n,m} \mu_{n,m} \exp(-E_{n,m}/kT)}{\sum_{n,m} \exp(-E_{n,m}/kT)} \qquad (3)$$

where N_A is the Avogadro number. The theory is developed for paramagnetic substances for which there is no magnetization in the absence of an applied field. The magnetic susceptibility,

defined as $\chi_i = M_i/H_i$, is given by the Van Vleck equation:

$$\chi_i = \frac{N_A \sum_{n,m} [E_{n,m}^{(1)^2}/kT - 2E_{n,m}^{(2)}] \exp(-E_{n,m}^{(0)}/kT)}{\sum_{n,m} \exp(-E_{n,m}^{(0)})/kT} \tag{4}$$

The terms $E_{n,m}^{(1)}$ and $E_{n,m}^{(2)}$ in the Van Vleck equation are the first- and second-order Zeeman coefficients obtained from the expansion of the magnetic moment in terms of a power series of the magnetic field.

2.2 The Curie Law

Consider an octahedral molecule with the direction of the applied field H taken parallel to z, so the $L_z + 2S_z$ components of the Zeeman operator $L + 2S$ may be used. Thus

$$E_{n,m}^{(1)} = \langle \psi_{n,m} | L_z + 2S_z | \psi_{n',m'} \rangle \mu_B H \tag{5}$$

and

$$E_{n,m}^{(2)} = \frac{\sum_n |\langle \psi_n | L_z + 2S_z | \psi_0 \rangle \mu_B H|^2}{(E_0 - E_n)} \tag{6}$$

Ignoring the second-order term, the magnetic susceptibility of an orbitally nondegenerate ground state becomes

$$\begin{aligned} \chi_z &= \left(\frac{N\mu_B}{k_B T}\right) \frac{|\langle \psi_{n,m} | 2S_z | \psi_{n',m'} \rangle|^2}{(2S+1)} \\ &= \left(\frac{N{\mu_B}^2 g^2}{k_B T(2S+1)}\right) \\ &= \left[\frac{N{\mu_B}^2 g^2}{k_B T(2S+1)}\right] \left[\left(\frac{1}{3}\right) S(S+1)(2S+1)\right] \\ &= \left(\frac{N{\mu_B}^2 g^2}{3k_B T}\right) [S(S+1)] \end{aligned} \tag{7}$$

This last equation is the spin-only formula where the Landé g factor has been introduced to take account of any spin–orbit coupling with excited states. The Landé g factor is given by

$$g = \frac{1 + [J(J+1) + S(S+1) - L(L+1)]}{[2J(J+1)]} \tag{8}$$

In the case of spin-only paramagnetism, the Landé g factor is 2, since $L = 0$. The Curie law

$$\chi = \frac{C}{T} \tag{9}$$

where C is the Curie constant, is frequently used. Thus

$$C = \frac{N{\mu_B}^2 g^2 S(S+1)}{3k} \tag{10}$$

The Curie law was found experimentally in the 1890s.

2.3 Paramagnetism

In the general case, magnetic properties will depend on the total angular momentum J, the magnetic moment will be μ_J, and the Hamiltonian for a single magnetic ion will be

$$\mathrm{H} = -\mu_J \cdot H_0 \tag{11}$$

where H_0 is the applied magnetic field. Along one direction, say the z direction, the Hamiltonian becomes

$$\mathrm{H} = -\mu_{Jz} H_z \tag{12}$$

The eigenvalues are $-g\mu_B m_J H_z$, where m_J can take on the values J, $J-1, \ldots, -J$. The partition function is

$$\begin{aligned} Z_J &= \sum_{m_J} \exp\left(\frac{g\mu_B H_z}{k_B T}\right) \\ &= \left(\sinh\left[\left\{\frac{(2J+1)}{2J}\right\} x\right]\right) \left(\sinh\left(\frac{x}{2J}\right)\right) \end{aligned} \tag{13}$$

where $x = g\mu_B J H_z / k_B T$ is the ratio between magnetic and thermal energies. The magnetic moment becomes

$$M = \frac{N\mu_B \sum_{m_J} m_J \exp(m_J x/J)}{Z_J(x)} \tag{14}$$

which can be expressed in terms of the Brillouin function as[14]

$$M = Ng\mu_B J B_J(x) \tag{15}$$

where

$$\begin{aligned} B_J(x) &= \left[\frac{(2J+1)}{2J}\right] \coth\left[\left\{\frac{(2J+1)}{2J}\right\} x\right] \\ &\quad - \left(\frac{1}{2J}\right) \coth\left(\frac{x}{2J}\right) \end{aligned} \tag{16}$$

There are two limiting cases. In the first case, $x \ll 1$. This would correspond to a typical paramagnetic substance at room temperature. For example, with $J = 1$, $g = 2$, and $H_0 = 10\,000$ Oe at room temperature, x may be calculated to be 5×10^{-3}. In such a case the Brillouin function reduces to

$$B_J(x) = \left[\frac{(J+1)}{3J}\right] x \tag{17}$$

and the magnetic moment is given by

$$M = \frac{Ng^2{\mu_B}^2 J(J+1) H_z}{3k_B T} \tag{18}$$

Since the magnetic susceptibility is defined by $\chi = M/H$, then

$$\chi = \frac{C}{T} \tag{19}$$

where the Curie constant C is

$$C = \left[\frac{Ng^2\mu_B{}^2 J(J+1)}{3k}\right] \tag{20}$$

in agreement with the results obtained earlier considering only the spin.

An effective magnetic moment may be defined as

$$\mu_{\text{eff}} = g[J(J+1)]^{1/2} \tag{21}$$

or, for spin-only paramagnetism, by

$$\mu_{\text{eff}} = g[S(S+1)]^{1/2} \tag{22}$$

The spin-only formula may also be expressed as

$$\mu_{\text{eff}} = [n(n+2)]^{1/2} \tag{23}$$

where n is the number of unpaired electrons, and g is taken to be 2.0. Magnetic moments calculated with these simple formulas are compared with experimental magnetic moments in Table 2.

The other limiting case occurs when the magnetic energy is large with respect to the thermal energy, in other words x takes on large values. This corresponds to paramagnetic saturation. The following expression may be written:

$$\frac{M}{Ng\mu_B J} = B_J(x) = 1 - \left(\frac{1}{J}\right)\exp\left(\frac{-g\mu_B H_z}{k_B T}\right) \tag{24}$$

Plots of $B_J(x)$ as a function of x are shown in Figure 1 for several x values. It is clear that magnetization studies can

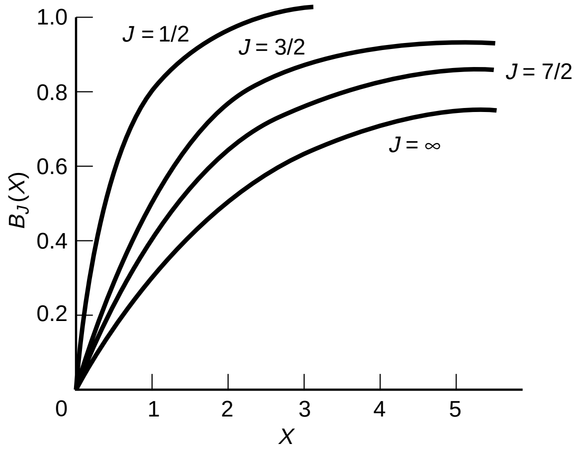

Figure 1 The functional form of the Brillouin function for selected J values

be very useful in determining angular momentum quantum numbers since the shape of the magnetization curves are very sensitive to the value of J.

Table 2 Typical experimental magnetic moments of first-row transition metal-ion complexes compared with theoretical predictions

Ion	Ground state O_h	Ground state S	Free ion L	Free ion J	$\mu_{\text{eff}} = g[J(J+1)]^{1/2}$	$\mu_{\text{eff}} = g[S(S+1)]^{1/2}$	μ_{eff} expt (BM)

Cu^{2+}	^2E	1/2	2	5/2	3.55	1.73	1.9

2.4 Data Analysis

Measurements of magnetic properties at one temperature, say room temperature, or over a limited temperature range yield data that may be useful, but generally measurements should be made over wide ranges of temperatures and magnetic field strengths. Such measurements may yield valuable information for detailed descriptions of electronic structure and bonding.[15]

2.5 Diamagnetic Corrections

Experimental magnetic susceptibility data must be corrected for the diamagnetism of the constituent atoms, a quantity that is practically temperature independent. Diamagnetism may be estimated rather precisely by the following procedure developed by Pascal:

$$\chi_M(\text{dia}) = \sum_i n_i \chi(A)_i + \sum_j n_j \chi(B)_j + \text{K} \tag{25}$$

where n_i is the number of atoms of kind i and diamagnetic susceptibility $\chi(A)_i$, and $\chi(B)_j$ is the susceptibility associated with n_j structural features (such as double or triple carbon–carbon bonds). Extensive self-consistent tables of magnetic susceptibilities of atoms, ions, and structural features have been tabulated.[15] Some commonly used diamagnetic corrections are collected in Table 3.

As an example of the use of Table 3, consider the diamagnetic susceptibility of $[Cu(bipy)_3](ClO_4)_2 \cdot 4H_2O$,

Table 3 Diamagnetic corrections ($\chi_{dia} \times 10^{-6}$ emu mol^{-1})

Atoms		Anions		Cations	
H	2.93	F^-	9.1	Li^+	1.0
C	6.0	Cl^-	23.4	Na^+	6.8

Se	23.0	OH^-	12.0	Cu^{2+}	12.8
Te	37.3				
P	26.3				
As^{III}	20.9				
As^{V}	43.0				
Sb^{III}	74.0				
Li	4.2				
Na	9.2				
K	18.5				

Common ligands		Constituent corrections	
Water	13.0	C=C	−5.5
2,2′-Bipyridine	105.0	C≡C	−0.8
Phenanthroline	128	C=C–C=C	−10.6
		C (in aromatic ring)	1.4
		N=N	−1.9
		C=N–	−8.2
		–C≡N	−0.8
		C–Cl	−3.1
		C–Br	−4.1
		C–I	−4.1

for which

$$\begin{aligned}\chi_M(\text{dia}) &= \chi(\text{Cu}) + 3\chi(\text{bipy}) + 2\chi(\text{ClO}_4^-) + 4\chi(\text{H}_2\text{O})\\ &= 12.8 + 315 + 64 + 52\\ &= 443.8 \times 10^{-6}\text{cgs units}\end{aligned} \qquad (26)$$

Thus, the quantity 443.8×10^{-6} must be added to the measured magnetic susceptibility in order to arrive at the corrected molar magnetic susceptibility of the compound.

2.6 Graphical Treatment of Experimental Data

The molar magnetic susceptibility, χ_M, which has been corrected for the diamagnetism of the constituent atoms, is plotted versus T^{-1}. If a straight line is obtained, then the data follow the Curie law, $\chi = C/T$. The effective magnetic moment is given by

$$\mu_{\text{eff}} = 2.828(\chi_M \cdot T)^{1/2} \qquad (27)$$

and the Bohr magneton number can be used in the solution of the chemical problem under study.

If a straight line that intercepts the positive χ_M axis at $T^{-1} = 0$ is obtained, then it is possible that temperature-independent paramagnetism (see below) is present, or alternatively, that the diamagnetic correction has been overestimated. If the straight line intercepts the negative χ_M axis at $T^{-1} = 0$, it is likely that the diamagnetic correction has been underestimated.

If the line in the plot of χ_M versus T^{-1} is not straight, then χ_M^{-1} must be plotted versus T. A straight line here indicates that the data obey the Curie–Weiss law

$$\chi = \frac{C}{(T - \theta)} \qquad (28)$$

which, when recast, yields

$$T = \frac{C}{\chi_M + \theta} \qquad (29)$$

The slope of the line is the Curie constant, and the intercept is the Weiss constant.

It is usually instructive to plot $\chi_M{\cdot}T$ versus T. Curie law behavior holds if a straight line parallel to the T axis is obtained. For orbitally nondegenerate systems, deviations from straight line behavior toward larger $\chi_M{\cdot}T$ values with decreasing temperature indicate an array of populated electronic states with states of larger spin multiplicity lying lowest. The array of states may arise from ferromagnetic interactions. Deviations of $\chi_M{\cdot}T$ to smaller values with decreasing temperature indicate the presence of an array of populated electronic states with lower spin multiplicities lying lowest. Such an array of states may arise from antiferromagnetic interactions.

If a straight line is not obtained from the Curie–Weiss plot, then it is clear that more detailed theory is necessary for data analysis, and the Van Vleck equation or other more sophisticated theory must be used.

3 THEORETICAL ANALYSIS OF EXPERIMENTAL DATA

Crystal-field theory and its modifications are very useful in discussions of magnetic properties of transition metal compounds even though the theories are well known to be highly artificial. This arises from the assumption that the bonding between the transition metal ion and the ligands is considered to be totally ionic or can be parameterized. The ligands are assigned a passive role in that they provide a constant electric field that has the symmetry of the ligand nuclei, and this electric field destabilizes the free ion energy levels of the transition metal ion.

3.1 Basic Theoretical Concepts

Crystal-field theory will be briefly described here using a weak-field approach. Those interested in complete treatments beyond the scope of this article are referred to discussions in appropriate monographs.[1–6] Perturbation theory is used assuming free ion eigenfunctions and eigenvalues, and the Hamiltonian is

$$\mathrm{H} = -\left(\frac{h}{8\pi^2 m}\right)\sum_i \nabla_i^2 - \sum_i\left(\frac{Ze^2}{r_i}\right) + \left(\frac{1}{2}\right)\sum_{i\neq k}\left(\frac{e^2}{r_{i,k}}\right) + \sum_i (\zeta_i(r) l_i{\cdot}s_i) + V_{\mathrm{CF}} \qquad (30)$$

The following cases may be envisaged:

1. $V_{\mathrm{CF}} < l{\cdot}s$
2. $l{\cdot}s < V_{\mathrm{CF}} < e^2/r_{ij}$
3. $V_{\mathrm{CF}} > e^2/r_{ij}$

Table 4 Crystal-field splitting of ^{2}D free ion state

E = −4Dq	E = 6Dq
$\psi_1 = (\|2\rangle - \|{-2}\rangle)/\sqrt{2}$	$\psi_4 = (\|2\rangle + \|{-2}\rangle)/\sqrt{2}$
$\psi_2 = \|1\rangle$	$\psi_5 = \|0\rangle$
$\psi_3 = \|{-1}\rangle$	

Complexes of the rare earth elements provide examples of case (1), many complexes of the first-transition series metals provide examples of case (2), and complexes with covalent bonds provide examples of case (3). Case (2) will be considered here. Excellent monographs cited above are available in which the theory is developed in detail.

The calculation reveals that the octahedral crystal field removes the fivefold orbital degeneracy of the ^{2}D free ion state, yielding a threefold degenerate state at $-4Dq$ and a twofold degenerate state at $+6Dq$. The results of the crystal-field calculation are collected in Table 4. The representations spanned by the crystal-field states are determined by an examination of the transformation properties of $\psi_1, \ldots, \psi_5$ in the point group O, since it is known that d wavefunctions are even under inversion and O_h is $O \times i$. In O_h, these become T_{2g} and E_g, respectively. In this manner, it has been determined that the octahedral crystal field removes the orbital degeneracy of the ^{2}D free ion state, resulting in the formation of two crystal-field states, those being $^2T_{2g}$ and ^2E_g.

3.2 Spin–Orbit Coupling in Octahedral Crystal-field States

Under certain circumstances, the degeneracies of the crystal-field states are further split by coupling of the orbital angular momenta of the electrons to their spin angular momenta. The splitting of these crystal-field states by spin–orbit coupling can be determined by use of group theory, and in the case of odd numbers of electrons, double groups must be used.

The technique proceeds as follows. The representations spanned by the spin function and by the orbital function in the double group are determined, the direct product of these representations is taken, and the direct product representation is reduced to a sum of irreducible representations. In an octahedral crystal field, the ^2E_g state is not split by spin–orbit coupling but transforms as the irreducible representation Γ_8 in the double group O', while the $^2T_{2g}$ state is split by spin–orbit coupling giving new states Γ_7 and Γ_8. In many instances, the influence of the ^2E_g state cannot be ignored, since symmetry arguments show that it can mix with the ground state by spin–orbit coupling. For the purposes of this discussion, these interactions will be neglected.

The term that is added to the Hamiltonian to account for spin–orbit coupling is valid for spherical symmetry only, but the error introduced in lower symmetry cases is not great. The spin–orbit coupling constant could be taken from the spectra

of gaseous ions, but it is usually treated as a parameter with the fitted parameter in the complex being less than that of the free ion.

If the interactions between different Russell–Saunders states are not large, the spin–orbit coupling operator may be written

$$\mathrm{H}_{LS} = \lambda L\cdot S \tag{31}$$

For a shell less than half filled

$$\lambda_{LS} = \frac{\zeta}{2S} \tag{32}$$

while a shell that is more than half filled has

$$\lambda_{LS} = \frac{-\zeta}{2S} \tag{33}$$

The secular determinantal equation is set up in the usual manner, the wavefunctions corrected for the crystal-field interaction are used in the perturbation treatment, energies are generated, and these are used in conjunction with the secular equations to generate new wavefunctions that have now been corrected for spin–orbit coupling. These corrected wavefunctions are used for the calculation of the Zeeman effect.

3.3 The Zeeman Effect

It is appropriate to use perturbation theory to approximate the Zeeman energies since λ is typically much greater than the quantity $\mu_B H$. The first-order Zeeman energy is the first-order perturbation energy, and the second-order Zeeman energy is the second-order perturbation energy. An energy level diagram that shows the effects of the octahedral crystal field, spin–orbit coupling, and an external magnetic field on the ^{2}D free ion term is shown in Figure 2. An expression for magnetic susceptibility may be generated by substitution of the first- and second-order Zeeman coefficients and the zero-field energies into the Van Vleck equation.

Since

$$\mu_{\text{eff}} = \left(\frac{3k_B T}{N\mu_B{}^2}\right)\chi_M \tag{34}$$

then the temperature variation of the magnetic moment for the $^2T_{2g}$ state arising from the d^1 electronic configuration in an octahedral crystal field is

$$\mu_{\text{eff}} = \left[\frac{\{8 + (3\lambda/k_B T - 8)\exp(-3\lambda/2k_B T)\}}{(\lambda/k_B T) \times \{2 + \exp(-3\lambda/2k_B T)\}}\right]^{1/2} \tag{35}$$

The magnetic moment tends toward zero at low temperatures because, as shown in Figure 2, there is no first-order Zeeman effect in Γ_8. At the level of approximation presented here the moments arising from the orbital and spin motions cancel.

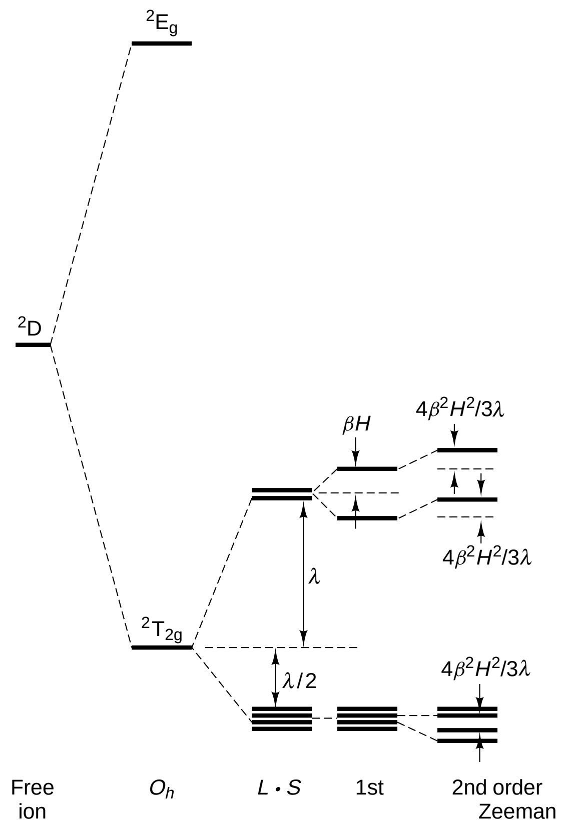

Figure 2 Successive perturbations of an octahedral crystal field, spin–orbit coupling, and the first and second Zeeman interactions on the ^{2}D state

The magnetic susceptibility data for a transition metal complex with a d^1 electronic configuration may obey the Curie–Weiss law above about 200 K, usually with a large θ value. At lower temperatures the magnetic susceptibility deviates from the Curie–Weiss law and becomes constant. This behavior may be understood in terms of the calculation outlined above. At low temperatures, only Γ_8 is populated, and this state exhibits only a second-order Zeeman effect. This example illustrates an important result; large θ values in the Curie–Weiss law are not always associated with long- or short-range cooperative magnetic effects.

3.4 Magnetism of a d^1 Ion in a Tetrahedral Environment

Many of the results obtained for the octahedral crystal-field calculation can be used for the description of the magnetic properties of ions in tetrahedral environments. If an S_4 axis of the tetrahedron is taken as the axis of quantization (being collinear with the C_4 axis of quantization of the octahedron), and the C_3 axes of the tetrahedron are collinear with the C_3 axes of the octahedron, then the crystal-field potential energy

operator for the tetrahedral environment is

$$V(T_d) = -\left(\frac{28}{27}\right)\pi^{1/2}\left(\frac{Z_j e^2 r^4}{a^5}\right) \times \left[Y_4{}^0 + \left(\frac{5}{14}\right)^{1/2}(Y_4{}^4 + Y_4{}^{-4})\right] \quad (36)$$

Comparison of $V(T_d)$ with $V(O_h)$ reveals that $V(T_d) = -(4/9)V(O_h)$. The Y_l^m are spherical harmonics.

The rotation group T is a subgroup of the rotation group O, and the degeneracy of the ^{2}D free ion state is lifted in the point group T yielding $^2T_2$ and ^{2}E, which correlate with $^2T_2$ and ^{2}E of O, respectively. At the same level of approximation described for the d^1 ion in an octahedral environment, the first-order Zeeman effect in the ^{2}E state leads to a doubly degenerate level at $+\mu_B H_z$ and a second doubly degenerate level at $-\mu_B H_z$.

If second-order effects are ignored, substitution into the Van Vleck equation yields for the magnetic susceptibility

$$\chi_M = \frac{N\mu_B{}^2}{k_B T} \quad (37)$$

This result shows that, to first order, the magnetic susceptibility of a d^1 ion in a tetrahedral environment should exhibit simple Curie law behavior, but this is rarely the case. Second-order effects may arise from interactions with the excited states.

Following the procedures outlined in the calculations presented above, substitution of the Zeeman coefficients and zero-field energies into the Van Vleck equation yields the following expression for the magnetic susceptibility:

$$\chi_M = \frac{N\mu_B{}^2}{k_B T} + \frac{4N\mu_B{}^2}{\Delta_t} \quad (38)$$

The second term is temperature-independent paramagnetism and can be verified independently if Δ_t is known from spectral studies. This is an excellent example of the complementary data that may be obtained from magnetic susceptibility and electronic spectroscopic studies.

3.5 Example of a Low-symmetry Crystal-field Component

Transition metal complexes rarely have structures that may be classified in high symmetry point groups such as O_h or T_d. The effect of a tetragonal distortion of an octahedron will be discussed here. The most important conclusion from the exercise is that additional parameters must be introduced. In optimum cases, these parameters may be obtained from detailed spectroscopic studies. Consider an elongation or contraction of an octahedron along a C_4 axis such that there are two equivalent metal–ligand bond distances along the z axis with length b, and four equivalent metal–ligand bond distances perpendicular to the z axis with length a. Following the procedures outlined earlier, it may be seen that some combination of $Y_2{}^m$ contributes to the crystal-field potential, as well as $Y_4{}^m$ combinations. Retaining quantization along C_4, it may be shown that only $Y_2{}^0$ contributes to $V(O_h)$.

Since D_4 is a subgroup of the point group O, it may be shown, from symmetry arguments, that the effect of the lower symmetry on the ^2E_g and $^2T_{2g}$ states is removal of some of the degeneracy. The results follow:

$$\begin{aligned} {}^2E_g &\longrightarrow {}^2A_{1g} + {}^2B_{1g} \\ {}^2T_g &\longrightarrow {}^2B_{2g} + {}^2E_g \end{aligned} \quad (39)$$

The energies of the states must be calculated. For example, for $^2A_{1g}$ the integral $\langle d_0|V(D_{4h})|d_0\rangle$ must be evaluated. $V(D_{4h})$ has additional terms as a result of the lower symmetry, and it is necessary to define new constants in addition to *Dq*. Two popular constants are *Ds* and *Dt*. Other constants appear in the literature, but *Ds* and *Dt* predominate. The energies are

$$\begin{aligned} A_{1g} &= 6Dq - 2Ds - 6Dt \\ B_{1g} &= 6Dq + 2Ds - Dt \\ B_{2g} &= -4Dq + 2Ds - Dt \\ E_g &= -4Dq - Ds + 4Dt \end{aligned} \quad (40)$$

Since the low-symmetry component of the crystal-field and spin–orbit coupling are of comparable magnitude, these perturbations to the octahedral results must be applied simultaneously. The spacing and ordering of the array of states will depend on the nature and magnitude of the distortion. Corrections to the energies and corrected wavefunctions may be generated by substitution of the energies into the appropriate secular equations. For the details and solutions, an excellent paper by Figgis[16] provides such information and results. It is sufficient to note that the details of the low-lying energy levels, which determine the magnetic properties, are dependent on the spin–orbit coupling constant and the crystal-field component.

Anisotropic magnetic properties are anticipated in the axial system under consideration, where the Zeeman effect in the direction parallel to the C_4 axis may be calculated with

$$(l_z + 2s_z)\mu_B H_z \quad (41)$$

and in the perpendicular direction by use of

$$(l_x + 2s_x)\mu_B H_x \quad (42)$$

The steps to be followed may be summarized. Secular determinants must be constructed for each of the doubly degenerate levels in both directions. First-order Zeeman coefficients must be evaluated for each direction. Matrix elements connecting the three secular determinants must be evaluated to yield second-order Zeeman coefficients. The first- and second-order Zeeman coefficients must be substituted into the Van Vleck equation to yield the anisotropic magnetic susceptibilities $\chi_\parallel$ and $\chi_\parallel$. Generally, anisotropic magnetic properties are discussed in terms of $\mu_\parallel$ and $\mu_\parallel$ since the variation of these anisotropic components are much more easily visualized.

4 MULTIELECTRON TRANSITION METAL COMPLEXES AND COMPOUNDS

Important problems arise for complexes and compounds with two or more electrons. It is known that an array of states will arise from interelectronic interactions. Furthermore, the treatment of the magnetic problem depends on the magnitude of the perturbation of the metal-ion electrons by the surrounding ligands. The weak-field approach described above works well for complexes and compounds of transition metal ions with ligands at the weak end of the spectrochemical series. Examples are provided by low-oxidation state complexes of first-transition series metal ions with ligands such as halides, hydroxide, water, and ammonia, among many others. In these complexes and compounds, the spectroscopic terms of the free ion are maintained, but the degeneracies may be lifted by the symmetry provided by the ligands.

At the other end of the scale the perturbation may be very strong, the orbitals of the free ion may be viewed as being highly separated in energy, the electrons may occupy only the lowest lying orbitals, and in some cases the electron may be paired in these low-lying orbitals. As an illustrative example, consider the d^2 electronic configuration in an octahedral environment. Under the influence of a very strong perturbation, the t_{2g} orbitals will lie lowest in energy, the electronic configuration will be $(t_{2g})^2$, and states will arise from interelectronic interactions in these orbitals. Since the e_g level lies at a much higher energy, the next electronic configuration will be $(t_{2g})^1(e_g)^1$, which will give rise to a number of states, and the highest lying configuration will be $(e_g)^2$ with its resultant states. The states that arise from these configurations will correlate exactly with the states that arise from the action of the ligand field on the Russell–Saunders states found in the weak-field approach. It is instructive and useful to construct correlation diagrams linking the states from the weak-field and the strong-field approaches. A lucid description of the procedures to be followed and the application of these diagrams has been given by Cotton.[17]

A third case arises when the perturbation from the ligand field is intermediate between the weak-field case and the strong-field case. There is no sharp dividing line between the three cases given here. The calculational approach to be used depends on the identities of the transition metal ion and the ligands. The results of this third case have been presented by Figgis.[16] Applications have also been discussed by Mabbs and Machin.[18]

4.1 Weak-field Approach for a d^2 Ion in an Octahedral Environment

The Russell–Saunders states that arise from interelectronic interactions in a free ion with an electronic configuration d^2 are ^3F, ^1D, ^3P, ^1G, and ^1S, with the ^3F being the ground state as dictated by Hund's first and second rules. An approximate calculation in which the ^3F state is outlined here.

In an octahedral environment with O_h symmetry, the degeneracy of the ^3F state is lifted and $^3T_{1g}$, $^3T_{2g}$, and $^3A_{2g}$ states arise. A crystal-field calculation shows that the $^3T_{1g}$ state is the ground state with an energy of $-6Dq$, with the $^3T_{2g}$ state lying at $2Dq$, and the $^3A_{2g}$ state at $12Dq$. Since Dq is on the order of $1000\,cm^{-1}$, then the two higher lying states will be omitted from the calculation of spin–orbit coupling. Precise treatments of data from some experiments may require the mixing in of excited states, especially the $^3T_{1g}$ provided by the ^3P Russell–Saunders state.

A spin–orbit calculation using the crystal-field corrected wavefunctions yields a fivefold degenerate level at $-\zeta/2$, a threefold degenerate level at $\zeta/2$, and a singly degenerate level at ζ. Calculation of the Zeeman coefficients and substitution into the Van Vleck equation is straightforward, and an equation for the temperature variation of the magnetic moment may be generated from the magnetic susceptibility expression. If x is taken to be ζ/k_BT, then the latter equation becomes

$$\mu_{eff}{}^2 = \frac{3[5x/2 + 15 + (x/2 + 9)\exp(-x) - 24\exp(-3x/2)]}{x(5 + 3\exp(-x) + \exp(-3x/2))} \quad (43)$$

It is instructive to examine the temperature dependence of the magnetic moment. As the temperature approaches 0 K, the magnetic moment approaches $1.2\,\mu_B$, while at very high temperatures the magnetic moment approaches $3.2\,\mu_B$. At room temperature, the magnetic moment given by the above equation is about $2.8\,\mu_B$, a remarkable coincidence with the magnetic moment predicted by the spin-only formula. The calculation proceeds in the same manner for a d^3 ion in an octahedral environment of ligands. The steps of the calculation are described in much detail by Theissing and Caplan.[19] Useful formulas for the analysis of magnetic data for complexes of transition metal ions have been given by König and König.[15]

5 HIGH-SPIN AND LOW-SPIN COMPLEXES AND COMPOUNDS

An interesting situation arises for octahedral complexes in which the metal ion has electronic configurations d^4, d^5, d^6, and d^7. The electronic configurations that may be written for d^4 are $(t_{2g})^3(e_g)^1$ or $(t_{2g})^4$, for d^5 are $(t_{2g})^3(e_g)^2$ or $(t_{2g})^5$, for d^6 are $(t_{2g})^4(e_g)^2$ or $(t_{2g})^6$, and for d^7 are $(t_{2g})^5(e_g)^2$ or $(t_{2g})^6(e_g)^1$. The former in each case is called high spin and the latter is called low spin. To a good approximation, the electronic configuration adopted is determined by the magnitude of the crystal-field splitting Δ as compared to the electron–electron (repulsion) or pairing energy, P. If P is greater than Δ, the high-spin configurations arise, while low-spin configurations arise when Δ is greater than P. As a general rule, ligands at the low end of the spectrochemical series, such as halides, water, and ammonia, give rise to high-spin complexes with first-row transition metal ions, while ligands at the high end of the spectrochemical series, such as nitrite and cyanide, give

rise to low-spin complexes for first-row transition series metal ions. There is no hard and fast rule concerning the crossover point and, for example, few ligands give high-spin complexes with cobalt(III).

5.1 Spin Crossover Complexes and Compounds

Very interesting phenomena may occur near the crossover point. There are frequently dramatic changes in magnetism, structure, and electronic, and vibrational spectroscopy of the complexes, and these changes may be continuous or discontinuous.[20] As implied by the nomenclature, in spin crossover compounds the properties of a complex in the continuous class exhibit gradual changes with an external perturbation such as a change in temperature, while those in the discontinuous class show abrupt changes in properties that may be first order in nature. There is frequently hysteresis in properties as the perturbation, say temperature, is cycled from high to low values; the observed changes in properties almost never obey a Boltzmann distribution law expected for two independent states, and frequently the properties reflect incomplete transitions from one state to the other. For example, spin crossover complexes of iron(II), which should be diamagnetic in the low-spin state, often show sizeable magnetic moments. This is an active field of research that has been stimulated recently by the LIESST effect (LIESST is Light Induced Electron Spin State Trapping).[21] In special instances, the excited states in these compounds have very long lifetimes, and, for example, the magnetic properties of these excited states may be determined. The potential for practical applications of these fascinating molecules are great.

6 SURVEY OF TYPICAL RESULTS FOR TRANSITION METAL COMPOUNDS

In view of the thousands of transition metal compounds, it is not possible to discuss here the diverse behavior exhibited by the many different classes of these compounds. The variables are numerous; these include structures, oxidation states, and ligands to name a few. Data for many transition metal compounds have been collected by König and König in a series of volumes.[15] They give the basic theory required for effective use of the tables, often summarize conclusions by the original author or authors, and show structures for complex ligands. This is an extremely valuable collection of data that is the starting point for critical analyses of the properties of the different classes of compounds. Reference to the current literature is necessary, for data on new and fascinating compounds are being generated at a very high rate. The research is stimulated by the invention of new chemistry and by the generation of new models for magnetic behavior. A new monograph has appeared on bioinorganic aspects of the subject,[22] as well as a book on molecular magnets, a topic of great current interest.[23]

1 BACKGROUND AND GENERAL CHEMISTRY

Manganese is a relatively abundant metal, constituting about 0.085% of the earth's crust. Among the transition metals, only iron is more abundant. Manganese minerals are widely distributed; oxides, hydrous oxides, silicates, and carbonates are the most common. Large quantities (more than 10^{12} tons) of 'manganese nodules' that have been discovered on the floor of the oceans may become a source of manganese. These nodules contain about 24% of manganese together with many other metals in lesser abundance. Most manganese today is obtained from ores, pyrolusite (MnO_2) and rhodochrosite ($MnCO_3$) are the most common. The metal is produced by reduction of its oxides with sodium, magnesium, and aluminum, or by electrolysis. Nearly all manganese produced commercially is used in the steel industry as ferromanganese.

Manganese is roughly similar to iron (*see* ***Iron: Inorganic & Coordination Chemistry***) in its physical and chemical properties but is harder and more brittle, though less refractory (mp 1247 °C). At room temperature, manganese metal is not particularly reactive to air, despite it being quite electropositive; however it burns in O_2 to form the manganese oxide Mn_3O_4, in N_2 to yield the nitride Mn_3N_2, and in Cl_2 to form $MnCl_2$, and reacts with Br_2, I_2, or Br_2 to form $MnBr_2$, MnI_2 and both MnF_2 and MnF_3, respectively. It dissolves readily in dilute nonoxidizing acids to form manganese (II) salts ($[Mn(H_2O)_6]^{2+}$) together with H_2 gas.

Manganese resembles Ti, V, and Cr in that the highest oxidation state, Mn^{VII}, corresponds to the loss of all the 3d and 4s electrons. In common with V and Cr, the higher oxidation states form Mn=O and Mn=NBu^t multiple bond.[1,2] The oxo species are strong oxidants and some are very unstable and explosive. In the oxidation state, the most stable is II, with the +3, +4, +5, and +6 states becoming increasingly less stable. The oxidation states and common stereochemistries are summarized in Table 1 (*see* ***Manganese: Organometallic Chemistry***).

2 MANGANESE (II)

This is the dominant oxidation state and the most stable. In neutral or acidic aqueous solution, very pale pink $[Mn(H_2O)_6]^{2+}$ is present, which is resistant to oxidation, while in basic media, the hydroxide $Mn(OH)_2$ formed is easily oxidized by air (Figure 1).[2,3] Manganese (II) is a 'hard' acid and is quite distinctly a class (a) metal. This is manifest, for example, in the preference for O donors rather than N-donor

ligands. Few compounds are also known with P, As, and S-donor ligands.[4] Manganese(II) compounds are generally quite labile. The spin state of the majority of Mn^{II} complexes is high-spin d^5, because of their stable half-filled d electron shell. Few low-spin compounds have been isolated,[5] for example, $[Mn(CN)_6]^{4-}$. The coordination number and geometries are quite variable because of the lack of ligand-field stabilization energy for the high-spin configuration and appear to depend largely on ligand steric and electronic effects. Manganese (II) is larger (ionic or covalent radii, or metal–ligand distances) than other first-row (+2) transition metals and more 'plastic' (the metal–ligand bond distances are quite variable in response to ligand steric effects). Coordination geometry six appears to be the most common. Lower coordination numbers (three, four, and five) are fairly rare, while higher coordination numbers (seven and eight) are more common than for other first-row (+2) transition elements, a reflection of the larger size of Mn^{II}.[4]

In octahedral fields, the high-spin configuration gives spin-forbidden as well as parity-forbidden transitions, thus accounting for the extremely pale color of such compounds. In tetrahedral environments, the transitions are still spin-forbidden but no longer parity-forbidden; these transitions are therefore ~ 100 times stronger and the compounds have a noticeable pale yellow–green color.[2,4] In low-spin configuration, compounds are strongly colored since a spin-allowed absorption band is expected in the visible region.

Magnetic susceptibilities are easily recorded and the high-spin configuration gives an essentially spin-only, temperature independent magnetic moment of $5.92\mu_B$. The strong paramagnetic behavior unfortunately renders NMR useless, giving broad signals. Single-crystal X-ray diffraction still provides the only unequivocal form of characterization and is now used more and more routinely. The studies in solution remain a major difficulty with these labile systems, and assumptions about the nature of the compounds in solution are often necessary.

Conventional X- and Q-band EPR spectra are generally complex and often difficult to interpret.[6] The recent use of high-field and high-frequency EPR spectroscopy (HF-EPR) has led to simplified spectra with remarkable resolution and provides an accurate determination of the electronic parameters of the studied compounds.[7] Therefore, with this technique, structural information can be afforded both on solid state and in solution.

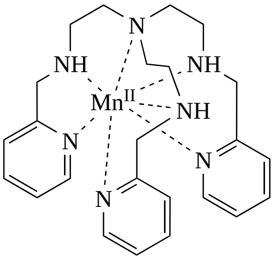
2.1 Nitrogen Ligands

The solution structure of the Mn^{2+} ion in CH_3CN and five other organic nitriles, as determined by EXAFS spectroscopy, is six-coordinate with Mn–N bond lengths of 2.21(1) Å,[8] while the octahedral $[Mn(CH_3CN)_6][MnI_4]$ crystals are obtained from CH_3CN solutions of MnI_2.[9]

Amine complexes are not particularly stable[2,4] but there are tertiary amine complexes, for example, $[MnI_3(NMe_3)]^-$ and $[Mn_2(\mu\text{-}I)_2I_2(NEt_3)_2]$.[10] The secondary amine can be three-coordinate[11,12] as in $[Mn\{N(SiMe_3)_2\}_3]^-$. Amides can be also three-coordinate with bridges as in $[Mn_2(\mu\text{-}NPr^i_2)_2(NPr^i_2)_2]$[13] and four-coordinate[14] in $[Mn(NPh_2)_4]^{2-}$.

With higher multidentate N-donor ligands, manganese (II) compounds become rather more robust.

Bridging ligands such as cyano[15,16] and azido[17] are used to form one-, two-, and three-dimensional polymeric systems and represent a fast growing research field because of their interesting magnetic properties. In addition to the polymeric binary dicyanamide and azide systems, for example, $[Mn\{N(CN)_2\}_2]$,[18] $[Mn\{N(CN)_2\}_3]^-$,[19] and $[Mn(N_3)_3]^-$,[20] ancillary organic ligands, such as pyrazine, 4,4′-bipy and 2,2′-bipy have been extensively used to create other lattice types.



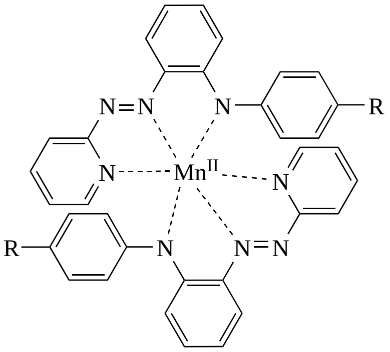
$[MnL^1]^{2+}$

(**1**)

Otherwise, many compounds, generally high-spin, with a variety of open-chain polydentate ligands (bidentate to septadentate) have been isolated with or without additional anion ligands, for example, halides or carboxylates. For example, the tripodal tetradentate ligand ntb with chloride, acetate, or nitride anions, forms the five to seven-coordinate mononuclear complexes, [Mn(ntb)X]Cl (X = Cl, O_2CMe) and $[Mn(ntb)(NO_2)_2]$, having trigonal bipyramidal or distorted octahedral geometries.[21] 8 and 7 N coordinations are found respectively in $[Mn(tpa)_2]^{2+}$,[22] and $[MnL^1]^{2+}$ (**1**);[23] this latter complex has been investigated as superoxide dismutase mimics. The tridentate facially capping bpea ligand affords six-coordinate $[Mn(bpea)_2]^{2+}$, $[Mn_2(\mu\text{-}O_2CMe)_3(bpea)_2]^+$, and $[Mn_2(\mu\text{-}Cl)_2Cl_2(bpea)_2]$ complexes.[24,25] The new structure of a rare low-spin, six-coordinate complex $[Mn(L^2)_2]$ (**2**) has been obtained.[5]

2.2 Phosphorus Ligands

Although complexes of stochiometry $[MnX_2(PR_3)]$ are polymeric with halide bridges, there are also monomers such as the octahedral $[MnX_2(dmpe)_2]$, the distorted tetrahedral $[MnI_2(PEt_3)_2]$, and a dinuclear $[Mn_2I_2(\mu\text{-}I)_2\{P(NMe_2)_3\}_2]$. The complexes $[MnX_2(PR_3)]_n$ have the remarkable ability



$[Mn(L^2)_2]$

(**2**)

to reversibly bind O_2, CO, NO, and ethylene in THF at low temperatures and irreversibly bind SO_2 under ambient conditions. The O_2 species are deep blue or purple and probably peroxo ones. Irreversible oxidation of R_3P to R_3PO also occurs slowly to give, for example, $[MnI_2(OPPh_2Me)(PPh_2Me)]$ and $[MnI_2(OPPh_2Me)_2]$, both of which have been structurally characterized.[26]

Phosphine complexes with alkyl ligands are discussed in the chapter ***Manganese: Organometallic Chemistry***.

2.3 Oxygen Ligands

Manganese (II) oxide, a dark green powder, has the rock salt structure and is insoluble in water. There is little doubt that the species formed when almost any MnX_2 salt is dissolved in water is $[Mn(H_2O)_6]^{2+}$. Most of the salts crystallize from water as hydrate; those with weakly coordinating anions, such as $Mn(ClO_4)_2{\cdot}6H_2O$ and $Mn(SO_4){\cdot}7H_2O$, contain $[Mn(H_2O)_6]^{2+}$.[2] Solutions of MnX_2 in alcohols give $[Mn(ROH)_6]^{2+}$ species or polymeric $MnX_2{\cdot}nROH$ systems.[4] Few alkoxides are known and are usually made by interaction of MnX_2 with LiOR in the alcohol. Use of bulky OR groups can give monomeric species or bridged dimers such as $[Mn(OC_6Cl_3H_2)(\mu\text{-}OC_6Cl_3H_2)(bipy)]_2$.[2] Several tetrameric alkoxides are known to have the Mn_4O_4 cubane cores (see Section 5). The typical tetranuclear clusters $[Mn(OMe)(MeOH)L]_4$ (L = dpm, dbm) have four μ_3-OMe groups and four Mn^{II} atoms at alternating vertices of the cube with the chelate diketonate L and MeOH bound to the Mn atoms, which are thus octahedrally coordinated.[27] The disc-like molecule $[Mn_{19}O_{12}(moe)_{14}(moeH)_{10}]$moeH (moe = $OC_2H_5OCH_3$) recently synthesized is the largest alkoxide molecule[28] (others are heterometallic alkoxides containing Mn and Sn or Sb). In solvent ethers such as THF and dioxane, MnX_2 form stable species, which are probably polymeric chain structures such as $[MnCl_2(THF)_{1.6}]_n$.[29]

2.3.1 *Oxides of Phosphorus and Arsenic*

The air stable tetrahedral $[MnX_2(OEPh_3)_2]$ (E = P, As; X = Cl, Br, I, NCS, NO_3) and the octahedral $[MnX_2(OEPh_3)_4]$ (X = I, NCS) complexes have been known for many years.[4] Some compounds, such as $[MnX_2(OPPh_3)_2]$ (X = Br, I), exhibit triboluminescence properties.[30] Complexes of the type $[Mn(NCS)_2(OPR_3)_n]$ (R = Ph, Et, *n*-Bu, *n* = 1−4) and $[MnX_2(OPR_3)_2]$ (R = Et, *n*-Pr, *n*-Bu, X = Cl, Br, I) have been also synthesized.[31] The new 'Chinese lantern' complexes $[XMn(\mu\text{-dppO}_2)_4MnX]^{2+}$ (X = Cl, Br, I) have been shown to have an increasing affinity for SO_2 across the series Cl < Br < I.[32]

2.3.2 *Oxyanions*

Crystalline borates, carbonates, and silicates of manganese (II) have been characterized for a long time. Manganese (II) nitrites and iodates are only stable at low temperatures. Anhydrous $Mn(NO_3)_2$, $MnSO_4$, and $Mn(ClO_4)_2$ and their hydrates are stable under ambient conditions although manganese(II) nitrates are very hydroscopic.[4] Nitrate[33,34] and sulfate[35–38] groups acting as bidentate or monodentate ligands are also found in various mixed ligand species, and several of these complexes have been explored crystallographically, for example, $[Mn(dmu)_3(NO_3)_2]$,[33] $[Mn(\mu\text{-bipym})(NO_3)_2]_n$, and[34] $[Mn(phen)(H_2O)_3(SO_4)]$[35] and with sulfato bridges $[Mn(H_2O)_4(SO_4)]_2$,[36] $[Mn(phen)(H_2O)_2(SO_4)]_n$[37] and $[Mn_2(bpman)(SO_4)_2]$.[38] Perchlorato coordination exists, for example, $[Mn(bipy)_2(H_2O)(ClO_4)]^+$.[39]

Several new layered manganese(II) phosphates and phosphonates have been synthesized, generally under hydrothermal conditions, and their magnetic properties investigated. Some examples are $NaMnP_2O_7$,[40] $[Mn_3(P_2O_7)_2(H_2O)_2](NH_4)_2$,[41] $[Mn(HPO_4)(H_2O)_3]$, $[Mn_5(\mu\text{-OH})_2(HPO_4)_2(H_2O)_2]$,[42] and $[Mn_3(HPO_3)_4](C_3H_{12}N_2)$.[43] New selenite[44] and selenate[45] species have been crystallographically characterized, for example, $Mn_4(H_2O)_3(SeO_3)_4$, $Mn_3(H_2O)(SeO_3)_3$, and $Mn(H_2O)_4(SeO_4)\cdot H_2O$, and all these show $[MnO_6]$ octahedra as the previous ones.[4]

2.3.3 *Monocarboxylates and Multidentate Oxygen Ligands*

Mono and dicarboxylates are interesting ligands because of their biological relevance and because their wide variety of coordination modes make them key building blocks for the synthesis of one-, two- and three-dimensional polymeric networks in the presence of other organic nitrogen ligands. Compounds with manganese (II) can be also monomeric, dimeric, or clusters of higher nuclearity and can exist in mixed-valent species (see Section 5). Some examples with monocarboxylate ligands are $[Mn_2(\mu\text{-O}_2CR)_2(bipy)_4]^{2+}$, $[Mn_3(\mu\text{-O}_2CR)_6(bipy)_2]$, and $[Mn(\mu\text{-O}_2CR)_2(bipy)]_n$ with R = 2-ClPh, 3-ClPh, 4-ClPh.[46]

Dicarboxylates such as malonate,[47] adipate,[48] fumarate, and maleate[49] generally produce polymeric compounds with a variety of bridging modes. Mono and binuclear malonate, and adipate complexes with bipy, phen,[50,51] and a high nuclearity cluster with phthalate $[Mn_{10}(OH)_3(phth)_9(bipy)_6][NH_2Et_2]$, with a pinwheel-shaped $[Mn_{10}O_9]$ core, have also been reported.[52]

The oxalate $[Mn(C_2O_4)_3]^{4-}$, like the catecholate $[Mn(cat)_3]^{4-}$ compounds, can be readily oxidized to Mn^{III} state.[2] Otherwise, oxalate can form polymers[53] and the combination of phosphate and oxalate in forming hybrid framework materials has been also explored.[54] Several hydroxycarboxylates exist as monomers or polymers[4] and the first mononuclear manganese citrate complex, $(NH_4)_4[Mn(C_6H_5O_7)_2]$, has been recently isolated and crystallographically characterized.[55]

Multidentate oxygen ligands such as the symmetric tetraketone (H_2L) give an asymmetric complex, $[Mn_3L_3]$, which has been reported as the first asymmetric homometallic helicate formed from a symmetric ligand.[56] A wide variety of compounds have been studied with the β-diketonate monoanions such as acetylacetonate (acac) and hexafluoroacetylacetonate (hfacac) that have been used as ligands in many polymeric systems.[57]

2.4 Sulfur Ligands

Structural data are available for a range of bi-, ter- and quaternary sulfides of manganese (II), which contain four-coordinate $[MnS_4]$ tetrahedral and six-coordinate $[MnS_6]$ octahedral; no other polyhedra have been detected.[4] The thiolates may be tetrahedral complexes of the type $[Mn(SR)_4]^{2-}$,[58] $[Mn_2(SR)_4(\mu\text{-SR})_2]^{2-}$, and $[Mn_4(SPh)_{10}]^{2-}$.[2] Thiolates with bulky aryl groups can stabilize low-coordination numbers as in the three-coordinate $[(ArS)Mn^{II}(\mu\text{-SAr})]_2$, Ar = 2,4,6-$Bu_3{}^tC_6H_2S$. The crystal structure of a five-coordinated compound $[Mn_2(C_3S_5)_4]^{4-}$, $C_3S_5{}^{2-}$ = 4,5-dimercapto-1,3-dithiole-2-dithiole-2-thionate, has also been reported.[59] There are dithiocarbamates, as well as the sulfido anion, $[Mn(S_6)_2]^{2-}$, that are infinite polymers with bridging S atoms. Some Se and Te analogue compounds are also known.[2]

2.5 Halide Ligands

The halide complexes exhibit a wide structural diversity. Anhydrous MnF_2 and $MnCl_2$ have the tetragonally distorted (TiO_2) rutile and the hexagonal layer-type structures (defined first for $CdCl_2$) respectively, while both $MnBr_2$ and MnI_2 have the CdI_2 layer structure.[4]

The formation constants of Mn^{2+} with X^- in aqueous solution are very low, but when ethanol or acetic acid is used as a solvent, salts of complex anions of varying types may be isolated,[2,4] such as $MnX_3{}^-$ (octahedral with

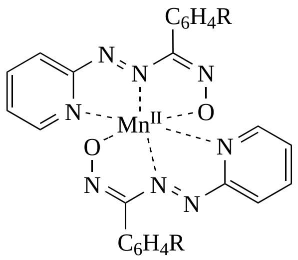
perovskite structure), MnX_4^{2-} (tetrahedral or polymeric octahedral with halide bridges),[30] $MnCl_6^{4-}$ (octahedral), $Mn_2Cl_6^{2-}$ (tetrahedral),[60] and $Mn_2Cl_7^{3-}$ (linear chain face-sharing $MnCl_6$ octahedra, also discrete $MnCl_4^{2-}$, tetrahedral). The precise nature of the product obtained depends on the cation used and also on the halide and the solvent. There is a variety of halide complexes containing other ligands present, such as $MnI_2(THF)_3$ trans-$[MnCl_4(H_2O)_2]^{2-}$, and amine and phosphine species.

2.6 Mixed-Donor Atom Ligands

For this area of chemistry, the use of X-ray diffraction is necessary to assign unambiguously which ligand donor atoms are bound. The preference of manganese(II) for O rather than N donors is seen in the amino acid complexes, in which the amino acids generally bind only through the O atoms of the carboxylic acid group. In polymeric species, for example, $[Mn(gly)_2Cl_2]_n$, the carboxylate acts as a bridge between adjacent manganese(II) atoms[61] and in monomeric ones, only one of the O atoms is coordinated.[4] Manganese(II) complexes of several amino acids catalytically disproportionate hydrogen peroxide in the presence of imidazole.[62]

In several multidentate ligands associating one carboxylate and pyridine/imidazole moieties, the coordination involves both the N and O atoms. Dimeric,[63] but also trimeric,[64] or polymeric[65,66] complexes can be formed in which metal centers are linked by one or two oxygen of the carboxylate moiety of the ligand.

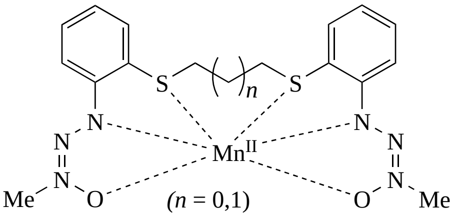
Manganese(II) compounds with several types of Schiff-base ligands are known. A linear tetranuclear $[\{Mn_2(L)(O_2CMe)_2(CH_3OH)\}_2]$, where L is a N_2O_2 donor set, has an unprecedented arrangement of five N_2O_3 and six-coordinated O_6 manganese ions.[67] A (pyridylazo)oxime ligand forms the low-spin mononuclear $[Mn(L^3)_2]$ (**3**) complex with the very rare mononuclear oximato-O coordination.[68]



$[Mn(L^3)_2]$

(**3**)

There is sound evidence that mixed O, S donors can bind both donor atoms to manganese(II), while there are few examples of N, S donors.[69,70] A rare example of a complex with N, O, S donors is the octahedral low-spin thioether complexes $[Mn(L^4)]$ (**4**) that can be electrochemically oxidized to



$[MnL^4]$

(**4**)

$[Mn(L^4)]^+$; one example of each has been structurally characterized.[71]

2.7 Macrocyclic Ligands

There has been a large number of studies involving coordination of Mn(II) by a wide variety of nitrogen and mixed-oxygen nitrogen macrocyclic ligands. Among them, as for the higher oxidation states of manganese, a significant number of investigations were made using pendant arm polyazamacrocycles. For the mixed-donor Schiff-base macrocycles, complexes are formed by a template reaction and the solution complexation properties (determination of the stability constant) of a large range of ligands have been reported. The main applications of those mixed-donor macrocycles and their resulting manganese (II) complexes concern the separation and analysis of Mn^{2+}, the epoxidation of olefin, and modeling of biological redox processes (superoxide dismutase and catalase activities) (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***). All these studies are not detailed here and an extensive review of this topic can be found in Reference 1.

In manganese(II) compounds incorporating crown ether macrocycles, the metal is generally H-bonded to the crown via water molecules, although it has been possible to isolate some compounds such as $[Mn(12\text{-crown-}4)_2]^+$ and $[Mn(15\text{-crown-}5)(CF_3SO_3)_2]$, in which all the ether oxygen atoms of the crown bind directly to manganese(II).[72–74]

3 MANGANESE (III)

The aqua ion of manganese(III) can be obtained by electrolytic or peroxo sulfate oxidation of Mn^{2+} solutions, or by reduction of MnO_4^-.[2] The ion plays a central role in the complex redox reactions of the higher oxidation states of manganese in aqueous solutions, although it is often subject to disproportionation into manganese(IV) (MnO_2) and manganese(II). It is more stable in acidic solution. The chemistry of manganese(III) is dominated by dinuclear, trinuclear, and tetranuclear complexes with oxo, alkoxo, and carboxylates bridges. The propensity of these complexes to be in mixed-valence states such as manganese(II,III) or manganese(III,IV)

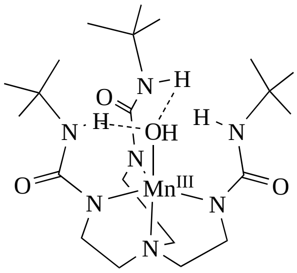
require the confirmation of their structures by spectroscopic and X-ray structural methods (see Section 5).[1] Mononuclear compounds can be stabilized by Schiff-base ligands, nitrogen-base ligands, and macrocyclic ligands. The most commonly observed coordination numbers of manganese(III) are 5 and 6. Few compounds are known with S and P donors ligands.

The electronic configuration of manganese(III) is $3d^4$, and therefore, the high-spin configuration in an octahedral field is subject to Jahn–Teller distortion like for Cu^{II} and Cr^{II} compounds. Such distortions often serve to identify the Mn^{III} polyhedra in mixed oxidation state compounds (see Section 5). There are few examples of low-spin compounds, for example, $[Mn(CN)_6]^{3-}$, $[MnH_3(dmpe)_2]$, and there are other examples among macrocyclic compounds. The electronic spectra of these d^4 systems have spin-allowed d-d transitions, and accordingly the compounds have more color than those of manganese(II). All high-spin manganese(III) complexes have magnetic moments very close to $4.9\,\mu_B$. The recently developed techniques of HF-EPR have now proven to be effective at elucidating the electronic structure of integer-spin systems such as high-spin manganese(III) ($S = 2$) compounds, which are usually EPR silent at X- and Q-band frequencies. Mononuclear complexes with axial[75,76] (macrocyclic ligands) and rhombic symmetries[77,78] have been studied and this technique has been proposed as a useful tool for the structural investigation of these complexes and also for mixed-valence clusters incorporing manganese (III)[79] (see Section 5).

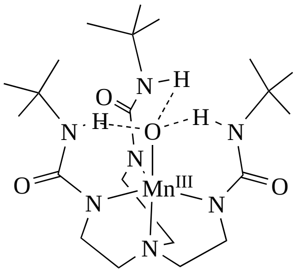
3.1 Nitrogen Ligands

The chemistry of manganese(III) with nitrogen ligands, other than macrocycles or mixed N, O donors is still quite limited. Amido species include the three-coordinate planar $[Mn\{N(SiMe_3)_2\}_3]$ and the a trigonal pyramidal four-coordinate complex $Mn(N_3N)$, where $N_3N = [(Bu^tMe_2Si)NCH_2CH_2]_3N$.[2] The interaction of alkaline-earth nitrides and manganese nitride at high temperatures leads to compounds such as Ca_3MnN_3 or Ca_6MnN_5 that have sheet structures involving the trigonal planar $[Mn(N)_3]^{6-}$ anion.[80] Octahedral mononuclear complexes with bi- or tridentate N-ligands and halides or pseudohalides have been structurally characterized such as $[Mn(L)(X)_3(H_2O)]$[81–83] (L = bipy, phen; X = Cl, F), $[Mn(phen)_2(Cl)_2]^+$[84] and $[Mn(L)(X)_3]$[77] (L = terpy, bpea; X = F, N_3). Tripodal N-ligands allowed the isolation and structural characterization of very rare mononuclear manganese(III) complexes: the side-on peroxo pyrazolate-pyrazolylborate, $[Mn(\eta^2\text{-}O_2)(3,5\text{-}Pr^i pzH)HB(3,5\text{-}Pr_2{}^i pz)_3]$,[85] the hydroxo, $[Mn(LH_3)(OH)]^-$ (**5**) and the oxo, $[Mn(LH_3)(O)]^{2-}$ (**6**).[86]

Various reactions with open-chain mono to hexadentate N-ligands have produced multinuclear μ-alkoxo, oxo, and/or carboxylato bridged manganese(III) compounds and some examples are given in Section 5.[1]



(**5**)



(**6**)

3.2 Oxygen Ligands

Manganese(III) complexes with a variety of oxygen ligands constitute the largest group next to those with mixed-donor ligands. The carboxylate chemistry of manganese(III) is mainly represented by monocarboxylates compounds, such as acetate, benzoate, and their derivatives, while with bidentate carboxylates such as oxalate, malonate, and salicylate, there is a limited number of compounds. This chemistry can be extremely complicated and often has mixed valencies (see Section 5). The chemistry of manganese(III) with monocarboxylates is extensive and results in the formation of clusters with nuclearities of 2, 3, 4, 6, 7, 8, 9, 10, and 18, and polymers with or without coligands such as Schiff bases.[1] Examples of compounds are the elusive manganese(III) formate formed by the reaction of $KMnO_4$ and formic acid that has finally been crystallographically characterized as the polymeric $Mn(\mu\text{-}O_2CH)_3\cdot 5CO_2\cdot 0.25HCO_2H\cdot 0.67H_2O$ with a carboxylate cage encapsulating the other molecules.[87] The 'manganic acetate' still often referred to as $Mn(OCMe)_3\cdot 2H_2O$ has the well-known trinuclear oxocentered core $[Mn_3(\mu_3\text{-}O)(\mu_2\text{-}O_2CMe)_6]^+$.[88] Otherwise, the oxidation of $Mn(OCMe)_2\cdot 4H_2O$ with $KMnO_4$ in acetic acid gives the triply bridged polymer $[\{Mn(\mu\text{-}OH)(\mu\text{-}OCMe)_2\}\cdot MeCO_2H\cdot H_2O]_n$.[89]

Mononuclear complexes are mostly obtained with hydroxycarboxylate (e.g. $(NH_4)_5[Mn(C_6H_5O_7)_2]$[55]) or β-diketones and related ligands.[1] Examples of carboxylate-free complexes of higher nuclearity with diketones are $[Mn_2(OMe)_2(dmb)_4]$ and $[NaMn_6(OMe)_{12}(dmb)_6]^+$, the latter displaying a 12-metallocrown-6 structure.[90] The nonalkoxo $[Mn_6O_4X_4(Me_2\ dbm)_6]$ (X = Cl, Br) has been also structurally characterized.[91] Detailed magnetic studies indicate that these three hexanuclear clusters have ground spin states of 12. Catecholate[92,93] and other diphenolates form manganese(III) complexes.

A rare example of a manganese(III) cluster with phosphinate and phosphonate ligands is $[Mn_6O_2(O_3PPh)_2(O_2PHPh)_2(O_2CPh)_8(py)_2]$ synthesized by the reaction of $[Mn_3O(O_2CPh)_6(py)_2(H_2O)]$ with an equimolar quantities of phenylphosphonic acid.[94]

3.3 Phosphorus, Sulfur, and Halide Ligands

Phosphorus compounds of manganese (III), except for alkyl and hydride species, are still limited to $[MnCl_2(diphos)_2]Cl_2$ and $[MnX_3(PMe_3)_2]$ (X = Cl, Br, I, NCS).[95] The tendency of manganese(III) to oxidize sulfur ligands results in the rarity of such compounds. Nevertheless, for simple thiols, a new species has been isolated and characterized such as the dimer with asymmetric Mn–S bridges $[Mn_2(pttd)_2]^{2-}$ ($pttd^{4-}$ = propane-1,2,3-trithiol), which is very similar to the previously reported $[Mn_2(edt)_4]^{2-}$ (edt^{2-} = ethane-1,2-dithiolate) species.[96]

The only binary compound of manganese(III) with the halides stable at room temperature is MnF_3. Hydrated salts of the anions MnF_4^-, MnF_5^{2-}, and MnF_6^{3-} are known.[97] The salt $Tl_2MnF_5 \cdot H_2O$ has chains of $(MnF_5)_n^{2n-}$ units, and some other fluoromanganese(III) complexes are $[MnF_3(urea)_3]\cdot 3H_2O$, $K_3[MnF_2(C_2O_4)_2]\cdot 3H_2O$ and those with N-donor ligands (see Section 3.1).[2] Although several methods of making $MnCl_3$ in solution are known, the best is the interaction of $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]$ in acetonitrile or other solvents, with Me_3SiCl. The resulting purple solutions are useful starting materials for synthesis of $(Et_4N)MnCl_5$, or amine complexes such as $[MnCl_3(bipy)]_n$, $[MnCl_3(H_2O)(bipy)]$, and the imido species $MnCl(NBu^t)_3$ (see Section 6). Other important compounds are the Schiff-base species, such as MnCl(salen), porphyrins, and related macrocycles.[2]

3.4 Mixed Donors and Macrocycles Ligands

Most of the polydentate ligands that stabilize manganese(III) are Schiff bases and their derivatives. Square planar and pyramidal mononuclear manganese(III) complexes with tetradentate Schiff bases have been extensively investigated for the epoxidation of olefins.[98] Other types of mixed N, O-donor ligands form interesting compounds without carboxylates, such as a metallocrown-10 such as the decanuclear complex[99] generated from the pentadentate N_2O_3, N-phenylsalicylhydrazidate ligand and a trinuclear oxocentered one,[100] $[Mn_3O(bamen)_3]^+$ generated from a hexadentate N_4O_2 ligand.

The preparation and characterization of novel manganese(III) complexes of various porphyrin and porphyrin-likes macrocycles have continued to attract strong attention especially because of their importance in catalytical oxidation processes through the formation of a Mn(V)O intermediate (see Section 6) and as model for metalloenzymes.[2,101] In this line, an artificial enzyme formed through a directed assembly of a molecular square that encapsulated a Mn porphyrin has been prepared and investigated as a catalyst.[102] In contrast to symmetrical binuclear bis(phenoxo) bridged macrocyclic Mn(III)Mn(III) complexes, unsymmetrical ones are rare. A new series of these kinds of carboxylate-free complexes has been described and their redox properties investigated.[103]

4 MANGANESE (IV)

In aqueous solution, the insoluble MnO_2 is formed readily. Much of the manganese (IV) chemistry involves O-donor ligands. The compounds are generally high-spin d^3 ($S = 3/2$) species and many are octahedral showing magnetic moments close to the spin-only value of 3.87 μ_B.

4.1 Nonoxygen Containing Compounds

This class of compounds is relatively limited. Few examples of nonporphyrinic manganese(IV) complexes coordinated solely by nitrogen have been structurally characterized: $\{Mn[HB(3,5\text{-}Me_2Pz)_3]\}^{2+}$, the water stable $[Mn(biguanide)_3]^{4+}$,[104] and $Mn(bpy)(N_3)_4$.[105]

Compounds with dithiolates have been characterized.[4] The only binary halide known is the unstable MnF_4 that decomposes to MnF_3 and F_2. Room temperature syntheses of MnF_4 and hexafluoromanganate(IV) of alkali cations A_2MnF_6 (A = Li–Cs) have been reported.[106]

4.2 Oxygen-containing Compounds

These are of great variety and importance. A new tetrachlorocatecholate derivative $[Mn(Cl_4cat)_3]^{2-}$ has been isolated.[107] A wide variety of compounds with various multidentate mixed-donor ligands have been synthesized, the majority of which contain N and O donor atoms (see Section 5). Several mononuclear manganese (IV) of the type $Mn(L)_2$ with tridentate O,N,O ligands[108–110] and $Mn(L)Cl_2$ with tetradentate Schiff bases have been synthesized.[1,111] Complexes with oxo bridges are very characteristic of manganese (IV) chemistry and some examples are given in Section 5. Many porphyrins have Mn=O bonds and have been much studied as oxygen transfer agents, for example, in the epoxidation of C=C bonds.[101,112]

5 MIXED OXIDATION STATE (II–IV)

For about twenty years, there have been an increasing number of publications on mixed-valence manganese multinuclear complexes that are relevant to such diverse fields as metalloenzymes and single-molecule magnets (*see* ***Manganese Proteins with Mono- & Dinuclear Sites*** and ***Manganese: The Oxygen-evolving Complex & Models***). Besides the small clusters, comprising two to four metal ions relevant to biological systems such as manganese catalases and the oxygen-evolving complex of Photosystem II, a large interest has been invested in larger clusters, not only for their biological relevance, but also for their interesting magnetic properties. Hundreds of new compounds have been made, those with carboxylate ligands being the most common. However, other ligands employed

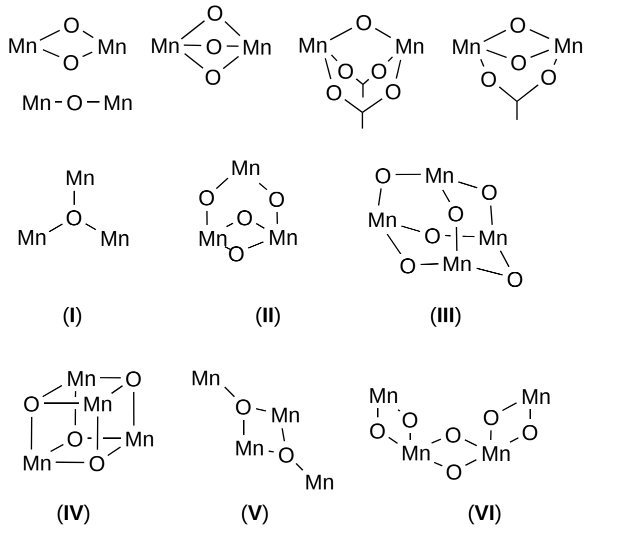


Figure 2 Various types of manganese oxo, alkoxo, or carboxylato core structures

have been pyridine, polypyridyl, pyrazolylborates, triazacyclononanes, and Schiff bases of various sorts. These have been obtained in oxidation states II–IV with both unitary and mixed valencies. The majority of mixed valency complexes form crystallographically valence-trapped species with distinct sites for each oxidation level. The electronic (EPR), magnetic, and electrochemical properties of these compounds have been largely investigated. Some of the core types are shown in Figure 2. The structures vary from quite simple to extremely complicated and the more complex species can have structures built up of different core units. This chemistry is too extensive to detail here and the reader should note the existence of several recent reviews, that cover this literature.[1,79,113–116] Only some recent examples are given here.

5.1 Dinuclear Complexes

The majority of Mn_2(III,IV) and Mn_2(IV,IV) compounds have bis-μ-oxo or bis-μ-oxo mono-μ-carboxylato cores, for example, $[Mn_2^{III,IV}(O)_2(terpy)_2(X)_2]^{n+}$ ($X = H_2O$ or CF_3CO_2),[117,118] $[Mn_2^{IV}(O)_2(terpy)_2(SO_4)_2]$,[119] and $[Mn_2^{IV}(O)_2(O_2CMe)(bpy)_2Cl_2(H_2O)]$,[120] while for Mn_2(III,III) complexes, mono-μ-oxo bis-μ-carboxylato and bis-μ-alkoxo mono-μ-carboxylato cores are the most common, for example, $[Mn_2^{III}O(O_2CMe)_2(HB(pz)_3)_2]$ and $[Mn_2^{III}$(5-Br-salpn)(OMe) $(O_2CMe)(MeOH)_2]^+$.[121] All complexes with a bis-μ-alkoxo mono-μ-carboxylato contain a Schiff-base coligand.[1] The only example of a bis-μ-oxo bis-μ-carboxylato Mn_2(III,IV) complex is $[Mn_2O_2(Ar^{tol}CO_2)_2(bipy)_2]^+$.[122]

Few examples of tris-μ-oxo, di-μ-oxo mono-$\mu_{1,2}$-peroxo, and mono-μ-oxo bridged dinuclear complexes are known. Examples are $[Mn_2^{IV}(O)_3(Me_3tacn)_2]^{2+}$,[123] $[Mn_2^{IV}(O)_2(O_2)(Me_3tacn)_2]^{2+}$, and $[Mn_2^{III}O(L)_2]^{2+}$ with a Schiff-base pentadentate monoanionic ligand (L = *N*,*N*-bis(2-pyridylmethyl)-*N*′-salicyliden-1,2-diaminoethane).[124] The one-electron oxidized complex $[Mn_2^{III,IV}O(L)_2]^{3+}$ has been electrochemically prepared and crystallized and is the only example of a structurally characterized mono-oxo bridged Mn_2(III,IV) complex.

Several Mn_2(II,II) complexes exist with different bridging patterns including solely carboxylates, or those associated with aqua, hydroxo, alkoxo, or phenoxo bridges.[114] Conversely, mixed-valent Mn_2(II,III) derivatives have received much less attention.[125]

Among these numerous dimeric complexes that have been prepared using a variety of ligands, very few exist in more than two stable oxidation states. Examples of complexes with three stable oxidation states are di-μ-oxo bridged dinuclears with tetradentate N-donor ligands such as $[Mn_2O_2(tpa)_2]^{2+,3+,4+}$ where the (III,III), (IIII,IV), and (IV,IV) states can be electrochemically generated. A rare example of complexes isolated and crystallographically characterized at the four oxidation states (II,II), (II,III), (III,III), and (III,IV) is the series $[Mn_2$(2-OHsalpn$)_2]^{2-,-,0,+}$.[126] Otherwise, core interconversions or changes in nuclearity have been observed for a series of compounds at different oxidation states. The complexes $[Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CMe)_2(bpea)_2]^{2+}$ and $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}O_2CMe)(bpea)_2]^{3+}$ can be selectively and quantitatively electrogenerated from $[Mn_2^{II}(\mu\text{-}O_2CMe)_3(bpea)_2]^+$ in acetonitrile solution and it appears that each substitution of an acetate group by an oxo group is induced by a two-electron oxidation of the corresponding dimanganese complexes.[24] Electrochemical oxidation of $[Mn_2^{III,IV}O_2(bipy)_4]^{3+}$ in water leads to the stable, linear tetranuclear $[Mn_4^{IV}O_6(bipy)_6]^{4+}$.[127]

5.2 Trinuclear and Tetranuclear Complexes

The number of trinuclear manganese(II) complexes with bridging carboxylates is limited and most possess the linear $[Mn_3(\mu\text{-carboxylate})_6]$ core[1] as in $[Mn_3(O_2CMe)_6(bipy)_2]$ and there is only one example of a hydroxocentered complex[128] $[(py)_5(Mn_3(\mu_2\text{-}O_2CMe)_3(\mu_3\text{-}OH)(catechol)]$ (Type I). Several mixed-valence $Mn^{III}Mn^{II}Mn^{III}$ or $Mn^{II}Mn^{III}Mn^{II}$ carboxylato compounds with open structures have been also isolated with Schiff-base ligands.[113] All the trinuclear manganese(III) carboxylate complexes possess the basic manganic acetate oxocentered structure, for example, $[Mn_3O(O_2CBu^t)_6(py)_3]^+$ and $[Mn_3O(O_2CMe)_6(py)_3]^+$, the latter is also crystallized in the $Mn^{III}Mn^{II}Mn^{III}$ oxidation state.[113] All trinuclear Mn_3(IV) complexes have the Mn_3O_4 core, for example, $[Mn_3O_4(phen)_4(H_2O)_2]^{4+}$ (Type II).[113]

Examples of tetranuclear adamantane-shaped complexes (Type III) are $[Mn_4^{IV}O_6(bpea)_4]^{4+}$ and its corresponding one-electron reduced species, while cubane cores (Type IV) are found in $[Mn_2^{III}Mn_2^{IV}O_4(O_2PPh_2)_6]$ and its one-electron reduced species. A large family of tetranuclear clusters is

now known with the distorted cubane core $[Mn_3^{III}Mn^{IV}O_3X]$ ($X = N_3^-$, ^-O_2CMe, ^-O_2CPh, NO_3^-, OMe...), supported by the chelating dbm^- ligand.[1] The planar or butterfly cores (Type V) are generally found in tetranuclear carboxylato manganese(III) complexes with a $[Mn_4O_2(O_2CMe)_6]^{2+}$ or a $[Mn_4O_2(O_2CMe)_7]^+$ core respectively.[1] The linear tetranuclear complex (Type VI), $[Mn_4^{IV}O_6(bipy)_6]^{4+}$ was also reported.[129]

Rare examples of complexes simultaneously containing manganese (II) and manganese (IV) are the trinuclear $Mn^{II}Mn^{IV}Mn^{II}$ $[Mn_3(pko)_4(CH_3O)_2(SCN)_2]$[130] and the tetranuclear $[Mn_3^{II}Mn^{IV}(\mu_4\text{-}O)(pko)_4(3,4D)_4]$ complexes.[131]

5.3 Higher Nuclearity Clusters

A novel hexanuclear high-valent species, $[Mn_2^{III}Mn_4^{IV}O_8(Ar^{tol}CO_2)_2(Me_2bipy)_6)]^{4+}$ where two cuboidal $[Mn_3O_4]$ units are fused together through a pair of 'T-shaped' μ_3-O groups has been isolated.[122] Novel octanuclear[132] and nonanuclear[133] clusters have been also reported, such as $[Mn_2^{III}Mn_6^{IV}O_{10}(O_2CMe)_6(H_2O)_2(bpy)_4]^{4+}$ (S = O) with a 'serpentine' core and $[Mn_9O_7(O_2CMe)_{11}(thme)(py)_3(H_2O)_2]$ (S = 17/2) with a $[Mn_4^{III}Mn_2^{II}O_6]^{4+}$ unit and a smaller $[Mn_3^{IV}O]^{10+}$ unit embedded in it. The cluster with one of the largest ground spin states is $[Mn_6^{II}Mn_4^{III}O_4(biphen)_4X_{12}]$ (S = 12) with an adamantine-like inner $[Mn_2^{II}Mn_4^{III}]$ core connected through the four oxygen atoms to four Mn^{II} atoms (see also Section 3.2).[79] Another class of clusters with a large ground spin state (S = 10) that has attracted attention for their unique properties at very low temperatures is the dodecanuclear $[Mn_{12}O_{12}(OCR)_{16}(H_2O)_n]$ cluster (R = Me, Et, Ph; $n = 3$, 4). The structure consists of a central $[Mn_4^{IV}O_4]^{8+}$ cuboidal unit surrounded by a ring of eight Mn^{III} ions. These molecules possess the useful property of retaining their magnetization in the absence of an applied magnetic field, a classical property of a magnet.[1,79] The monoanions $[Mn_{12}O_{12}(OCR)_{16}(H_2O)_4]^-$ (R = Et, Ph) formed by reduction of the neutral molecules have a spin state of 19/2 with the localized ground-state [4Mn(IV)7Mn(III)Mn(II)] for R = Et and with eight delocalized Mn(2.875) centers for R = Ph. Higher nuclearity clusters such as $[Mn_6^{IV}Mn_{10}^{III}O_{16}(OMe)_6(O_2CMe)_{16}(MeOH)_3(H_2O)_3]$, $[Mn_9^{IV}Mn_{12}^{III}O_{24}(OMe)_8(O_2CCH_2Bu^t)_{16}(H_2O)_{10}]$ (S = 13/2) and the largest known $[Mn_3^{II}Mn_{26}^{III}Mn^{IV}O_{24}(OH)_8(O_2CCH_2Bu^t)_{32}(H_2O)_2(CH_3NO_2)_4]$ (S = 7) have also been reported.[1]

6 MANGANESE (V) (VI) AND (VII)

Most of the manganese compounds that have high oxidation states involve oxo compounds; however some other compounds in these oxidation states have been synthesized and characterized, especially those based on nitrodo and imido ligands.

6.1 Oxochemistry

Reduction of the tetraoxomanganates MnO_4^-, MnO_4^{2-}, and MnO_4^{3-} by pulse radiolytically–generated free organic radicals leads to the unstable $[Mn^VO_3(OH)]^{2-}$ and $[Mn^{VI}O_3(OH)^\bullet]^-$ species. They were characterized by their UV-visible spectra and their corresponding acid dissociation constants have been determined.[134]

The permanganate anion is well-known as a convenient oxidizing agent in inorganic and organic chemistry.[2] Its utilization for synthesis has been investigated following several procedures. The oxidizing properties of MnO_4^- have also been applied to the destruction of pollutants in groundwater or as a chemiluminescent analytical agent.[1]

Crystals of $Na_4Mn_{0.5}P_{0.5}O_5$, a mixed-metal Mn(VII)/P(V) oxide, were synthesized via a sodium hydroxide flux.[135]

Manganyl [Mn(V)O] complexes have drawn considerable attention over the past 15 years because they are generally accepted to be the key reactive intermediates in many catalytic oxidation processes, especially those related with biomimicry.[101,112] However, only a few Mn^VO species have been isolated and their structures resolved. Two well-characterized species involving the use of a tetraanionic ligand to stabilize the high-valent manganese center have been reported.[136,137] The very short bond distance suggests a Mn≡O bond. One of these complexes can be activated for O-atom transfer by the addition of a secondary cation like Na^+. A major advance in this chemistry was made with the isolation and characterization of a porphyrin Mn^VO species.[112,138] Besides studies in the porphyrin series, some oxomanganese (V) corrole complexes have been generated, characterized spectroscopically, and investigated in catalytic oxidations.[139–141] Direct proof of the existence of discrete $[Mn^VO(salen)]^+$ complexes has been obtained by means of electrospray tandem mass spectrometry.[142]

6.2 Nonoxo Chemistry

Nitrido macrocyclic complexes containing a terminal Mn^V≡N bond have proven to be versatile and effective aminating agents with a different class of olefins;[143] an asymmetric version of this methodology was also reported.[144] The complexes $[L_nMn^VN]$ are usually made by photolysis of azide precursors $[L_nMn^{III}(N_3)]$ (Arshankkow–Poznjak reaction). The ligands L_n are the regular macrocycles: porphyrins, corroles, cyclams, salens. Alternative methods for their synthesis have been developed using an oxidizing agent (e.g. NaOCl), and some of these nitrido manganese complexes have been structurally characterized.[145] An extremely short Mn≡N bond distance (1.50–1.55 Å) was observed.[146] Since the manganese (V) species have a d^2 electron configuration,

they are nonmagnetic with a low-spin ground state. A terminal imido complex of a Mn(V), the postulated intermediate in amination and aziridination reactions with nitrido complexes, has been synthesized and fully characterized.[147]

Ligand substitution by CN^- of nitrido complexes of Mn(V) leads to the simple nitrodo cyanometalate of Mn(V): $[Mn^V(N)(CN)_5]^{3-}$, which has been structurally characterized, together with an assignment of its electronic transitions and orbital energies.[148]

The interaction of $MnCl_3$ with $NHBu^t(SiMe_3)$ gave the thermally and air stable Mn(VII) species $[Mn(NBu^t)_3Cl]$.[149] *Tert*-butyl imido chemistry has been further developed and over 40 imido compounds are now known.[150] The Cl atom of $[Mn(NBu^t)_3Cl]$ can be substituted by, for example, Br, O_2CR, SC_6F_5, and $NHBu^t$; all these compounds are green. Reduction of $[Mn(NBu^t)_3Cl]$ can give the dimers $[Mn^V(NBu^t)_2(\mu\text{-}NBu^t)]_2{}^{2-}$ and $[Mn^{VI}(NBu^t)_2(\mu\text{-}NBu^t)]_2$. Another unusual anion is $[Mn^{VII}(\equiv N)(NBu^t)_3]^{2-}$.

Glossary

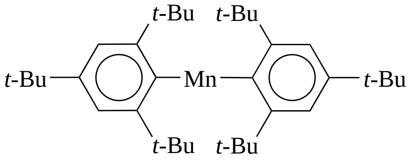
Organomanganese compounds: compounds that contain at least one Mn–C bond, where the carbon donor is CO, alkyl, aryl, π-hydrocarbon, and so on

1 INTRODUCTION

This review summarizes advances in the organometallic chemistry of manganese over the period 1994–2002. As will be shown, there have been very significant advances in this area of organometallic chemistry. Especially noteworthy are novel applications of π-bonded organomanganese complexes in organic synthesis, in the activation of covalent chemical bonds in organic molecules, and in the synthesis of polymeric coordination networks. The low cost of manganese, its many available oxidation states, and the general ease of carrying out transformations involving ligands bonded to the metal suggest that manganese will assume an increasingly important role in synthetic chemistry and will be a vehicle for important technological advances in industrial, biomedical, and materials science.

2 COMPLEXES WITHOUT CO LIGANDS

Treatment of $MnCl_2$ with $MgAr_2$ (Ar = 2,4,6-t-$Bu_3C_6H_2$) affords the thermally stable two-coordinate diaryl $MnAr_2$ (**1**).[1] The low-coordination number is a consequence of the sterically demanding t-Bu groups, which also accounts for the lack of any reaction between (**1**) and simple ligands such as THF, pyridine, and MeCN. High yields of benzylic manganese halides, sulfonates, and phosphates can be obtained by the reaction of organic benzylic precursors with highly activated manganese metal prepared via a lithium/naphthalene/THF reduction of Mn(II) halides.[2] Such benzylic organometallic reagents play a significant role in organic synthesis. The manganese reagents are quite selective in cross-coupling reactions, one of which is shown in Scheme 1.

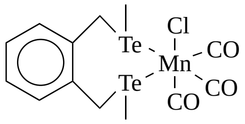


(**1**)

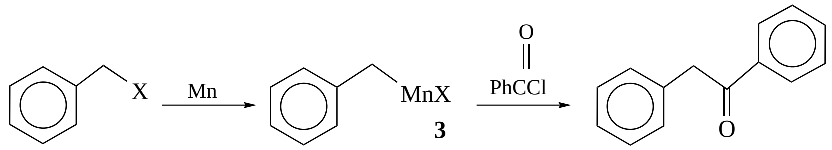
A useful review on organomanganese reagents in organic synthesis has appeared.[3] As described therein, one of the most stable alkyl Mn(II) reagents is trialkyl manganate, MnR_3^-, which can be conveniently prepared as the Li^+ or $MgBr^+$ salt and used at 0 °C. These have been utilized for a variety of reactions, such as the stereoselective alkylation of *gem*-dibromocyclopropanes (Scheme 2), the silylation of acetylenes, and the radical cyclization of allylic ethers. Some of these transformations can be made catalytic.[3]

3 CARBONYL COMPOUNDS

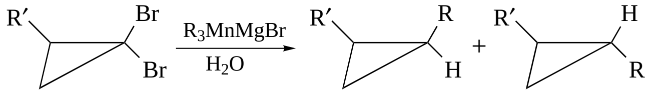
Simple manganese carbonyl complexes (*see* ***Carbonyl Complexes of the Transition Metals***) containing σ-bonded ligands comprise a vast array of compounds. The ligands, other than CO, include halides, phosphines, amines, alkyls, aryls, and so on. The resultant complex can be neutral, cationic, or anionic and may exhibit a wide range of chemical reactivity centered at the metal or at the ligands. Noteworthy additions to the recent literature in this area include ligands based on antimony[4] and tellurium:[5] $Mn(CO)_4(SbPh_3)Cl$, $[Mn(CO)_5SbPh_3]^+$, and $Mn(CO)_3(TeTTe)Cl$ (**2**). Interestingly, ^{55}Mn NMR of (**2**) indicate the existence of three slowly interconverting stereoisomers based on pyramidal inversion at the Te centers.



(**2**)

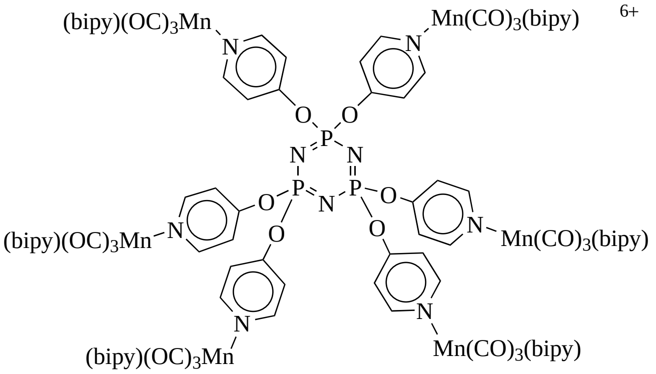


Scheme 1



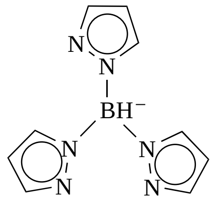
Scheme 2

The aqua complex [*fac*-Mn(CO)$_3$(dppe)OH$_2$]$^+$ (dppe is bis-diphenylphosphinoethane) contains a fairly labile water that can be conveniently replaced by OMe$^-$-, CN$^-$-, RCN-, and RNC-type ligands.[6] An attempt to prepare the fluoro complex led to the isolation of [(OC)$_3$Mn(dppe)OH$_2\cdots$FMn(CO)$_3$(dppe)]BF$_4$, which is held together by a very strong hydrogen bond (O$\cdots$F = 2.46 Å, *see Hydrogen Bonding*).[7] The nucleophilic carbonyl anion [Mn(CO)$_3$(bipy)]$^-$ attacks the electrophile ClCH$_2$SR to afford the alkylthiomethyl complex *fac*-Mn(CO)$_3$(bipy)CH$_2$SR, which is easily methylated at the sulfur.[8] In other work, it was shown that the hexafunctionalized cyclotriphosphazene N$_3$P$_3$(*p*-OC$_5$H$_4$N) reacts with *fac*-Mn(CO)$_3$(bipy)OClO$_3$ to give the interesting hexametallic complex (**3**).[9]

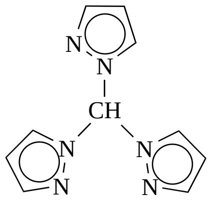


(**3**)

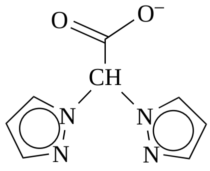
Manganese carbonyl complexes containing σ-bonded ligands that are related to the celebrated tris(pyrazolyl)borate ligand (*see Tris(pyrazolyl)borates*) (**4**) have been reported. These include tris(pyrazolyl)methane[10] (**5**) and bis(pyrazolyl)acetate[11] (**6**), which function as tridentate ligands in complexes [Mn(CO)$_3$(**5**)]$^+$ and [Mn(CO)$_3$(**6**)]. The solvent-coordinated Mn(I) carbonyl (**7**) containing a tied-back phosphite ligand is formed by treating the methyl



(**4**)



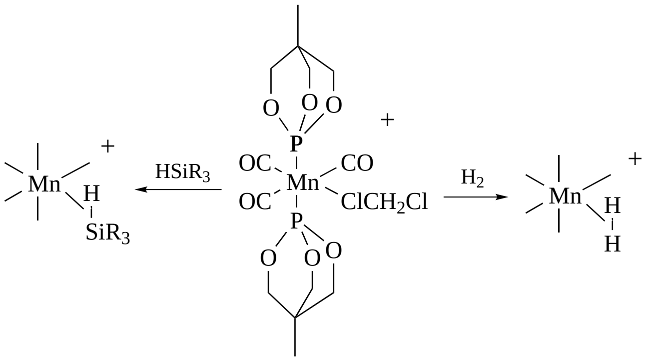
(**5**)



(**6**)

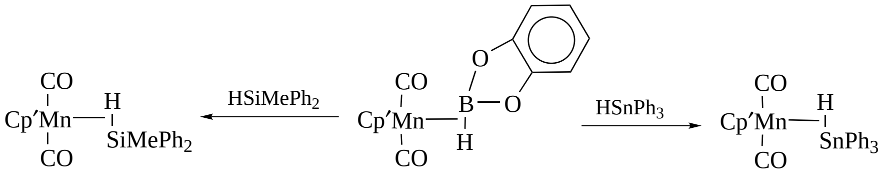
analogue of (**7**) with trityl cation in CH$_2$Cl$_2$.[12] Complex (**7**) is highly electrophilic and readily forms ''σ-bond'' complexes with H$_2$ and HSiR$_3$, according to Scheme 3. The 'tied-back' nature of the phosphite ligands prevents intramolecular agostic bonding (*see Agostic Bonding*), which would hinder external ligand binding. Other η^2-H$_2$ complexes of manganese recently reported include [Mn(CO)(dppe)$_2$(η^2-H$_2$)]$^+$, [Mn(CO)$_3$(PCy$_3$)$_2$(η^2-H$_2$)]$^+$, [Mn(CO){P(OEt)$_3$}$_4$(η^2-H$_2$)]$^+$, and Cp*Mn(CO)$_2$(η^2-H$_2$).[13–16]

The boryl complex Mn(CO)$_4$(PR$_3$)(BH$_2$PMe$_3$) is protonated to the borane analogue,[17] which also contains a σ-bond η^2-ligand (HBH$_2$PMe$_3$) similar to that obtained with H$_2$ and HSiR$_3$ in Scheme 3. In a similar vein, the σ-borane complex



(**7**)

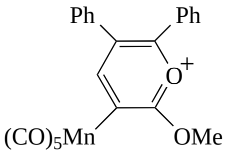
Scheme 3



(**8**)

Scheme 4

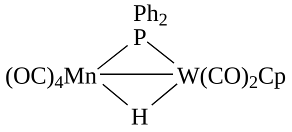
$CpMn(CO)_2(HBH_2PMe_3)$ has been characterized, with the conclusion that the bonding consists primarily of σ-donation from the B–H bond with little d orbital back donation into the B–H σ^* orbital.[18] An upper limit of 100 kJ has been estimated for the η^2 bond in the σ-borane complex (**8**).[19] The borane ligand in (**8**) is readily replaced by CO, PhC≡CPh, $HSiMePh_2$, and $HSnPh_3$, with the latter two ligands forming H–Si and H–Sn σ-bond complexes, as indicated in Scheme 4.



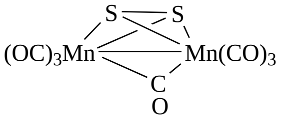
(**9**)

The pyrylium complex (**9**) was found to be surprisingly resistant to protolytic Mn–C bond cleavage and CO insertion reactions.[20] It undergoes electrocatalytic CO substitution upon reduction in the presence of PPh_3. The dimeric complex $[Mn(CO)_4Br]_2$ was found to be a catalyst precursor for the alcoholysis of silanes.[21] Similarly, manganese carbonyl complexes, for example $Mn(CO)_4(PPh_3)C(O)Me$, are very effective catalysts for the hydrosilylation (*see Hydrosilation*) of ketones.[22] Nucleophilic attack of hydride on electrophilic metal carbonyls is a favorite route to formyl complexes. An example is provided by the reaction of borohydride with $[Mn(CO)_4(dppe)]^+$ to generate an observable formyl intermediate, $Mn(CO)_3(dppe)(CHO)$, which slowly decarbonylates to *fac*-$Mn(CO)_3(dppe)H$.[23] Manganese acyls, $(OC)_5MnC(O)CH_2R$, can be converted into the α-ketoacyl derivatives $(OC)_5MnC(O)C(O)CH_2R$ by treatment with $HSiEt_3$, followed by carbonylation and protonlysis.[24]

A rather large number of multimetallic complexes containing manganese carbonyl units have been reported during the last 10 years. The one-pot synthesis of the selenolato-bridged bimetallic (**10**) follows the chemistry shown in Scheme 5.[25] A variety of bimetallic complexes containing one or more bridging μ-PPh_2 phosphido groups have been synthesized,[26–29] including the heteronuclear manganese–tungsten complex (**11**).[26] The latter complex is especially interesting because phosphine and phosphite ligands were found to substitute for a CO ligand at the manganese center only, while ^{13}CO substitutes at both metal centers. New bimetallic complexes containing bridging thiolates have appeared.[30,31] Most significant was the report[32,33] in 2001 of the isolation of the simplest disulfide of manganese carbonyl, $Mn_2(CO)_7S_2$ (**12**), from the reaction of $Mn_2(CO)_9(NCMe)$ and thiirane. Chemical reduction of (**12**) affords[34] the trimetallic carbonyl anion $[Mn_3(CO)_{10}(\mu\text{-}S_2)_2]^-$. Also of interest is the synthesis of the first dinuclear complex with bridging borylene ligands, $Cp_2Mn_2(CO)_4(\mu\text{-BR})$ (R = NMe_2, CMe_3).[35,36]



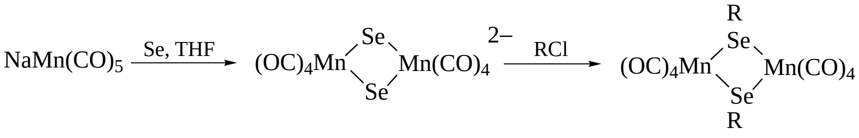
(**11**)



(**12**)

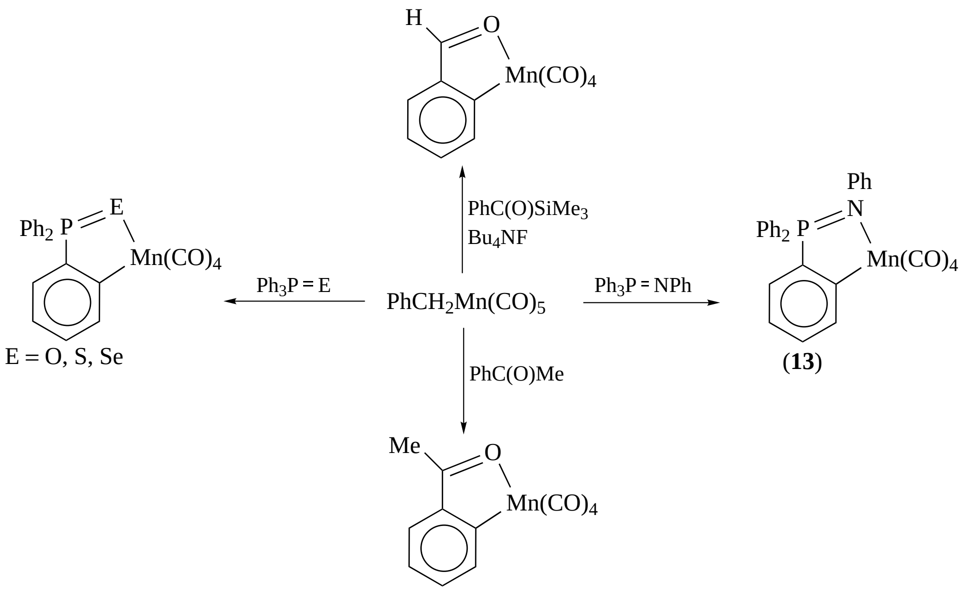
4 INSERTION REACTIONS

The migratory insertion (*see Migratory Insertion*) reactions of manganese carbonyls have been studied for many



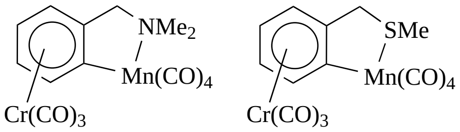
(**10**)

Scheme 5

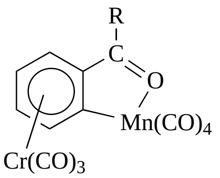


Scheme 6

years. A useful starting reagent is $PhCH_2Mn(CO)_5$, which reacts with many suitably substituted aromatic substrates in a ‘cyclomanganation’ reaction. Scheme 6 provides a number of examples.[37–47] Complex (**13**) is especially interesting because it is thermochromic in solution, changing abruptly from ambient yellow to intense purple as the solution is heated to 100 °C.[39] Cyclomanganated species frequently undergo insertion reactions with a variety of reagents. Scheme 7 illustrates a recently reported typical example of alkyne insertion.[46] Cyclomanganation of aromatic *complexes* of chromium, such as those shown in structures (**14**)– (**16**), hold significant promise.[48–50] In some cases, the use of these bimetallic cyclometallated products allows enhanced diastereoselectivity in subsequent insertive cyclization sequences to generate indanol and other heterocycles.[50]



(**14**) (**15**)



(**16**)

The manganese carbonyl disulfide complex (**12**) inserts various metal fragments into the S–S bond (Scheme 8).[51–55] On the other hand, Me_2S inserts into the Mn–Mn bond and tertiary phosphines substitute CO ligands. *Heterobimetallic* disulfides and diselenides analogous to (**12**) have been reported.[54,55] These fascinating compounds insert ethylene, CO, and $Pt(PPh_3)_2$ according to Scheme 9. Another interesting report concerns the insertion of imines and carbon monoxide into manganese–alkyl bonds. The double insertion of these species into $MeMn(CO)_5$ affords the manganese-chelated amide (**17**).[56]

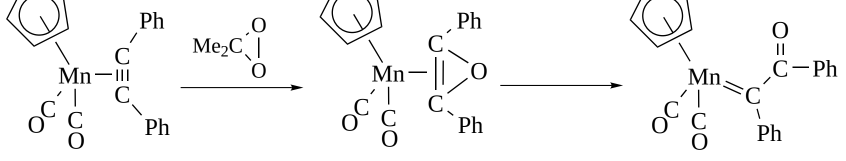
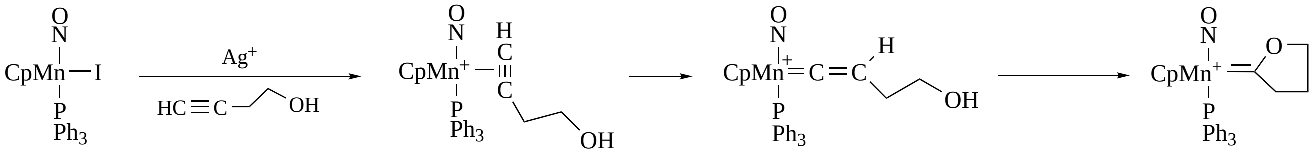
5 CARBENES AND RELATED COMPOUNDS

Transition metal carbenes constitute a very important class of molecules that have found a multitude of applications. With reference to manganese, a number of new carbene complexes have been reported recently. The η^2-alkyne complex (**18**) was found[57] to undergo oxidation by dimethyldioxirane to afford the α-keto carbene (**19**). The fascinating aspect of this reaction is the likely existence of an oxirene intermediate (**20**). Stable oxirene complexes have never been reported, undoubtedly because of the extreme instability of the antiaromatic oxirene ring. The possibility of trapping an oxirene by epoxidation of a coordinated alkyne is intriguing. Scheme 10 summarizes the chemistry involved.

Chiral-at-the-metal Fischer carbene complexes are formed when the 16-electron fragment $[CpMn(NO)(PPh_3)]^+$ is treated with hydroxyalkynes.[58] The likely mechanism of this reaction is given in Scheme 11. Abstraction of iodide from precursor (**21**) allows coordination of the alkyne, which rearranges to the vinylidene (**22**). The latter undergoes intramolecular nucleophilic (*see Intramolecular*) attack of the alcohol at the α-carbon to generate the chiral carbene (**23**). The carbene complex $Cp(CO)_2Mn{=}C(OAc)(Ph)$ reacts with chiral aminoalcohols (R^*OH) to afford $Cp(CO)_2Mn{=}C(OR^*)(Ph)$ complexes, which are converted diastereoselectively to $Cp(CO)(PR_3)Mn{=}C(OR^*)(Ph)$ when photolyzed in the presence PR_3 ligands.[59] A number of bis(carbene) complexes of manganese have been synthesized, for example (**24**)



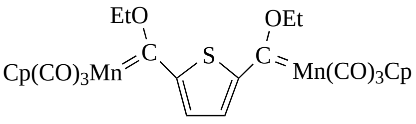
Scheme 10



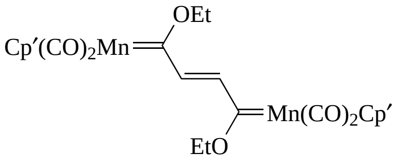
(**21**) (**22**) (**23**)

Scheme 11

and (**25**).[60–62] The coordination of a $CpMn(CO)_2$ fragment to the alkyne in the carbene complex $Cp(CO)_2Mn{=}C(R)C{\equiv}CR'$ yields a highly fluxional (*see Fluxional Molecule*) bimetallic species in which the η^1-carbene and η^2-alkyne moieties rapidly exchange as pictured in Scheme 12.[63]



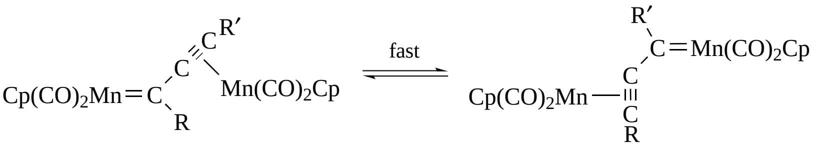
(**24**)



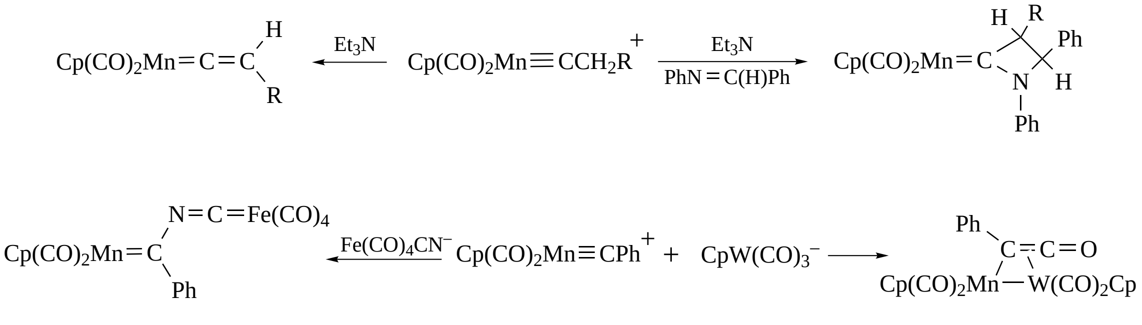
(**25**)

The paramagnetic 17-electron alkynyl complex $CpMn(dmpe)(C{\equiv}CPh)$ reacts with hydride donors to give the vinylidene $Cp(dmpe)Mn{=}C{=}CHPh$ or with itself to generate the bimetallic bis-vinylidene $[Cp(dmpe)Mn{=}C{=}C(Ph)]_2$.[64] The analogous $[Cp(CO)_2Mn{=}C{=}C(Ph)]_2$ complex has been made by an oxidative dehydrodimerization process.[65] The alkynyl complex $Cp^*(CO)_2FeC{\equiv}CH$ combines with $Cp'Mn(CO)_2(THF)$ to afford the bimetallic vinylidene $Cp'(CO)_2Mn{=}C{=}C(H)(Fp^*)$, where Fp^* stands for the $Cp^*Fe(CO)_2$ fragment.[66] Manganese vinylidene complexes may also be obtained by treating $Cp'Mn(CO)_3$ with organolithium reagents to form acyl anions $Cp'Mn(CO)_2C(O)CH_2R^-$ that react with electrophiles such as acetyl chloride to afford the carbenes $Cp'(CO)_2Mn{=}C(OC(O)Me)(CH_2R)$. The latter complexes eliminate acetic acid and convert to the vinylidenes $Cp'(CO)_2Mn{=}C{=}CHR$.[67]

Carbyne complexes containing the $Mn{\equiv}CR$ moiety undergo an interesting variety of reactions.[68–70] Scheme 13 provides a sampler of these reactions. The electrophilic nature of the carbyne in the cationic $Cp(CO)_2Mn{\equiv}CR^+$ has been exploited in cycloadditions, metatheses, and ketene formation methodologies. Extended chains containing unsaturated carbon networks that are truncated by metal

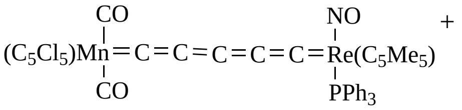


Scheme 12

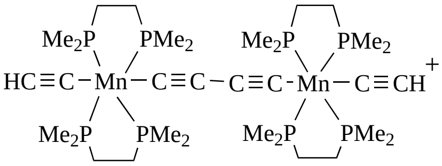


Scheme 13

fragments are being developed as 'molecular wires'.[71–73] Structures (**26**) and (**27**) illustrate two examples of these. In (**26**), the cumulenic chain is capped by different metals. In (**27**), the unsaturation is provided by acetylide linkages.



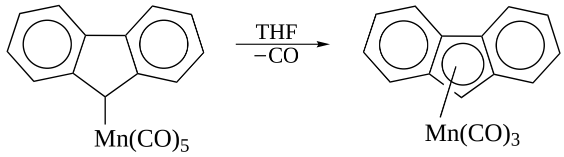
(**26**)



(**27**)

6 CYMANTRENES

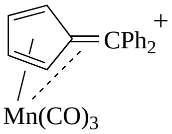
$CpMn(CO)_3$, known as cymantrene, is a robust molecule whose chemistry has been extensively developed. The cyclopentadienyl (*see Cyclopentadienyl*) ring in $CpMn(CO)_3$ can be functionalized with alkyl, aryl, and alcoholic substituents.[74,75] Even pentamercuration has been reported, affording (**28**), from which the pentahalo derivatives (**29**) can be obtained.[76] Photolysis of cymantrenes-bearing ring substituents with donor atoms can lead to intramolecular ring closure following CO dissociation to yield products such as (**30**).[77] Photoacoustic calorimetric measurements indicate that the ring closure occurs with a rate constant greater than $10^7\ s^{-1}$ at room temperature. Lithium fluorenide ($LiC_{13}H_9$) reacts with $Mn(CO)_5Br$ to give an η^1 complex, which slowly dissociates CO and rearranges to the η^5 analogue (**31**) shown in Scheme 14.[78] Other noteworthy



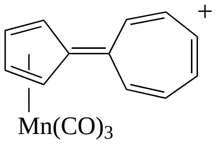
(**31**)

Scheme 14

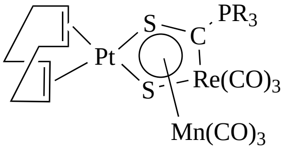
complexes, recently reported, that are related to cymantrene include the fulvene (**32**), sesquifulvalene (**33**), and the rather bizarre metallacycle (**34**).[79–81]



(**32**)

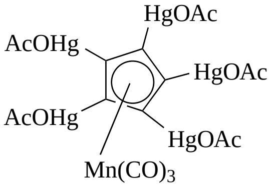


(**33**)

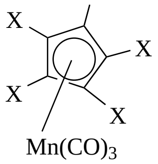


(**34**)

UV photolysis of $CpMn(CO)_3$ in toluene leads to loss of CO and formation of $CpMn(CO)_2(\eta^2$-toluene). Kinetic studies suggest that the binding energy of the toluene is ca. $60\ kJ\ mol^{-1}$.[82] The η^2 binding of H_2 to $CpMn(CO)_2$ has been studied in supercritical CO_2 solvent.[83,84] It has been proposed that pyrylium and pyridinium salts such as (**35**) can be used to label proteins and thereby aid in the detection and characterization of receptor sites.[85] Cymantrene bound to lysine residues of bovine serum albumin (BSA) has been used as a redox label.[86] Electrochemical reduction of the label established an impressive BSA detection limit of 2×10^{-7} M.

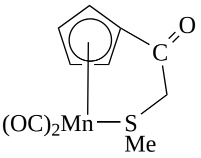


(**28**)

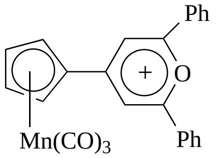


(X = Cl, Br, I)

(**29**)

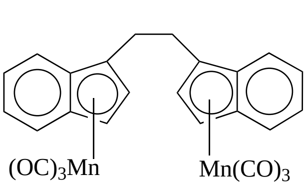


(**30**)

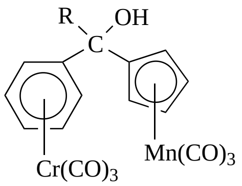


(**35**)

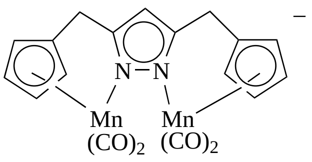
Multimetallic cymantrenes such as (**36**) and (**37**) have recently been reported.[87,88] An especially interesting multimetallic system is (**38**), in which two cymantrene units are linked by a pyrazolate bridge.[89] Electrochemical measurements show that the two metal centers in (**38**) interact



(**36**)



(**37**)



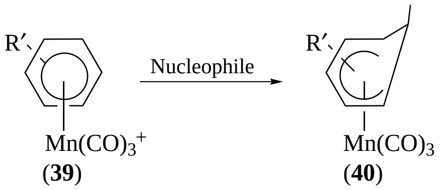
(**38**)

significantly, which results in a consequent stabilization of the Mn(I)/Mn(II) mixed-valence one-electron oxidation product.

7 CYCLIC π-HYDROCARBON COMPOUNDS

With the possible exception of the cyclopentadienyl ring system, described in the last section, the most important cyclic π-hydrocarbon ligands in manganese chemistry are six-electron donors based on the benzene nucleus. The use of ^{55}Mn NMR in characterizing manganese sandwich complexes has been examined with the series $(\eta^5\text{-}C_5H_4R)Mn(\eta^6\text{-}C_6H_5R')$.[90] The ^{55}Mn nucleus has a spin of 5/2 and a sizable quadrupole moment, resulting in line-widths of several kHz in the compounds studied. Nevertheless, the chemical shift δ covers a sufficiently large range that well-resolved spectra may be obtained. The ^{55}Mn chemical shifts were found to be usefully dependent on the nature of the π-hydrocarbon ring substituents R and R′.

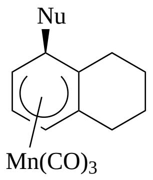
The complexes $[(\eta^6\text{-arene})Mn(CO)_3]^+$ constitute a very important class of compounds that have been shown to undergo a rather amazing range of useful chemical reactions.[91–93] The synthesis of such complexes is generally straightforward, unless the arene contains an electron-withdrawing substituent.[94,95] The most useful reaction of $[(\eta^6\text{-arene})Mn(CO)_3]^+$ is the very facile addition



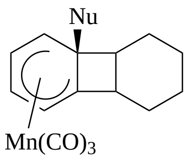
(**39**) (**40**)

Scheme 15

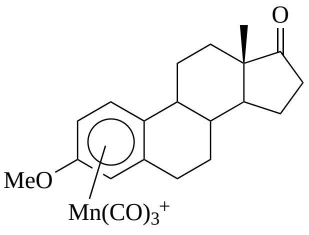
of a wide range of nucleophiles to afford stable cyclohexadienyl complexes, as illustrated in Scheme 15.[96–108] The nucleophiles utilized include Grignard reagents, benzylic zinc reagents, stabilized enolates, borohydride, aryl lithium reagents, anionic metal complexes, and so on. The stereoselectivity of these addition reactions is almost always exclusively exo to the metal, as shown in (**40**). The regioselectivity depends on the substituent R′. When R′ in (**39**) is -OMe, for example, the addition is highly selective for the meta position. Ring strain can influence the result in some cases. Thus, $[(\eta^6\text{-tetralin})Mn(CO)_3]^+$ adds nucleophiles α to the bridgehead to give (**41**), while $[(\eta^6\text{-biphenylene})Mn(CO)_3]^+$ prefers to be attacked at the bridgehead (**42**), with concomitant release of ring strain.[101,102] Interestingly, it proved possible to functionalize the aromatic steroid estrone and the diterpenoid podocarpic acid by initial complexation of manganese tricarbonyl to the aromatic ring to afford (**43**) and (**44**), respectively.[103–105] It was also found that $[(\eta^5\text{-thiophene})Mn(CO)_3]^+$ complexes readily undergo nucleophilic addition (*see Nucleophilic Addition: Rules for Predicting Direction*) at the sulfur atom, which leads to zwitterionic $(\eta^4\text{-}C_4H_4SR)Mn(CO)_3$ products.[109,110] Complexes (**39**) that contain a phenolic arene are readily and reversibly deprotonated by weak bases to oxocyclohexadienyl derivatives.[111,112]



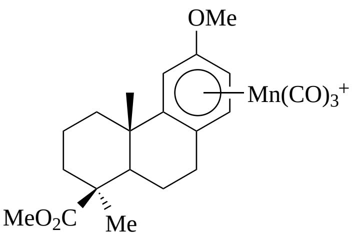
(**41**)



(**42**)



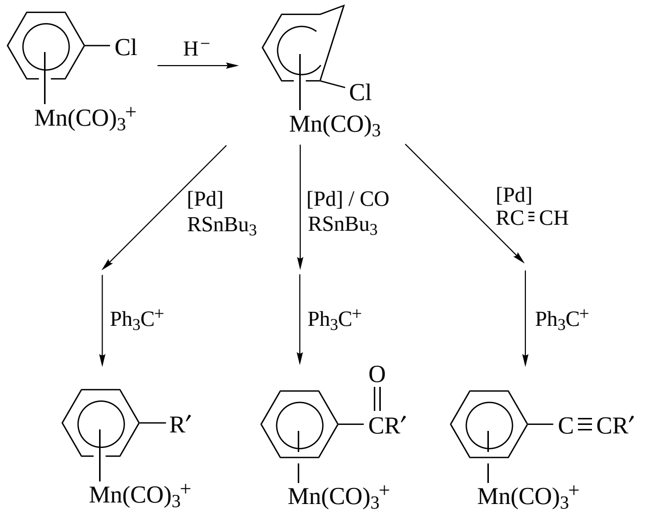
(**43**)



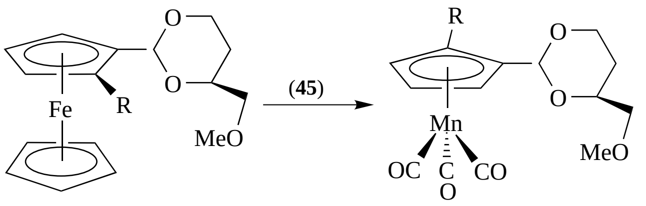
(**44**)

In a new and significant development, it was found that chlorocyclohexadienyl manganese tricarbonyl complexes undergo palladium-catalyzed coupling reactions with a variety of carbon nucleophiles to afford products from which hydride may be abstracted with trityl cation, thus generating new $[(\eta^6\text{-arene})Mn(CO)_3]^+$ complexes containing substituents that cannot be introduced in any other manner.[113–117] This is particularly true of electron-withdrawing substituents. Scheme 16 illustrates the chemistry involved.

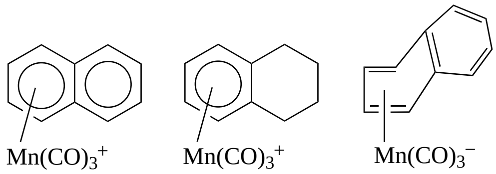
One of the most exciting developments in organomanganese chemistry concerns the synthesis of naphthalene and



Scheme 16



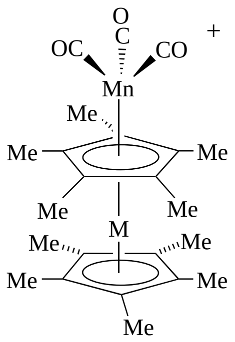
Scheme 17



(**45**) (**46**) (**47**)

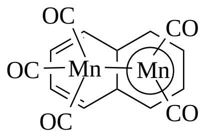
related complexes (**45**).[118] This compound, although erroneously reported in 1961, had never before been synthesized and characterized in spite of numerous attempts to do so. The reason for the synthetic difficulties becomes apparent when the chemistry of (**45**) is compared to that of the analogue (**46**) having one ring saturated (tetralin). Both complexes react cleanly with acetonitrile with displacement of the arene and formation of $[(MeCN)_3Mn(CO)_3]^+$. However, the half-lives are tremendously different: 2 years for (**46**) and one minute for (**45**)! Thus, it became apparent that the naphthalene-type complexes are generally very sensitive to potential nucleophiles, which accounts for the previous difficulty in synthesis. The use of a nonnucleophilic solvent under moisture-free conditions permits the ready synthesis of (**45**) and its analogues in good yields.[118] The great reactivity of (**45**) does not imply a weak bond. It merely means that a low-energy pathway exists for arene displacement. This pathway involves $\eta^6 \rightarrow \eta^4$ ring slippage that accompanies associative attack by a nucleophile. Such slippage entails a loss in aromatic resonance energy that contributes to the activation energy. However, the loss in resonance energy upon slippage is not nearly as much as that for a monocyclic unsaturated system (benzene, tetralin, etc.). In fact, the differences in ring-displacement rates for complexes containing monocyclic unsaturated arene rings and rates for complexes containing polycyclic unsaturated arene rings almost exactly match the anticipated differential in resonance energy loss upon ring slippage. Relevant to this is the known stability of the slipped $[(\eta^4\text{-naphthalene})Mn(CO)_3]^-$ complex (**47**).[119]

The ease of arene ring displacement from (**45**) makes it an excellent manganese tricarbonyl transfer (MTT) reagent.[118] In particular, many free arenes react readily with (**45**) to generate new $[(\text{arene})Mn(CO)_3]^+$ complexes by a mild and useful synthetic route. In this manner, hydroquinones, centropolyindanes, and even $(\eta^6\text{-biphenyl})Cr(CO)_3$ are readily coordinated to manganese tricarbonyl.[118,120,121] In a dramatic illustration of the utility of (**45**) as an MTT reagent, it was found that merely refluxing equimolar amounts of (**45**) and $Cp^*{}_2M$ (M = Fe, Ru, Os) produces air-stable capped metallocenes (**48**) as BF_4^- salts.[122] In a similar vein, it has been shown that the reaction of (**45**) with planar chiral ferrocenes (*see Ferrocene*) results in transfer of planar chirality as illustrated in Scheme 17.[123] The resulting chiral cymantrenes are useful as chiral auxiliaries in asymmetric allylic alkylations and other reactions.

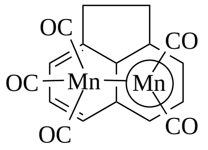


(**48**)

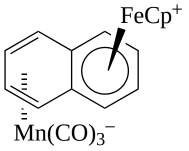
The facile ring slippage that occurs in (**45**) upon nucleophilic attack or upon reduction has been combined in a rather extraordinary reaction that utilizes both types of slippage to produce novel syn-facial and anti-facial bimetallic complexes such as (**49**)– (**52**).[124] In cyclohexadienyl derivative (**53**), ligand addition to the metal occurs reversibly concomitant with $\eta^5 \rightarrow \eta^3$ ring slippage according to Scheme 18.[125–127] Because of the facile ring slippage, (**53**) is an effective catalyst for the hydrosilylation (*see Hydrosilation*) of ketones[126] and also undergoes the rapid 1,4-hydride shift illustrated.[128–130] In an interesting series of reactions,[131–134]



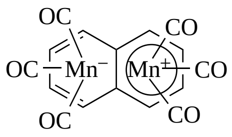
(**49**)



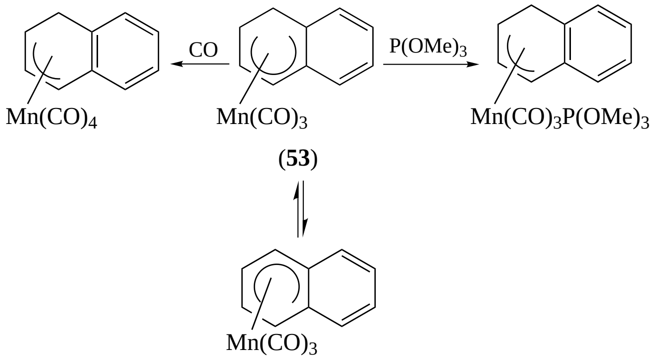
(**50**)



(**51**)



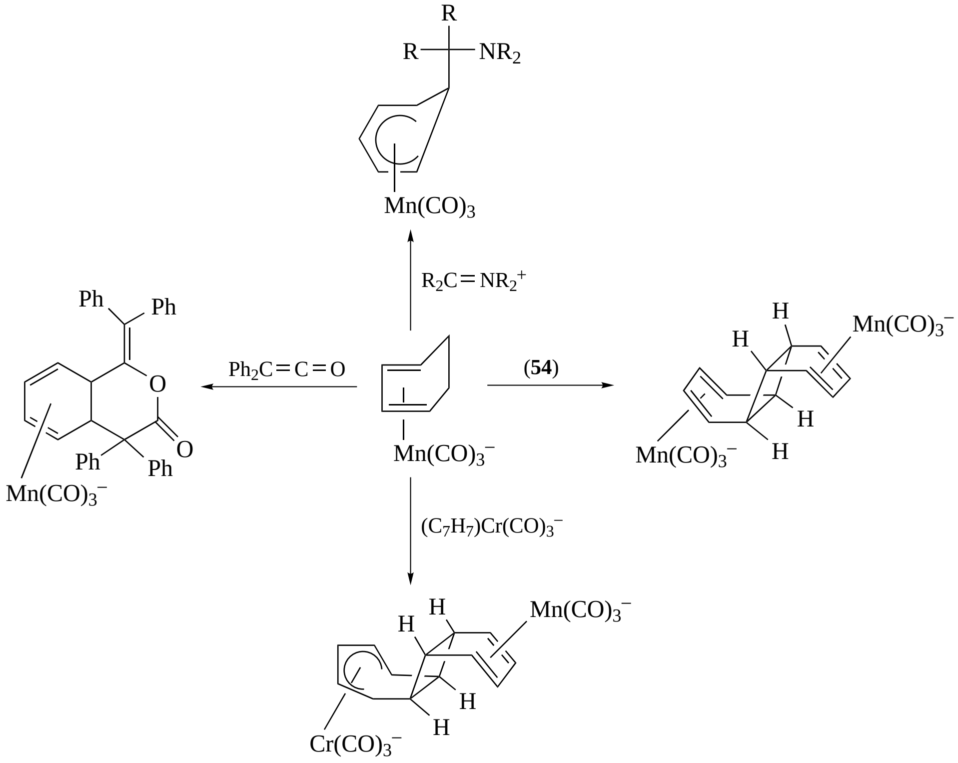
(**52**)



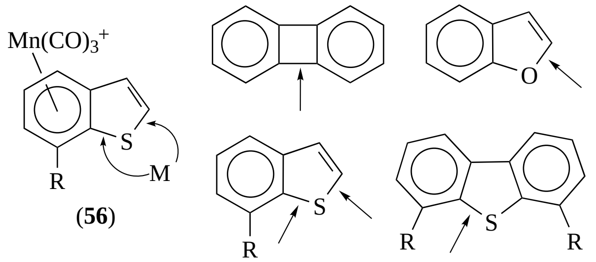
Scheme 18

it been reported that $[(\eta^6\text{-benzene})Mn(CO)_3]^+$ (**54**) undergoes two-electron reduction by potassium naphthalenide at low temperatures to afford $[(\eta^4\text{-benzene})Mn(CO)_3]^-$. The latter complex survives long enough to react with a variety of electrophiles, according to Scheme 19. Cyclohexadienyl complexes $(\eta^5\text{-}C_6H_6R)Mn(CO)_3$ (**55**) react with $[NO]BF_4$ to generate $[(\eta^5\text{-cyclohexadienyl})Mn(CO)_2NO]^+$ cations that add a (second) nucleophile to give neutral difunctionalized cyclohexadiene complexes.[135] Treatment of complexes (**55**) sequentially with a hydride and a proton source leads to hydrodechlorination, hydrodesulfurization (HDS), and so on, when there is a heteroatom substituent present on the cyclohexadienyl ring.[136] Deprotonation of an α-carbon substituent in (**55**) produces a nucleophile that adds to a range of electrophiles, including metallic ones such as (**54**).[137] Single and double cycloaddition of alkynes to (**55**) has been reported.[138]

The ability of the $Mn(CO)_3{}^+$ moiety to activate aromatic rings to nucleophilic attack and/or deprotonation of side-chain substituents has been extended to the activation of strong covalent bonds in regions of the molecule adjacent to the coordinated aromatic ring.[139] This is called ‘remote activation’. For example, coordinating $Mn(CO)_3{}^+$ to the benzene ring in benzothiophene to give (**56**) activates both C–S bonds to



Scheme 19



(**56**)

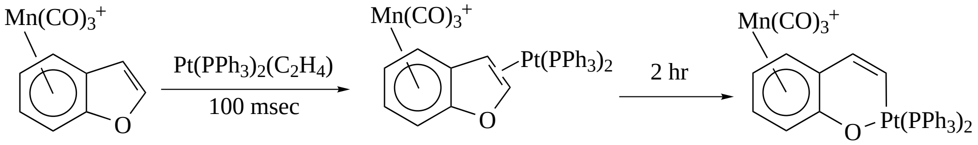
Scheme 20

cleavage upon the addition of a mild metal nucleophile. Which C–S bond is broken depends on the substituent R. Scheme 20 illustrates some of the systems reported, with the arrows indicating which bond is broken after the molecule is activated to bond fission by nucleophilic insertion or by reduction.[139–152] For example, the C–C bond in $[(\eta^6\text{-biphenylene})Mn(CO)_3]^+$ is rapidly broken by the mildly nucleophilic $Pt(PPh_3)_3$. The same is true of the vinylic C–O bond in benzofuran, in which an intermediate could be observed containing the $Pt(PPh_3)_2$ unit π-bonded to the furan C=C prior to fission of the adjacent C–O bond, as shown in Scheme 21.

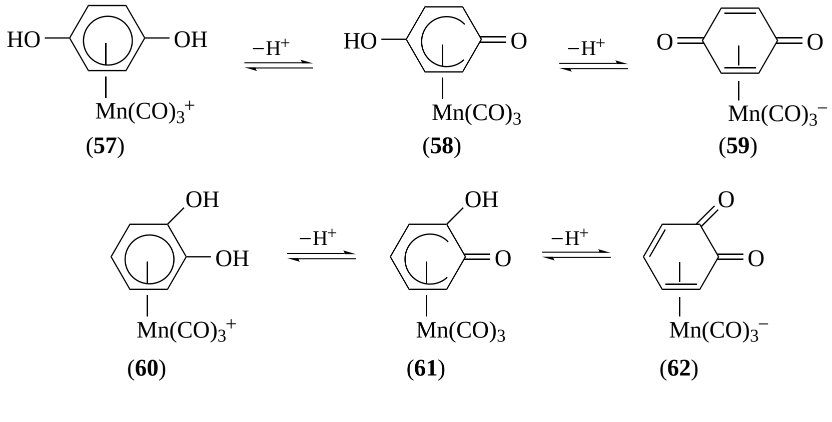
It is remarkable indeed to observe that precoordination of $Mn(CO)_3{}^+$ to dibenzothiophenes, even 4,6-dialkylated ones, activates a C–S bond to cleavage by a mild nucleophile within *seconds* at room temperature. C–S bond fission is the first step in sulfur removal, and the methodology described could point the way to catalytic desulfurization of the major and most intractable sulfur-containing contaminant in fossil fuels – alkylated dibenzothiophenes. The removal of sulfur by reaction with hydrogen to yield H_2S is practiced on a massive scale by the petroleum industry. Indeed, HDS is the largest-scale industrial chemical reaction in the world. The removal of sulfur is required for industrial and environmental reasons, and getting the content down to tens of parts-per-million, as soon required by Federal legislation, is a difficult proposition termed 'deep hydrodesulfurization'. Organometallic model systems such as that described above for manganese may contribute significantly in this regard in the twenty-first century.

8 METAL-ORGANOMETALLIC COORDINATION NETWORKS

An especially interesting example of the use of an MTT reagent is in the high-yield synthesis of π-bonded η^6-hydroquinone and η^6-catechol manganese complexes.[153–155] The transition metal chemistry of π-bonded hydroquinones is little developed because of difficulty in synthesis and/or instability. Furthermore, hydroquinones have a strong propensity to bind through the oxygen atoms rather than through the π system. Nevertheless, η^6-hydroquinone, resorcinol, and catechol π complexes of $Mn(CO)_3{}^+$ are thermally stable species and undergo interesting reactions. For example, complexes (**57**) and (**60**) are easily deprotonated to afford η^5-semiquinone and η^4-quinone derivatives (Scheme 22). The semiquinone (**58**) exists in linear polymeric arrays in the solid state with a structure



Scheme 21



(**57**) (**58**) (**59**)
(**60**) (**61**) (**62**)

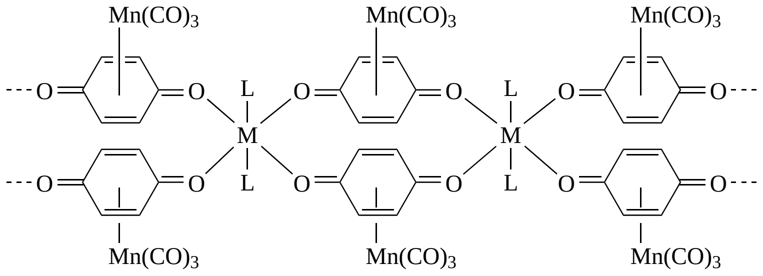
Scheme 22

dictated by strong intermolecular hydrogen bonding. By comparison, the catechol analogue (**61**) exists as discrete hydrogen-bonded dimers.

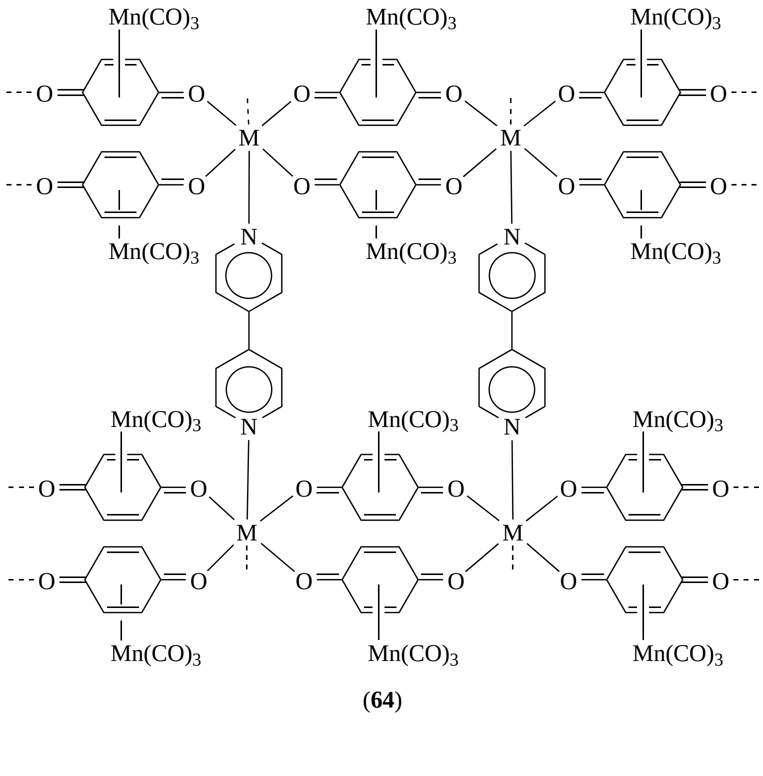
The anionic η^4-quinone complexes (**59**) and (**62**) have been shown to function as good ligands toward transition metals by σ-binding through the oxygen atoms.[156–160] Accordingly, complexes (**59**) and (**62**) are termed 'organometalloligands'. The catecholate (**62**) functions as a chelating ligand and with divalent metal ions forms complexes $[M(\mathbf{62})_2(L_2)]$ (M = Mn, Cd, Co; L_2 = phen, 2,2′-bipy, 2 py). The electron-sink nature of the manganese carbonyl moiety combined with the redox-active nature of quinones make these complexes interesting in the context of 'redox tautomerization', meaning that they show a dynamic electronic environment (oxidation state) at the metal M that self-adjusts to changes in the binding properties of the nonquinonoid ligand L.

In contrast to the discrete complexes formed by organometalloligand (**62**), the benzoquinone complex (**59**) is geometrically prevented from chelating a metal ion and instead functions as a bifunctional ligand to form supramolecular coordination networks. These consist of metal ions, called *nodes*, connected by organometalloligand spacers. The whole assembly is termed a metal-organometallic coordination network (MOMN).[156] For example, in DMSO (**59**) reacts to form the 1-D MOMN (**63**). By using a bifunctional organic spacer as the axial ligand, the 1-D 'string' polymers in (**63**) can be tied together to give the 2-D MOMN (**64**). With suitable experimental conditions, it is possible to construct 3-D MOMNs that contain 2-D quinonoid planes connected by the bipyridine spacers. Significantly, it appears that the architectures that obtain can be rationally designed based upon the coordination number, oxidation state, and geometrical requirements of the metallic nodes that link the organometalloligands.

In other work involving organometallic supramolecular systems containing manganese, the incorporation of the $Mn(CO)_3^+$ fragment into poly(methylphenylsilane) has been achieved with 10% loading by using the MTT reagent (**45**).[161]



(**63**)



(**64**)

The manganese is η^6-bonded to the silane phenyl groups. Cyclodextrins are known to function as hosts for a variety of guest substrates. Monomeric and dimeric β-cyclodextrins have been shown to bind $CpMn(CO)_3$ as a guest, allowing water solubility and/or photosubstitution to be studied.[162,163]

1 INTRODUCTION: ORIGIN AND SIGNIFICANCE OF OXYGENIC PHOTOSYNTHESIS

The production of O_2 by the oxidation of water within photosynthetic organisms is a striking signature of life on Earth. This biological innovation appeared in the precursors to contemporary cyanobacteria circa 2.2−3.8 billion years ago and had profound global geological consequences.[1,2] Very little is known about how water splitting chemistry was invented.[3–5] By using water as an inexhaustible source of electrons and protons, it enabled the proliferation of phototrophic life everywhere on the planet. This event was nature's analog of the 'universal big bang'. It transformed the atmosphere from anaerobic to O_2-rich, perfused phototrophic life throughout the oceans, pigmented the surface of Earth in a carpet of green chlorophyll, and enabled the biogeochemical cycles to develop their present forms. The emergence of atmospheric O_2 permitted the development of respiratory metabolism with its vastly more efficient energy production. This new boost in metabolic energy *supercharged* the engine of life and led to all complex life as we know it.

O_2 is a by-product of splitting water into electrons and protons within a wide variety of photosynthetic organisms, including both prokaryotes (cyano- and oxyphoto-bacteria), and eukaryotes (green algae and higher plants). Water splitting is driven by the membrane pigment-protein complex known as the photosystem II−water oxidizing complex (PSII-WOC) or oxygen-evolving complex (PSII-OEC). The electrons and protons are ultimately used to store energy in the phospho-anhydride bond of ATP and to reduce CO_2 to carbohydrate, the precursors for synthesis of the biopolymers needed by the organism. Some cyanobacteria and green algae also use the protons and electrons to synthesize hydrogen under anaerobic conditions, presumably to eliminate excess reducing capacity.

A single class of PSII-WOC enzymes is found in all O_2-producing (oxygenic) phototrophs that have been studied to date. No variation of the inorganic core $Mn_4Ca_1O_xCl_{1-2}(HCO_3)_y$ has been identified among them. The PsbA gene encoding the D1 reaction center protein subunit that binds this inorganic core is highly conserved in more than 180 sequences. This invariance of both the protein and cofactors is an extraordinary feature that is not found anywhere else in biology. It is as if nature has performed combinatorial synthesis through evolution over 2.2−3.8 billion years, using all possible ecological habitats that are permissive of photosynthetic metabolism and has been able to invent *only one biological blueprint for water splitting.* This lesson is vital to appreciate by all who are engaged in creating biomimetic catalysts or engineered PSII enzymes for practical applications.

Two applications for which catalysts are sought are the direct solar splitting of water for hydrogen production, and the reversible reduction of O_2 to water in fuel cell cathodes. Nature uses abundant metals (Mn, Ca) organized into a novel, self-repairing, cluster to achieve water splitting. By contrast, man-made water splitting catalysts use rare noble metals (Pt) that operate inefficiently and create damaging reactive intermediates. The lessons learned from photosynthetic water splitting are beginning to contribute to more practical solutions.

In this article, we offer a brief and select overview of the literature on the atomic and electronic structure of the water-splitting enzyme,[5–7] the chemical basis of its catalysis, and insights learned from functional model complexes. Citations cover the main review articles that are available rather than primary works.

2 THE O_2 CLOCK REACTION STEPS: THE 'S-STATE CYCLE'

The PSII-WOC accomplishes a complex task of converting the one-electron photoexcited state of chlorophyll into the concerted four-electron (all-or-nothing) oxidation of two water molecules. The working model used to discuss the intermediate oxidation states of all PSII-WOC enzymes comes from studies of flash O_2 yield measurements by Joliot and coworkers and the interpretation by Kok and coworkers.[8,9] Illumination of dark-adapted chloroplasts or algal cells with saturating flashes of light leads to the production of O_2 in a characteristic pattern peaking on flash #3 and repeating each four flashes. It was therefore concluded that O_2 production takes place at a catalytic center and that each flash advances the oxidation state of the WOC by removal of one electron. O_2 is formed and released only after four oxidation equivalents are accumulated. The 'S-state cycle' which describes this sequence is shown in Figure 1. The stoichiometry of the inorganic cofactors which make up the WOC is $Mn_4Ca_1O_xCl_{1-2}(HCO_3)_y$ and has been determined by various spectroscopic, extraction,

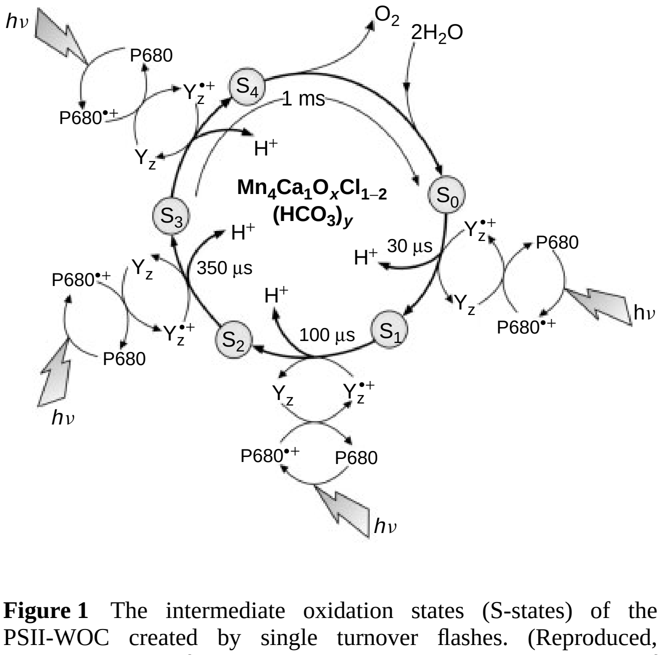

Figure 1 The intermediate oxidation states (S-states) of the PSII-WOC created by single turnover flashes. (Reproduced, with permission, from J. Nield, ''Structural Characterisation of Photosystem II'' Ph.D. thesis, University of London, 1997)

Table 1 Half-life ($T_{1/2}$) for the S-state transitions $S_i \rightarrow S_{i+1}$,[16] the stoichiometry of proton release[14] and the rate of exchange of the two substrate water molecules with bulk solvent water[17,18]

Reaction $S_i \rightarrow S_{i+1}$	$T_{1/2}$ (μs)	# H^+ pH 7.4/6.3	H_2O exchange rate in S_i Fast (s^{-1})	Slow (s^{-1})
$S_0 \rightarrow S_1$	30	0.5/1.5	>100	13.6
$S_1 \rightarrow S_2$	100	1.0/1.1	>100	0.02
$S_2 \rightarrow S_3$	250	1.5/0.5	>175	2.0
$S_3 \rightarrow S_4$	1300	1.0/0.9	37.5	2.0

and reconstitution studies.[10–12] The pattern of proton release during the cycle is also known and changes with the pH of the medium and the number of protein subunits present in the PSII complex.[13] Electrostatic effects on ionizable protein residues are involved (Bohr protons) as well as the intrinsic protons released from substrate water molecules. The latter stoichiometry has been estimated to be 1:0:1:2.[14] One or more essential Cl^- ions bind within the PSII-WOC complex and are postulated to play a role in proton transfer from the Mn cluster to the medium.[15] Additional information about the kinetics of the S-state advances, stoichiometry of proton release, and the rate of substrate (water) exchange with bulk water is given in Table 1.

3 X-RAY DIFFRACTION (XRD) STRUCTURE OF THE PSII PROTEIN COMPLEX

Three XRD models of the PSII-WOC complex from a thermophilic cyanobacterium *Thermosynechococcus* species have been published at resolutions ranging from 3.8 to 3.5 Å.[19–21] The most complete data set was calculated by the method of multiple isomorphus replacement using six heavy atom derivatives and has substantially reduced residuals (R-factor = 30.4% at 3.5 Å resolution vs >53% for the other structures). Hence, we shall discuss this more refined model.[21] The crystallographic asymmetric unit contains a dimer of PSII (640 kDa mass; dimensions: 105 Å depth, 205 Å length, and 110 Å width) with two nearly identical monomers. Within the PSII dimer, monomers are related by noncrystallographic twofold axis perpendicular to the membrane plane. Each monomer consists of 16 integral membrane subunits composed of 35 transmembrane helices and 3 peripheral subunits. The monomer is characterized by pseudo 2-fold symmetry, which rotates the D1, CP47 and *PsbI* subunits into the D2, CP43 and *PsbX* subunits. Each monomer contains 36 chlorophyll *a* (Chl), 7–8 all-trans β-carotene molecules, 1 WOC (Mn_4Ca cluster), 1 heme *b*, one heme *c*, 2 plastoquinones, 2 pheophytins, 1 nonheme Fe, and 2 putative bicarbonate molecules. A stoichiometry of 4Mn and 1 Ca for the WOC was previously established from several lines of evidence, including ^{55}Mn hyperfine structure in EPR,[22]

Mn EXAFS and the rate of O_2 evolution activity during light-driven reconstitution of the free inorganic cofactors to apo-WOC-PSII complexes (photoactivation).[12]

3.1 Charge Separation

Light-driven electron-transfer steps among pigments within the reaction center (RC), composed of the D1 and D2 subunits, serve to trap the light energy delivered from the inner antennas (CP43 and CP47) or outer antennas complexes. Figure 2 depicts the cofactors involved in these electron-transfer reactions. Upon illumination, an electron is transferred *ca.* 35 Å across the membrane from the excited primary electron donor P680 – comprising one or more of the four Chls symmetrically positioned with the D1D2 RC subunits near the lumenal surface – to the final electron acceptor plastoquinone Q_B via Chl_{D1}, pheophytin ($Pheo_{D1}$), plastoquinone Q_A, and nonheme Fe(II). After accepting two electrons and undergoing protonation, plastoquinonol $QH_{2(B)}$ is released from PSII into the membrane matrix. The photo-generated cationic radical $P680^{\bullet+}$ is reduced by a tyrosine residue known as Tyr_Z (D1Tyr161) to generate a neutral tyrosine radical $Tyr_Z^{\bullet}$ which acts as an oxidant for the water oxidation process at the WOC.

The radical cation $P680^{\bullet+}$ oxidizing potential, recently estimated to be 1.3–1.4 V, exceeds that required for water splitting and is the highest of all types of reaction centers.[23] The two Chls denoted P_{D1} and P_{D2}, equivalent to the 'special pair' of bacteriochlorophylls (Bchl) in the anoxygenic bacterial reaction center (BRC), are rotated by 20° to the membrane normal and separated slightly further (Mg–Mg distance of 8.2 Å) than in BRC. The tetrapyrrole head groups of P_{D1} and P_{D2} are in van der Waals contact, but do not have appreciable π overlap, which could explain why P680 shows more monomeric character and weaker electronic coupling than its bacterial counterpart. P_{D1} and P_{D2} Chls are close to Chl_{D1} and Chl_{D2}, suggesting that the P680 excited state is delocalized over the four Chls and that Chl_{D1}, which is closest to the active branch $Pheo_{D1}$, participates in the primary charge separation. The electrons are transferred from $Pheo_{D1}$ to Q_A, which is a firmly bound plastoquinone. Even though PSII and BRCs utilize different primary quinone acceptors, the Q_A binding pockets are structurally similar.

3.2 The Water-splitting Center[21]

The Mn_4Ca cluster is asymmetrically located off the pseudo twofold symmetry axis that relates the 4 Chl molecules comprising P680 and approximately 8 Å below the mean interface of the transmembrane domain. The edge of the closest Chl of P680 is located 8.1 Å from the edge of the photooxidizable tyrosyl radical Tyr_Z (closest non-H atoms) and the latter is located 5.1 Å to the Ca atom and 6.5 Å to the closest Mn atom. This asymmetrical location likely contributes to the strong bias for charge separation involving the closest branch of RC Chls. Water molecules are presumed to fill the gap between the Mn and Tyr_Z. The phenoxyl hydrogen of Tyr_Z is hydrogen bonded to D1His190 and is the presumed proton acceptor required for stable photooxidation to form the neutral

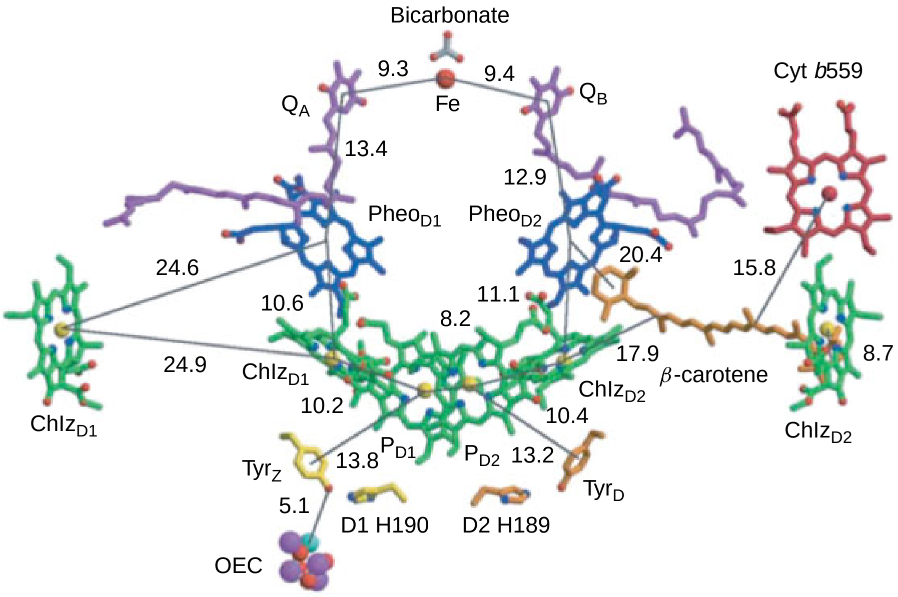

Figure 2 XRD model of the cofactors bound to photosystem II RC core and the water-oxidizing complex. The view is perpendicular to the membrane normal. (Reprinted with permission from K. Ferreira, T. Iverson, K. Maghlaoui, J. Barber and S. Iwata, Science Express, DOI 1093087 (2004). © 2004 AAAS)

tyrosyl radical. Together with the D1Glu189 these residues form hydrogen bonds that have been proposed to be involved in proton ejection into the lumenal space.[24] The distances and geometry provide no support for a mechanism in which Tyr_Z directly abstracts a H atom from substrate water bound to the Mn cluster. However, proton-coupled electron-transfer steps involving other bases in the active site may be involved as proton acceptors.

All of the protein ligands to the Mn_4Ca cluster come from side chains from three different domains of the D1 subunit and one domain of CP43. In D1 these domains are the carboxyl terminus (between H332 and D342), two residues within the interhelical CD luminal loop (D170 and E189), and one residue in the interhelical AB loop (D61). No homology to other protein folding domains is evident.

4 ATOMIC STRUCTURE OF THE INORGANIC CORE FROM XRD AND SPECTROSCOPY

The electron density attributed to the Mn_4Ca cluster is described as 'capped tetrahedral' when contoured at 8σ, with 4 metal atoms in the large end and one in a connected small end (Figure 3). A series of difference Fourier omit maps accommodates a tetrahedral array of 4 metal ions (3Mn + Ca) in the large end and one Mn in the small end. The small protruding density has been assigned to 1Mn based on comparing the anomalous scattering of X rays that are preferentially absorbed by Mn. A Ca atom is located in one of the corners of the tetrahedron based upon anomalous diffraction data taken at the Ca absorption edge. The presence of Ca is supported also by compelling evidence from three types of EXAFS measurements obtained at the Mn-, Ca- and Sr edges.[25] The EXAFS data clearly show that Ca is located at ~3.4 Å to Mn, but had anticipated only 1 or 2Mn scatters at this distance, not 4Mn as proposed in the XRD model. The intermetal distances within the cube are not adequately resolved in the XRD data and have been set equal for simplicity, yielding a symmetrical trigonal prism of $CaMn_3$. The authors postulate four bridging oxides (not directly observable) linking the tetrahedral array of $CaMn_3$ atoms, with one of these oxides (μ_4-oxo) bridging to the fourth Mn atom external to the cube (Figures 3 and 4). The resulting $CaMn_4O_4$ cluster can be classified also in terms of the two types of oxide bridges $(\mu_3\text{-oxo})_3(\mu_4\text{-oxo})$ that make up the core. The resulting $CaMn_4O_4$ core is novel; no exact structural analogs have been synthesized, although all manganese-oxo cubanes containing the $[Mn_4O_4]^{n+}$ are known.[26] Mn EXAFS and ^{55}Mn magnetic hyperfine (EPR) data had previously established the Mn stoichiometry of the WOC and were compatible with 8 possible Mn_4O_x core geometries, one of which has the same topology as the XRD model.[22,25] However, both the EXAFS and EPR data require that a lower symmetry cluster must exist in S_1 and S_2, with Mn EXAFS-derived intermanganese distances of 2.7 Å and 3.3 Å in S_1. This asymmetry could be accommodated if some of the bridging oxygen atoms are water or hydroxide molecules.

The 3Mn atoms within the cubane core each have one terminal carboxylate ligand, two from D1 (D342, E189) and one from CP43 (E354), while one Mn has an additional histidine ligand from D1 (H332). A proposed μ-oxo bridge that lies at the corner of the cube trans to Ca is H-bonded to a histidine of D1 (H337). The Mn atom external to the cube is ligated to two carboxylates from D1 (D170 and E333), two proposed water molecules (one of which is H-bonded to aspartate-61 carboxylate from D1), and an unidentified

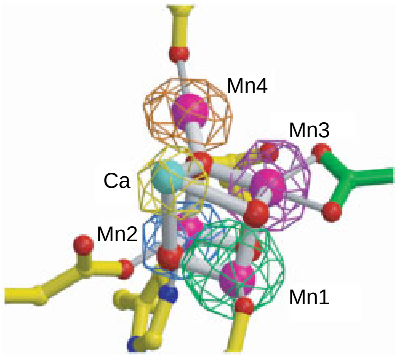

Figure 3 The electron density map of the Mn_4Ca cluster, calculated after omission of each metal of the WOC. The maps are contoured at 8σ for Mn1, Mn2, and Mn3 and 7σ for Mn4 and Ca. heavier scatterer X1 (possibly Cl^-, SO_4^{2-} or CO_3^{2-}). The Ca atom has no protein ligands but is coordinated to two solute molecules X21 and X22 having electron density greater than water (postulated as Cl^-, SO_4^{2}, or CO_3^{2-}). Arginine residue Arg357 from CP43 is positioned with its side chain fully extended and its cationic guanidinium group interacting with the nonprotein ligand X1 with a $N{\cdots}X_1$ bond length of 1.9 Å. In the current model the authors have positioned a tridentate carbonate ligand bridging between the exo-cuboidal Mn and Ca at these positions (both X22 and X23 carbonate(O)$\cdots$Ca distances = 2.26 Å). The authors postulate that these sites constitute the likely substrate water sites.

The net charge of the core of the WOC is not known experimentally. The XRD model for the $[Mn_4CaO_4]^n$ core suggests charges of $n = 6+$ or $8+$ for S_1 (assuming $4Mn^{III}$ or $2Mn^{III} + 2Mn^{IV}$ as suggested by EPR and Mn XAS, respectively). Assuming that the coordinated protein carboxylates are ionized, there are a total of 6− charges from the ligands. This leaves a minimal net charge for the WOC of zero or 2+, respectively, and possibly greater assuming that some of the oxo bridges are protonated. Charge neutralization within buried active sites suggests that the nonprotein ligands (X1, X22, X23 and possibly other Mn coordinate sites) are most likely anionic ligands. The possibilities include solute (OH^-), other native cofactors required for water splitting (Cl^-, CO_3^{2-}) or precipitant (SO_4^{2-}).

5 INSIGHTS FROM MUTAGENESIS

The XRD model of the PSII monomer contains assignments for 19 of the 21 known PSII gene products except for the genes PsbW and PsbY. Mutagenesis studies have been carried out on some of these protein subunits, with the majority directed at the D1 protein and more recently CP43.[24,27–29] The consequences of point mutations in selected residues of the D1 and CP43 proteins are summarized in Figure 5 and discussed below.

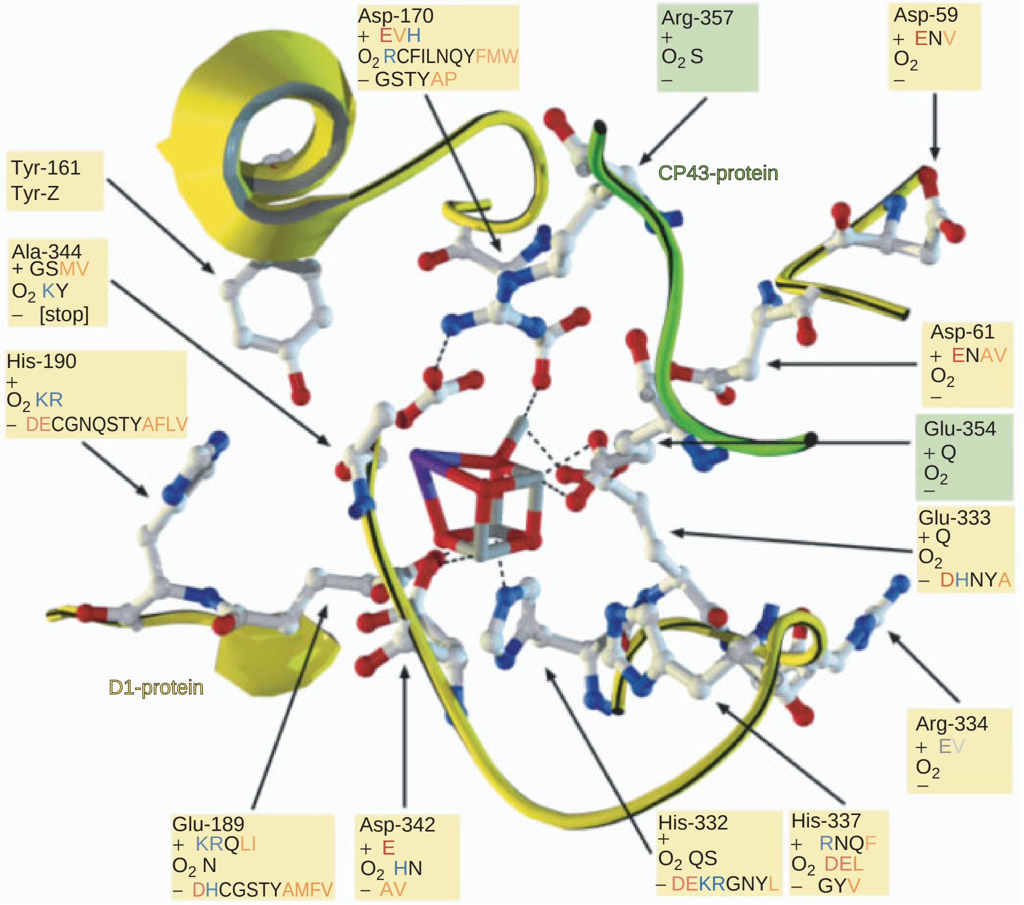

Figure 5 Consequences of point mutations in D1 (yellow) and CP43 (green). In the boxes, the first line (+) indicates amino acids mutations that support photoautotrophic growth (light + CO_2) and evolve O_2. The second line (O_2) indicates mutants that do not grow photoautotrophically but retain an initial O_2 evolution rate when grown heterotrophically (≥5% vs. the wild-type strain). The third line (−) indicates lethal mutants that do not grow photoautotrophically, have no O_2 evolution activity, and in some cases no photooxidizable Mn. Amino acid color coding: acidic (red), basic (blue), hydrophobic (brown)

The primary aims of mutagenesis are to identify those amino acid residues that control the assembly and functioning of the $Mn_4Ca_1O_x$ cluster and the reactivity of D1Tyr_Z161.

Mutagenesis studies have identified three domains of the D1 protein implicated in assembly of a stable WOC or expression of O_2 evolution activity. In D1 these domains are the carboxyl terminus, the interhelical CD lumenal loop, and residues in the interhelical AB lumenal loop. These loci agree with the amino acid sites identified by XRD.

Within the carboxyl-terminus of D1, multiple residues play a role in stabilizing the WOC by interaction with one or more of the three internal Mn ions of the $Mn_3Ca_1O_x$-cube. Studies have been performed on D1Ala244, D1Asp342, D1His332, D1His337, D1Arg334, and D1Glu333, of which Asp342, His332, and Glu333 ligate the $Mn_4Ca_1O_x$-cluster according to the crystal structure (see Figure 5). There is solid evidence from pulsed EPR studies and FTIR for one histidine ligand to the $Mn_4Ca_1O_x$ cluster which may correspond to D1His332. Most mutants of the ligating amino acid residues do not grow photoautotrophically and possess diminished oxygen evolution rates. Although the Ala344 is not ligating manganese (Reanalysis of the 3.6 A XRD data[30] has shown that two oxos at the corners of the Mn_3CaO_4 cubane-like core (O_1 and O_3, Figure 4) interact by hydrogen bonding to carboxylate residues (D1-Glu189 and D1-Ala 344-C-terminus). These oxos exhibit bonding interactions consistent with identification as water molecules. Mutagenesis studies are consistent with these carboxylate residues serving in proton pathways for substrate water deprotonation. On this basis and other evidence, the O_1 and O_3 corner sites have been proposed as the substrate water oxidation sites[30]), there is a requirement for the presence of an amino acid residue at this position.

The interhelical CD lumenal loop contains the Tyr_Z (D1Tyr161), probably hydrogen bonded to D1His190. It contains the D1Asp170 residue which ligates the high affinity Mn (exocubical Mn). Mutagenesis on this important residue shows that Glu, His, and even Val mutants grow photoautotrophically, while 11 other mutants show at least some oxygen evolution, albeit only when grown heterotrophically on glucose. The latter mutants fail to grow photoautotrophically apparently due to photoinactivation of the WOC. It was concluded from EPR measurements that Asp170 ligates the high affinity Mn site, as the binding and/or photooxidation of Mn(II) was altered in mutants at that site. Remarkably, some positively charged, polar, and hydrophobic mutants of D1Glu189, which is a ligand of the $Mn_4Ca_1O_x$ cluster, show photoautotrophic growth. An hypothesis is that mutants at this residue are involved in a network of hydrogen bonds, possibly in which additional bicarbonate or chloride ions might compensate for loss of the carboxylate charge in some mutants.

According to mutagenesis studies, the amino acid residues in the interhelical AB lumenal loop are involved in coordination of the Ca^{2+}, especially D1Asp59 and D1Asp61. The crystal structure does not yield evidence for direct binding of these residues to Ca. All examined mutants at these positions exhibit an elevated requirement for Ca^{2+} and show photoautotrophic growth. The mutagenesis and XRD results appear inconsistent but may not be. Since the Ca^{2+} binding assays used with the mutants are actually O_2 evolution assays performed in the presence of Mn, these assays reflect the cooperative binding between the high affinity Mn and Ca sites during assembly.[12]

Mutagenesis studies have examined the CP43 protein. First segment deletion studies were conducted, followed by site-directed mutagenesis. The point mutant, Glu354Gln, exhibits reduced photoautotrophic growth rate, although normal PSII content (e.g. no photoinactivation) and an 80% reduction in the O_2 evolution rate due to a specific impairment to the WOC.[31] The Arg357Ser mutant is the only available mutant at this site. It is unable to grow photoautotrophically, but does grow heterotrophically on glucose. It accumulates a normal amount of PSII core proteins, but these exhibit low electron-transfer rates, weak O_2 evolution activity (10%) and strong photoinactivation kinetics (fourfold).[32] These results clearly show an important role that both of these residues play in water-splitting chemistry, as would be expected by the XRD structure (Figure 4).

Mutagenesis studies together with the emerging PSII XRD structures at higher resolution offer future opportunities for detailed mechanistic insight at the molecular level in the coming years.

6 Mn OXIDATION STATES AND ELECTRONIC (SPIN) STATES

The electronic states of the $Mn_4Ca_1O_x$ cluster, for example, the spatial distributions and energies of the electrons in the various S-states are vital to understanding water-splitting chemistry. Tools such as electron paramagnetic resonance (EPR) and X-ray absorption spectroscopies (XAS) have been indispensable to characterize both the redox chemistry of PSII-WOCs and the atomic structure of the inorganic core. Historically, EPR provided the first experiments to identify an electronically coupled Mn cluster at the catalytic site. Shortly thereafter, spectral simulations of the extensive ^{55}Mn hyperfine structure in the S_2 oxidation state indicated electronic coupling of 4Mn ions (Mn^{3+} and Mn^{4+} oxidation states) in a low-spin ground state ($S = 1/2$). EPR signals are now available for four of the five S-states and each in multiple perturbed forms.[22,33–36] An important conclusion is that all of the S-states are formed in low-spin ground electronic states in native (unperturbed) PSII-WOC complexes (Table 2).[22] This conclusion comes from measurements of the electronic Zeeman g−factor and zero-field splittings (for $S > 1/2$). The ^{55}Mn hyperfine structure (magnetic and quadrupole tensors) has given a detailed description of how the unpaired spin density is distributed among the four Mn ions in the S_2 state.

Table 2 Electronic spin states (Zeeman g factors): S ($g_{\text{effective}}$) and changes in the room temperature magnetic susceptibility ($\Delta\chi$) upon advances in oxidation states of the spinach WOC induced by single turnover flashes in PSII complexes. *Syn.* denotes *Synechocystis* 6803[a]

	S_0	S_1	S_2	S_3
S (g_{eff}) ground first excited	1/2 ($g = 2$)	0 ≥ 1 integer ($g = 4.8$ spinach $g = 12$ *syn*)	1/2 ($g = 2$) 5/2 ($g = 4.1$)[a] 7/2 ($g = 10, 6$)[a]	0 ≥ 1 integer ($g = 12, 8, 6.7$)
$S_i \rightarrow S_{i+1} \Delta\chi$ (μ_B^2)	∼0	+ (14–17)	∼0	+10 (8 from O_2)

[a]The S = 5/2 and 7/2 spin states become ground states in modified samples.

The resulting spin densities are compatible with a limited set of cluster geometries and Mn oxidation states.

The lowest spin configuration occurs when all 4 paramagnetic Mn ions are coupled by pairwise antiferromagnetic interactions via bridging ligands, corresponding to favorable bonding interactions between the Mn electrons. In addition, low-lying excited electronic states are found to be thermally populated, as revealed by both EPR and magnetic susceptibility measurements in all S-states.

Additionally, the S_2 state (and probably others) can be produced in different ground states having discrete spin values S = 1/2, 5/2 or 7/2, depending upon how it is prepared from the S_1 state. For example, lower temperature illumination favors the S = 5/2 state, while NH_3 inhibition involves binding to a site between Mn ions that forms a different S = 1/2 state characterized by a redistribution of spin densities. Near-IR illumination of Mn^{3+} electronic transition forms an excited state that relaxes to a new ground state either an S = 5/2 or 7/2 state. These conditions change the ordering in energy of these discrete electronic spin states by changing the relative strength or number of intermanganese couplings and by changing the Mn d^n electronic configuration. The former is mediated by the bridging ligands while the latter is determined by the ligand field strength and symmetry. This flexibility of the electronic states does not happen in binuclear clusters or in higher nuclearity clusters that possess only nearest neighbor spins (e.g. linear). Hence, the Mn ions in the Mn_4O_x core are arranged with bridges between more than one other Mn ion. These competing pathways orient the Mn spins such that both low- and intermediate-spin configurations can be produced by modest changes to the intermanganese couplings. This phenomenon is called spin frustration. There are only 8 possible Mn_4O_x geometries which can account for the multiple spin configurations observed for the S_0 through S_3 oxidation states. Three of these cores are depicted in Figure 6. Topologically, they may be called funnel (4), cubane (12), and open cubane (13).

Among these 8Mn_4O_x core types, only those that produce the same distribution of unpaired electron spin density need to be considered further as structural models of the WOC. This distribution can be obtained from the ^{55}Mn hyperfine structure observable in EPR and ENDOR measurements of the S_0, S_1, and S_2 states.[22,34] A simple ionic model to predict the Mn spin densities has worked well in simulating the ^{55}Mn hyperfine structure, but not all 8 possible topologies have been fully investigated yet. The S_1 state EPR signal exhibits ^{55}Mn hyperfine structure with 21 lines separated by one observable hyperfine constant and a binomial pattern of intensities consistent with 4 magnetically equivalent ^{55}Mn ions (I = 5/2).[34] This indicates an approximately uniform spin density on all 4Mn ions and thus a single Mn oxidation state is indicated.

The native S_2 state EPR signal (ground spin S = 1/2) illustrates a more asymmetric distribution of spin densities. Assuming the Mn oxidation states are Mn_4(3III,IV) the deduced spin densities that simulate the EPR spectrum are given in Figure 7 (ionic model). This is illustrated using a $Mn_4O_2(OH)_2$ cubane-type model, although other spin-frustrated topologies like the open cubane core (13) in Figure 6 are also suitable. Future EPR simulations should examine the open cubane core (13) and the influence of Ca^{2+} on

(μ_2-oxo)$_4$(μ_2-hydroxo)$_2$ (μ_3-oxo)$_2$(μ_3-x,y)$_2$ (μ_3-oxo)$_2$(μ_2-oxo)$_2$

Figure 6 Three of the eight possible Mn_4O_x core topologies that could give rise to the observed spin states[22]

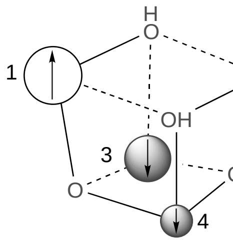

Figure 7 Unpaired spin density distribution on the four Mn ions in the native S_2 state (total spin S = 1/2). The size of the spheres reflect the spin densities: 5/3, 5/3, −4/3, −1. The two shades of sphere indicates + and − spin density. A distorted $Mn_4O_2(OH)_2$ cubane core was postulated

spin densities. A higher oxidation state Mn_4(III,3IV) has been proposed for the S_2 state based upon XAS and some EPR experiments, so that the question of Mn oxidation states remains unresolved. A good summary of the debated interpretations can be found in the following articles.[22,34]

Changes in the room temperature magnetic susceptibility upon photooxidation between S-states (Table 2) reveals that the third photooxidation step, for example, $S_3 \rightarrow S_0$, yields a large increase equal to 10 squared Bohr magnetons ($\mu_\beta{}^2$), comprising $8\mu_\beta{}^2$ owing to the O_2 product (proved by use of glucose oxidase trap) and $2\mu_\beta{}^2$ from reduction of the Mn_4 cluster. The O_2 product is therefore formed in the S = 1 (ground) triplet spin configuration ($\mu_{\text{eff}}{}^2 = 4S(S+1)$ for spin-only magnetism), as was anticipated based on thermodynamic predictions. The second and fourth photooxidation steps produce small or no change in $\Delta\chi$, while the first photooxidation step which converts the resting S_1 state to S_2 has a very large increase equal to $14{-}17\mu_\beta{}^2$. This large increase for S_1(resting) $\rightarrow S_2$ is not cyclic on the second turnover of S_1 and reflects the larger $\Delta\chi$ increase seen when the S_1 state is dark adapted for 15 minutes or longer prior to illumination. Hence, the active S_1 conformation which cycles during continuous O_2 production possesses considerably weaker antiferromagnetic couplings between some of the Mn spins. Studies of Mn_xO_y clusters reveals that ferromagnetic intermanganese pairings are not found between Mn ions in mono- and di-μ_2-oxo bridged Mn^{2+}, Mn^{3+} and Mn^{4+} complexes (dimers), but are observed in μ_3-oxo and μ_4-oxo bridged clusters where three or four Mn ions compete for spin alignment, respectively. These additional couplings produce spin frustration within the trinuclear and tetranuclear Mn-clusters causing a greater density of low-lying electronic spin states and an increase in χ. The very large increase in χ on the S_1(resting) $\rightarrow S_2$ step reflects conversion of a less frustrated, relaxed, $Mn_4Ca_1O_x$ topology to a more frustrated spin topology (exhibiting an increase in the number of Mn-μ-oxo bonds or a more equitable distribution of exchange couplings between the existing Mn-μ-oxo bonds.). Model compounds have shown that a plausible chemical process that could produce such a large increase in χ is the formation a μ_3-hydroxo/oxo bridge between three Mn ions, as occurs upon deprotonation of an aquo/hydroxo ligand.

7 ENERGETICS OF S-STATE TRANSITIONS: FREE ENERGY AND ACTIVATION ENERGY BARRIERS

The kinetics and thermodynamics of individual steps in the catalytic S-state cycle have been measured by time-resolved UV-absorption changes of Mn and lead to the picture shown in Figure 8 and Table 1.[13,37] The half-lives for reduction of the Tyr_Z radical ($Y_z{}^\bullet$) by the Mn cluster after flash excitation in the first three steps ($S_iY_z{}^\bullet \rightarrow S_{i+1}Y_z$; $i = 0,1,2$) are in the range of 30–50 µs, whereas the last step ($S_3Y_z{}^\bullet \rightarrow S_0Y_z + O_2$) is rate-limiting with a half-life for S_3 of 1 ms (Table 1). The H/D kinetic isotope effects using D_2O as substrate have been measured by three different groups and fall in the range for all four steps k_H/k_D = 1.3–1.4, 1.3–2.9, and 1.5–2.3.[38,39] The UV and near-IR spectral changes during S-state cycling have been attributed to oxidation of high-spin Mn(III) ions.[35]

The thermodynamic driving force (ΔG) for each of the S-state transitions has been estimated from measurements of the temperature-dependent equilibrium constants for the light-induced transient intermediate states: $P680^+/Y_z$ and $Y_z{}^\bullet$/WOC(Mn).[39] These values were then placed on

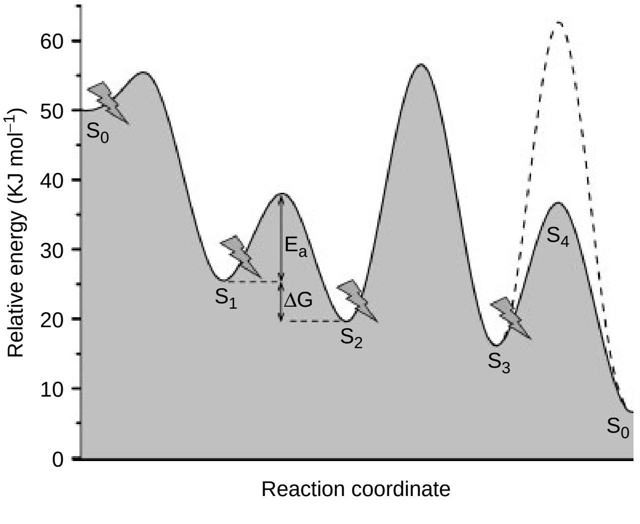

Figure 8 The free-energy changes of the S-state intermediates and their transition states: the reactions $S_iY_z{}^\bullet \rightarrow S_{i+1}Y_z (i = 0{-}2)$ and $S_3Y_z{}^\bullet \rightarrow S_0Y_z + O_2$ for spinach PSII membrane fragments measured at room temperature. The dashed line indicates a higher energy transition state that exists for $S_3Y_z^\bullet \rightarrow S_0Y_z + O_2$ when measured at T < 279 K. E_a = Arrhenius activation energy; ΔG = calculated net free energy change on each turnover. The constant energy offset for the cycle ($\Delta G = 42.9\,kJ\,mol^{-1}$) reflects the combined effects of oxidation $Y_z \rightarrow Y_z{}^\bullet$ and conversion of dark-adapted (resting) S_0 to active S_0-states

an absolute free energy scale using an estimated value for the P680$^+$/P680 reduction potential. The free energies vary between approximately $-4\,\mathrm{kJ\,mol^{-1}}$ and $-24\,\mathrm{kJ\,mol^{-1}}$ (Figure 8). Also shown are the corresponding experimental activation energies which vary between $+5\,\mathrm{kJ\,mol^{-1}}$ and $+36\,\mathrm{kJ\,mol^{-1}}$.[39] The highest activation barrier is found for the S_2 to S_3 step and was interpreted (together with EXAFS data) as evidence for a structural rearrangement of the Mn cluster which increases the intermanganese distances in two Mn_2 pairs by 0.1–0.15 Å.

8 SUBSTRATE BINDING, EXCHANGE, AND MECHANISM OF O_2 EVOLUTION

^{1}H/^{2}H-ENDOR and ESEEM methods have provided good evidence for water molecules in the active site.[40–42] Two exchangeable protons located at 2.5 Å have been assigned to a water molecule directly bound to a Mn ion in the native S_2 state.[42] A second pair of exchangeable protons lacking scalar hyperfine coupling but with large dipolar coupling is located at 2.7 Å from the nearest spin density center (Mn).[42] The latter water site is unlikely to be on Mn and has been suggested to represent water bound to the Ca^{2+} site. Both sites are located in an aqueous-like environment with additional exchangeable protons attributed to water molecules in the next coordination shell. The assignment of these water ligands as substrate molecules although plausible is speculative.

An alternative approach to characterize the chemical environment of the substrate water molecules is by the rate at which they exchange with bulk water. This experiment has been conducted using rapid-mixing mass spectrometry to measure the isotopic composition of the O_2 product following injection of ^{18}O-water in each S state.[17] Table 1 gives the rate constants for the two exponential kinetic phases that are present in the data. These phases have been attributed to two substrates sites that exchange with bulk water at slow and fast rates. The first conclusion is that there is no evidence for nonexchangeable substrate sites; for example, no irreversible step occurs that is not in equilibrium with bulk water. The authors interpret the rate data as evidence that the slow substrate water is bound to a Mn(III) site in all S-states, while the fast exchange site is unlikely to involve coordination to Mn prior to the S_3 state.

The large (100-fold) decrease in the exchange rate at the slow substrate site in the S_1 state and recovery in S_2 has not been satisfactorily explained, but should prove important in sorting out the correct mechanism. One hypothesis is that the slow exchanging substrate site may help to protect PSII against disassembly of the inorganic core caused by reduction of the S_1 core by diffusible reductants that are present in the cell or chloroplast (H_2O_2, ascorbate, glutathione). Mano *et al*. showed that the reaction of PSII membranes in the S_1 state with H_2O_2 is 100x slower than either the S_2 or S_0 states (catalase activity of PSII) suggesting that the H_2O_2 binding site (catalase dismutation) and the slow substrate site are the same site or are in rapid equilibrium.[12] Both of these sites were found to be distinct from the functional chloride site.

The most recent mass spectrometry data using Sr to replace Ca suggests that the fast exchanging substrate site may involve interaction with Ca.[18] This interpretation agrees with ^{1}H/^{2}H-ENDOR and ESEEM results showing that two water molecules are bound, one to a Mn site and the other to a nonmagnetic site postulated to be Ca.[42]

There has been wide debate about whether the kinetic data for S-state transitions discussed in Section 6 are evidence for concerted H atom transfer or proton-coupled electron transfer (pcet) involving more weakly coupled sites for the proton and electron. The small H/D kinetic isotope effect (KIE) for the S-state transitions (as little as 1.3–1.4) indicates little displacement of the H atom coordinates in the transition state. The 6.5 Å distance between the phenol oxygen of Tyr_Z and the nearest Mn ion observed in the XRD structure of PSII-WOC essentially eliminates a direct concerted H atom transfer mechanism, as the distance is too far for tunneling of H atoms. This has led to two pcet models for the S-state transitions that enable the longer-range, delocalized, electron-transfer pathway to be thermodynamically coupled to the shorter range proton transfer pathway of the reaction.[14,24,28] The first model involves oxidation of the $Mn_4Ca_1O_x$ cluster (molecular orbitals localized thereon) that is coupled to the ionization of substrate protons. The Tyr_Z radical is both the electron and proton acceptor in one view (phenol oxygen proton site). Another view argues that these functions are separated, such that the proton is delivered to other auxiliary proton carriers (water, bicarbonate, amino acids (Reanalysis of the 3.6 A XRD data[30] has shown that two oxos at the corners of the Mn_3CaO_4 cubane-like core (O_1 and O_3, Figure 4) interact by hydrogen bonding to carboxylate residues (D1-Glu189 and D1-Ala 344-C-terminus). These oxos exhibit bonding interactions consistent with identification as water molecules. Mutagenesis studies are consistent with these carboxylate residues serving in proton pathways for substrate water deprotonation. On this basis and other evidence, the O_1 and O_3 corner sites have been proposed as the substrate water oxidation sites[30])) in a distributed hydrogen-bonded network eventually reaching the aqueous lumen. In both cases, the reduction of the Tyr_Z radical is coupled to its protonation, either by a substrate proton or an alternative proton donor, likely D1His190.

No direct evidence for Mn(V) or peroxide-like intermediates have been observed yet in any native S_i state. However, release of hydrogen peroxide occurs in a modified S_2 state formed under a variety of conditions (removal of Cl^-, replacement of Cl^- by F^- and solubilization with lauryl choline chloride)(reviewed in[12]). These results show that the driving force for HO–OH bond formation already exists at the modified S_2 oxidation level.

There is little experimental information about the O–O bond formation step in the native S_4 state. Two general

mechanisms for the O–O bond formation step have been postulated (Figure 9), although definitive evidence to distinguish these possibilities or others is still lacking. The first mechanism (Figure 9(a)), involves homolytic intramolecular bond formation from two bridging substrate oxygen atoms in the $Mn_4Ca_1O_4$ core. In this mechanism the O=O bond enthalpy must contribute to overcoming the favorable Mn–O bond enthalpy in the transition state for reaction to occur. There is definitive experimental proof that this reaction coordinate is thermodynamically possible in symmetrical $Mn_4O_4^{6+}$ cubane clusters because they have long (e.g. weak) Mn–O bonds, but not in simpler $Mn_2O_2^{2+/3+/4+}$ cores which have much shorter (e.g. stronger) Mn–O bonds (see final section).[43]

A heterolytic pathway, Figure 9(b), has been proposed which involves attack by a nucleophilic OH^-, possibly generated by ionization of water bound to Ca^{2+}, at an electrophilic oxygen atom. The latter oxygen atom has been attributed to either a putative Mn(V)=O 'manganyl oxo' intermediate as envisioned in Figure 9(b),[44] or a bridging oxyl radical (μ_2-O$^\bullet$).[45] The latter proposal is supported by electron structure calculations showing that bridging μ_2-oxos can be sufficiently electron deficient in special Mn_xO_y topologies that nucleophillic attack may be possible by OH^-.[45]

Bicarbonate influences the activity of electron donation from Mn^{2+} to apo-WOC-PSII complexes depleted of manganese.[46] Photoactivation data show that bicarbonate interacts with the high affinity Mn^{2+} and stabilizes the photooxidized Mn^{3+} product during assembly of the WOC. These data and the hypothesis from XRD allowing the presence of bicarbonate as a core ligand in the holoenzyme (Figure 4) open up interesting new mechanistic possibilities to consider.

An alternative heterolytic pathway shown in Figure 10(a) can be envisioned based on the XRD evidence suggesting a μ_4-oxo (Figure 4). The μ_4-oxo will be electron-deficient and thus forms a potentially reactive site for O–O bond formation with a nucleophilic oxyanion. Here we postulate that the carbonate ion in the active site attached to Ca, Mn, and Arg357 residue serves as the nucleophile by forming peroxycarbonate, transiently as a bound intermediate that decays to the O_2 product. This proposal is supported by the occurrence of carbonates as nucleophiles in organic hydration reactions and the formation of peroxycarbonate as metastable intermediate in carbonate chemistry.[47] Unlike pathway Figure 9(b), which must form the Mn(V) oxidation state in order to form an electrophilic manganyl oxo complex, pathway Figure 10(a) produces a highly activated μ_4-O at the Mn(IV) level.

An alternative homolytic pathway shown in Figure 10(b) can also be envisioned in which intramolecular O–O bond formation occurs between the electrophillic μ_4-oxo and a transient nucleophilic μ_2-oxo released from Ca upon rearrangement of the carbonate ligand from monodentate to bidentate coordination. The figure shows the anticipated

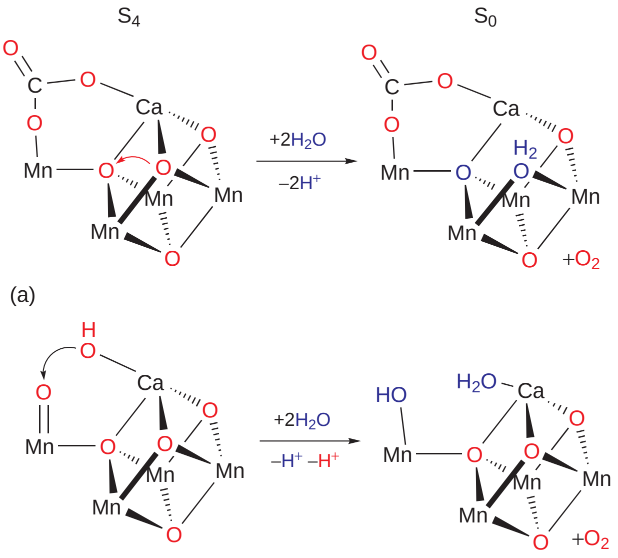

Figure 9 Two general mechanisms postulated for O–O bond formation. (a) involves homolytic intramolecular bond formation from two bridging substrate oxygen atoms, while (b) involves a nucleophilic attack at a an electrophilic oxygen atom

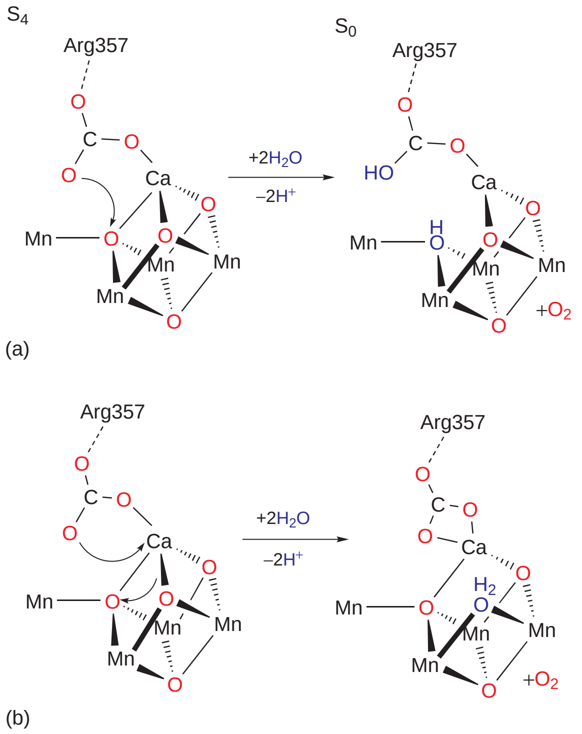

Figure 10 Two alternative hypothesized mechanisms for formation and release of oxygen in the $S_4 \rightarrow S_0$ step, incorporating hints yielded by the emerging crystal structures at higher resolution. (a) shows a heterolytic mechanism in which the electron-deficient μ_4-oxo acts as an electrophile, while (b) shows a mechanism involving the Ca^{2+} ion leading to the formation of a peroxo-intermediate

bond isomerization sequence leading to a transient peroxo-intermediate that decays to the O_2 product. In both of the mechanisms depicted in Figure 10(a) and (b), the Ca^{2+} participates directly in the O–O bond formation step. This key feature is in agreement with the experimental data on O_2 release in inorganic mutants replacing Ca^{2+} with Sr^{2+} (Reference 48).

With the rapid advances in knowledge that are taking place in the chemical basis of PSII catalysis, there will surely be exciting times ahead in sorting out these proposals for the mechanism of water oxidation.

9 WHY MANGANESE? INORGANIC MUTANTS

Several factors may have conspired to make manganese the universal metal for catalyzing water splitting in all oxygenic phototrophs. Transition metals are the clear winners versus main group atoms at storing/delivering large units of energy in the form of redox reactions, for example, atom transfer reactions, in contrast to acid-base chemistry and ion concentration gradients. This preference arises because transition metals store and deliver energy in the form of both charge (the number of electrons) and bond strengths (potential and kinetic energy of electrons and nuclei). Their versatility originates from the greater number and smaller energy spacing of their valence d orbitals which facilitates matching with substrate orbitals for maximal bond strength and accommodates a wider range of geometries. A direct consequence is that the geometrical constraints can be relaxed in cases where the redox changes involve nonbonding d orbitals. For the same reasons, the activ ation barriers between redox states in multistep catalysis are usually lower.

Phototrophs take up Mn^{2+} but use it in the WOC in the Mn^{3+} and Mn^{4+} oxidation states. Mn^{2+} is highly soluble, has weak or modest affinity for simple ligands, speciates as the simple aquo cation in water over a wide pH range and is readily transported into cells by a variety of redundant transport systems. Mn^{2+} is chemically stable in neutral solutions. It auto-oxidizes in O_2 saturated solutions only above pH 9.5 where most phototrophs do not function, or at ambient pH only if exceptionally strong chelates are accessible to stabilize the resulting Mn^{3+} (e.g. pyrophosphate^{4-}). Hence, there is usually no need for chaperone proteins in the cell to deliver Mn^{2+} or to protect the cellular matrix from auto-oxidation. Mn chaperones have not been identified (yet) for assembly of the WOC during biogenesis. What a great savings in energy and complexity for the primitive phototroph that first used Mn^{2+} over other more abundant redox metals (Fe^{2+}) in the anaerobic world when oxygenic photosynthesis was invented. The redox potential for oxidizing Mn^{2+} (aq) $\rightarrow$ Mn^{3+} (aq) $E^0 = 1.3\,V$ closely matches the redox potential of Chl-a, unlike the majority of other soluble transition ions. Thus, the biogenesis of Chl-a in phototrophs enabled the photooxidation of Mn^{2+} to occur on the surface of Chl-a proteins. The resulting Mn^{3+} binds more tightly by ca. $10^{12}-10^{15}$ and thus would be long-lived at the protein site. Importantly, loss of the redox energy by charge recombination is greatly slowed owing to the energy released upon dissociation of a proton to form $[Mn^{III}(OH^-)]^{2+}$ ($pK_a = 0$). Energetically downhill direct electron-hole recombination without reprotonation is also greatly slowed owing to the unusually large vibronic distortion that Mn^{3+} typically produces with its ligand environment (e.g. 1 eV barrier for pseudorotation of the Jahn–Teller axes in $MnF_6{}^{3-}$). The photooxidation of a second Mn^{2+} is catalyzed by formation of the first $Mn(OH)^{2+}$ photoproduct, as the OH^- can serve as a better ligand than water to template the binding of the next Mn^{2+}. The efficiency of this assembly process increases in the presence of bicarbonate which is a surrogate for hydroxide and can exist in neutral pH solutions at concentrations several orders of magnitude higher than hydroxide.

These properties of aqueous Mn redox chemistry are all utilized during the light-driven biogenesis of the $Mn_4Ca_1O_x$ core from the free inorganic cofactors and apo-WOC-PSII. Measurements of the kinetics of reconstitution of O_2 evolution activity and proton release during this photoactivation process have resolved three kinetic intermediates:[49] first $Mn^{II}(OH^-)$ or $Mn^{II}(HCO_3{}^-)$ binds to the high affinity Mn site, involving D1Asp170, followed by a slow (rate-limiting) dark step in which a proton is ejected and the affinity of Ca^{2+} increases substantially. This step is hypothesized to involve a conformational change of the D1 protein (carboxyl terminus or AB loop movement). It is followed by cooperative binding of 3 additional Mn^{2+} and photooxidation steps in rapid succession that are not resolved kinetically. This $1 + 3Mn^{2+}$ sequence and positive cooperativity in Ca^{2+} uptake after the first Mn^{2+} photooxidation step fits well with the XRD structural data. Bicarbonate was shown to specifically increase the affinity of Mn^{2+} at the high affinity site by stabilizing the photooxidized Mn^{3+} state. A second higher affinity bicarbonate site was found that stimulates the rate of photoactivation and was attributed to electrostatic attraction of Mn^{2+} caused by ionization of protein residues or ion-pairing between carbonate and arginine.

A nearly constant yield and rate of photoactivation is found over a 200-fold range in concentrations of Mn^{2+} and Ca^{2+}, provided the ratio is kept nearly constant at about 500 Ca/1Mn. If Ca^{2+} is left out of the solution, binding and photooxidation of many more Mn^{2+} occurs to the apo-WOC-PSII protein and no O_2 evolution activity is observable. Ca^{2+} can be replaced by Sr^{2+} and actually accelerates the assembly process by 4-fold,[12] but the O_2 evolution rate is reduced to 40%, apparently due to a slower terminal step $S_3 \rightarrow S_0 + O_2$.[48] It can be concluded that Ca^{2+} is specifically involved in the O–O bond formation step.

No functional replacement for manganese during the photoactivation process has been found to be effective (yet).

Several 3d, 4d, and 5d transition ions were tried, all at fixed pH (6) and fixed concentration without success.[12] It appears that manganese may be truly unique for biological water splitting.

10 FUNCTIONAL MANGANESE COMPLEXES THAT SPLIT WATER

There have been a large number of examples of Mn-oxo complexes that have contributed important insights to understanding the structure and function of the $Mn_4Ca_1O_x$ core.[43,50,51] However, only three systems have been shown to produce O_2 and will be highlighted here.

10.1 The Dimanganese(III,III)porhyrin Complex

The dimanganese(III,III)porphyrin complex (**1**) depicted in Figure 11 was shown to catalyze the anodic oxidation of water at low conversion (≤8 turnovers). The mechanism appears to proceed by formation of a $[Mn(V)=O]_2$ intermediate (**2**) which has recently been isolated by chemical oxidation with *m*-chloroperoxybenzoic acid (Figure 11). Subsequent acidification of (**2**) yields O_2 in a stoichiometric reaction that does not occur with the corresponding mono-manganese(V) porphyrin, nor with the corresponding $[Mn(IV)]_2$ dimer species. Two mechanisms were considered based on H/D-water isotopic labeling studies and the observation that the acidified intermediate also converts Cl^- to OCl^- quantitatively. The postulated active intermediate is $[H_2O–Mn(V)=O]_2$. This species may produce O_2 either by intramolecular coupling of the oxo groups, or by $[H_2O–Mn(V)=O]$ reaction with free water. The latter reaction could not be excluded, as the oxo in (**2**) exchanges with water rapidly. This chemistry suggests that the homolytic coupling of two electrophilic oxos is an observable pathway for O–O bond formation with strong π-acceptor porphyrin ligands. Geometrical constraints on the intermanganese distance and orientation imposed by the covalent bridge linking the porphyrin ligands were found important for O_2 formation in earlier work, further implicating a homolytic intramolecular pathway is observed.

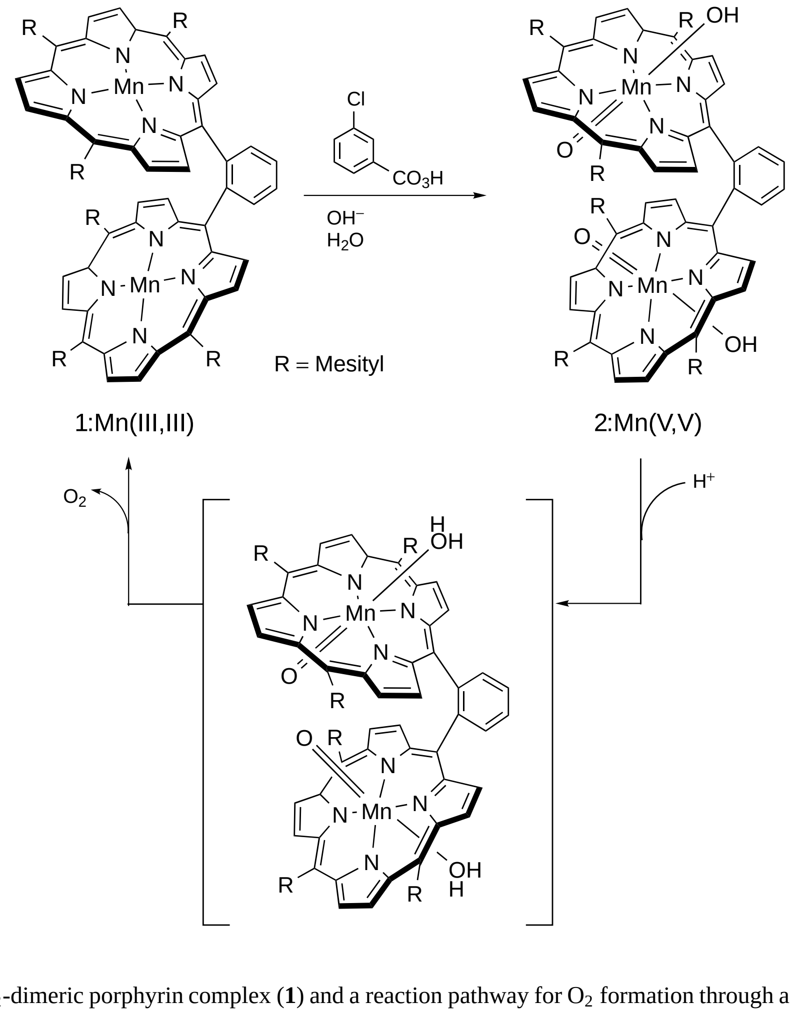

Figure 11 Structure of Mn_2-dimeric porphyrin complex (**1**) and a reaction pathway for O_2 formation through a dimanganyl (V,V) species (**2**)

10.2 Dimanganese(IV,V) Oxo Complexes

Although several examples of complexes containing the $[Mn_2O_2]^{n+}$ core type have been studied, only one has been found to catalyze O_2 evolution in water. The complex $[(terpy)(H_2O)Mn^{III}(\mu\text{-}O)_2Mn^{IV}(OH_2)(terpy)]^{3+}$ contains the tridentate terpyridine ligand that coordinates to three meridional sites on Mn and thus positions the two terminal aquo ligands trans to the μ-oxo bridges. The oxidation of this complex by SO_5^{2-} or OCl^- in water was shown to produce O_2 and permanganate.[52] Steady-state saturation kinetics were observed indicating the formation of an intermediate suggested to be a 1:1 precursor complex that decays to form a postulated manganyl intermediate $(H_2O)Mn^{III}(\mu\text{-}O)_2Mn^V{=}O$ that was not directly observed. The yields of labeled O_2 products were measured using ^{18}O-water by mass spectrometry. The authors show on the basis of the $m/z = 32$, 34, and 36 products that the oxidant SO_5^{2-} is directly responsible for forming O_2 by reacting with the kinetic intermediate which also reforms the starting catalyst $(H_2O)Mn^{III}(\mu\text{-}O)_2Mn^{IV}(OH_2)$. The yield of the m/z 34 and 36 products is argued to favor a second pathway in which (labelled) water or hydroxide is proposed to attack the kinetic intermediate to produce O_2 and a reduced $Mn^{II}Mn^{III}$ intermediate. The latter product is then recycled by reacting with excess oxidant to reform the original catalyst. This mechanism has been offered as indirect evidence for the possible presence of an analogous $Mn^V{=}O$ intermediate in PSII and for a heterolytic pathway for O–O bond formation. Additional evidence to identify the source of the m/z 34 and 36 products would be very helpful. The possibility of rapid exchange of oxygen atoms between water, the putative manganyl oxo and eventually into SO_5^{2-} could also explain the

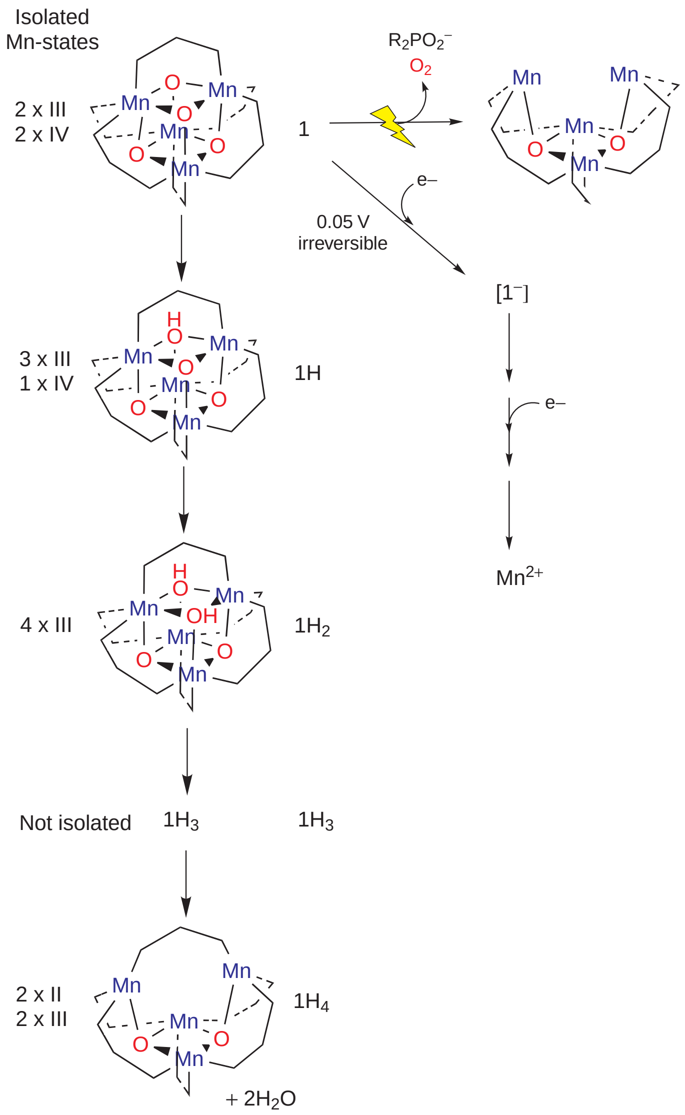

Figure 12 O_2 and water formation from $Mn_4O_4(Ph_2PO_2)_6$ complexes

isotope distribution of the O_2 product without invoking any water oxidation chemistry. The former exchange rate has been shown to be very rapid ($\sim$100 s^{-1}) in the case of the porphyrin class of $Mn^V{=}O$. Also, direct evidence to identify the formation of the manganyl intermediate and the use of innocent oxidants that do not deliver active oxygen atoms would also be very helpful in establishing the relevance of this chemistry to PSII-WOC. Recent studies using this same complex did not find evidence for the formation of O_2 in solution, but did find evidence that the complex forms a catalyst capable of low efficiency water splitting if adsorbed onto clays.[53] The active catalyst that produced O_2 was shown to involve two equivalents of the adsorbed dimanganese complex (e.g. 4Mn equiv.).

10.3 Mn_4O_4-Cubane-to-Mn_4O_2-Butterfly

A cubane/butterfly core rearrangement, represented by core type 12 (Figure 6), was proposed in an early hypothesis for the photosynthetic O_2 evolution step. The feasibility of this rearrangement has been demonstrated in a model cluster, as summarized in Figure 12.[26] The molecule $Mn_4O_4(Ph_2PO_2)_6$ can be synthesized from simple monomeric precursors (Mn^{2+} and MnO_4^-) in the presence of phosphinate anions which have long O–O' chelate distance that bridges between Mn ions. It contains a rare example of the symmetrical $[Mn_4O_4]^{6+}$ cubane core in the formal oxidation state Mn_4(2III, 2IV). The $[Mn_4O_4]^{6+}$ core has longer Mn–O bonds (by 0.15–0.2 Å) than the isoelectronic $[Mn_2O_2]^{3+}$ core complexes. By changing the type of phosphinate ligand, the core geometry changes from tetrahedral with equivalent Mn ions to C_2 with distinct Mn(IV) and Mn(III) sites.[54] Importantly, UV light absorption into a Mn–O charge transfer band efficiently releases an O_2 molecule in the gas phase together with one of the phosphinate chelates, leaving the intact cationic species $[Mn_4O_2(Ph_2PO_2)_5]^+$ (Mn_4O_2-butterfly core). This reaction proceeds with high quantum efficiency (>90%), is the only observable reaction channel (other than decay to the ground state), and is selective to the cubane core type (i.e. not observed for Mn_2O_2, Mn_2O, or Mn_3O_4 core complexes).[43] By comparing the isotopomers synthesized with $[Mn_4(^{18}O)_4]^{6+}$ and $[Mn_4(^{16}O)_4]^{6+}$ cores, the mechanism of O_2 formation was shown to proceed via intramolecular coupling of corner oxos. This chemistry illustrates that the cubane topology is intrinsically poised toward O_2 formation, in contrast to the $[Mn_2O_2]^{3+/4+}$ core complexes which do not release O_2 from the μ-oxos.

The mechanism of O–O bond formation has been supported by density functional calculations which show that, following removal of a phosphinate chelate, the resulting core is unstable towards O_2 release via a thermal pathway involving out of plane displacement of the oxygen atoms. This degree of freedom permits the oxygen atoms to approach one another in the transition state (ca 23–30 kcal mol^{-1}) in route to forming a peroxo-intermediate and O_2 release (F. De Angelis, R. Car, unpublished data). This appreciable activation barrier accounts for why the quantum yield is very low in solution owing to geminate recombination. The longer Mn–O bonds in the $[Mn_4O_4]^{6+}$ cubanes are weaker than those in $[Mn_2O_2]^{3+}$ core complexes, a feature which is believed responsible in part for their reactivity toward forming O_2.

Reduction of the parent cubane in solution using various H atom donors (organoamines and phenols) proceeds via successive intermediates differing by addition of H atoms to the corner oxos. A total of 4 H atoms can be delivered, but the isolated product is not the tetrakis μ-OH species $1H_4$, rather it is the dehydrated 'pinned butterfly' complex $Mn_4O_2(Ph_2PO_2)_6$ and two free water molecules.[55] The rate constants and H/D kinetic isotope effects were also examined. No further reduction below this oxidation state Mn(2II, 2III) is observed, indicating that the butterfly core topology is intrinsically resistant to further reduction.

The chemistry in Figure 12 gives direct experimental proof of the unique properties of the Mn_4O_2-butterfly/Mn_4O_4-cubane topology in the dehydrogenation of water to μ-oxos and coupling to form O_2. The possible relationship between this chemistry and the permissible mechanisms for biological water splitting is illustrated in Figures 9 and 10.

Glossary

Manganese-activated enzyme: an enzyme that does not bind Mn tightly, but for which the enzymatic activity is nevertheless enhanced by addition of Mn. Manganese may or may not be the cation bound in vivo

Manganoenzyme: an enzyme that binds Mn stoichiometrically. Mn is difficult to remove from the protein and is typically required for biological activity

1 INTRODUCTION

In contrast to iron and copper proteins (*see Polypeptide*), which are well-known and well-characterized, relatively little is known about the bioinorganic chemistry of manganese (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***; ***Iron: Heme Proteins & Electron Transport***; ***Iron: Heme Proteins, Mono- & Dioxygenases***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***; ***Copper Proteins: Oxidases***; ***Copper Proteins with Type 1 Sites***; ***Copper Proteins with Type 2 Sites***; ***Copper Enzymes in Denitrification***; ***Cytochrome Oxidase*** for examples of some of the well-characterized iron and copper proteins). In part, this is simply a matter of detectability: proteins that have heme-iron or blue copper-active sites (*see Active Site*) are characterized by intense UV–visible absorption bands; Cu proteins often have easily detectable EPR (*see Electron Paramagnetic Resonance*) signals. Manganese, however, is often difficult to detect spectroscopically. In the biological milieu, the accessible Mn oxidation states are Mn^{II}, Mn^{III}, and Mn^{IV}. Of these, Mn^{II} is by far the most common. Unfortunately, most Mn^{II} complexes, including Mn^{II} proteins, have very weak UV–visible transitions. When it is present in a high symmetry environment, Mn^{II} has an easily detectable EPR signal. In lower symmetry environments, the Mn^{II} EPR signal can become broad and hard to detect. Nevertheless, EPR studies have been extremely useful in characterizing the role of Mn in proteins.[1,2]

A second difficulty in studying Mn proteins is the lability of protein-bound Mn. Complexes of Mn^{II} typically have binding constants that are somewhat smaller than those for the corresponding Fe^{II} complexes and substantially smaller than those for Cu^{II} and Zn^{II} complexes (this is the so-called *Irving–Williams Series*). For heme–iron proteins, the porphyrin cofactor (*see* ***Iron Porphyrin Chemistry***) increases the stability of the Fe–protein interaction. No such small molecule cofactors are known for Mn proteins. Small binding constants mean that Mn is readily lost from a protein during purification.

In describing this phenomenon, it is common to distinguish between manganese-activated enzymes and manganoenzymes.[3,4] Manganese-activated enzymes do not contain tightly bound Mn ions, and often contain no Mn whatsoever when they are isolated. The activity of these enzymes is dependent on the amount of free Mn^{II} in solution, with Mn^{II} dissociation constants typically in the μM to mM range. In some cases, there is an absolute requirement for Mn. In others, Mn is not essential: either there is activity in the absence of added metal (basal activity) or activation can be observed using divalent cations other than Mn. Unfortunately, it is often difficult to establish that Mn^{II} is the in vivo activator for a Mn^{II}-activated protein. Since Mn^{II} and Mg^{II} have similar chemistry and since intracellular Mg^{II} concentrations are roughly 10^3 higher than intracellular Mn^{II} concentrations, the mere observation of activation by Mn^{II} does not prove that a protein is manganese-activated in vivo.

In contrast to manganese-activated enzymes, manganoenzymes contain tightly bound Mn and it is often quite difficult to remove the Mn from the protein. The activity of manganoenzymes is not enhanced by the addition of free Mn to the assay medium. Both classes of proteins are discussed since the distinction involves only the relative strength of the Mn–protein interaction and not any fundamental properties of the Mn active site.

There have in addition been numerous studies of Mn-substituted proteins. In these, Mn is substituted for a metal found naturally in the protein (most often Mg^{II}, but also Zn^{II}, Ca^{II}, or Fe^{II}). This substitution is generally used to permit spectroscopic characterization of the native metal site, using Mn^{II} as the reporter. Often (although not always) the Mn-substituted protein is active. Manganese-substituted proteins are discussed briefly where they illustrate important properties of Mn–protein interactions.

2 BIOLOGICAL DISTRIBUTION OF MANGANESE

Manganese is one of the most common elements in the Earth's crust; thus it should not be surprising that manganese is an essential trace element for a variety of organisms (both prokaryotes and eukaryotes (*see Prokaryote* and *Eukaryote*) including humans). Manganese deficiency has been implicated in numerous diseases including skeletal abnormalities and depressed reproductive function.[5] Manganese is distributed throughout mammalian tissues, with the highest concentrations found in the liver, kidney, lung, heart, spleen, and brain. In some cases, it appears that Mn^{II} and Ca^{II} share the same intracellular transport mechanism, which is reasonable given their similar ionic radii (*see Crystallographic Radius*). In other cases, it is Fe^{II} and Mn^{II} that appear to share transport and regulation mechanisms.

Much of the manganese present in tissue can be accounted for by a few proteins: pyruvate carboxylase, superoxide dismutase, and arginase in the liver; glutamine synthetase in the brain. The location and function of the remainder of the Mn remains to be defined, although it may be associated with weak-binding Mn-activated enzymes. The biochemical significance of the 'remainder' Mn is not clear at present, although there is growing evidence (see Section 3) that Mn levels can be critical in determining the pathogenicity of bacteria.

Manganese may play a role in metabolic regulation. For Mn to function in intracellular control, several conditions must be met: (1) The kinetic constants for the interaction of Mn^{II} with the putative control target must approximate the intracellular free Mn^{II} concentration; (2) the binding site for Mn^{II} must discriminate strongly against Mg^{II}; (3) the amount of intracellular exchangeable Mn^{II} must approximate the concentration of target enzyme that is required to account for the observed metabolic flux; and (4) the intracellular free Mn^{II} concentration must change in response to altered physiological or hormonal states. These criteria seem to be met by several protein kinases, synthetases, and phosphatases. There is sufficient Mn in cells to accommodate additional control pathways. However, the putative protein targets remain to be identified.

3 MANGANESE TRANSPORT AND REGULATION

The last decade has seen an explosion of interest in Mn transport and regulation.[6] While this remains poorly characterized in comparison with the much better studied areas of Fe and Cu homeostasis (*see* ***Metallochaperones & Metal Ion Homeostasis***), the basic principles of Mn metabolism are beginning to be worked out. In yeast, there are at least two independent systems for importing Mn into the cell. The high-affinity transporter, operative under conditions of Mn starvation, is an Nramp (Natural resistance-associated macrophage protein) divalent cation transporter. Very recently, the low-affinity transporter has been shown to be a phosphate transporter.[7] In addition to these import systems, there is at least one additional transporter, a P-type ATPase, that is responsible for Mn export, in order to maintain an appropriate intracellular Mn level. Bacterial Mn transport also includes an Nramp protein (known as MntH) and a P-type ATPase, together with an ATP-binding cassette (ABC)-type Mn permease. Although these proteins are beginning to be well-characterized genetically, the details of the Mn sites, and the mechanisms of Mn transport remain to be elucidated. What is clear, however, is that careful control of Mn levels is critical for most cells, at least in part because of the importance of Mn ions and Mn-binding proteins in protecting cells from oxidative stress.[8]

As with transport, the biochemistry of Mn regulation (*see* ***Metalloregulation***) is only beginning to be worked out. In *B. subtilis*, Mn homeostasis appears to be maintained by the regulatory protein MntR. When the Mn^{II} concentration is low, MntR is present as the apo protein. In this form, MntR promotes transcription of an (ABC)-type Mn permease (MntA). At high Mn concentration, Mn binds to MntR, converting the protein to a form that is ineffective at promoting MntA and that in addition inhibits the Nramp transporter MntH.[9] MntR is a member of the diphtheria toxin repressor (DtxR) family of metalloregulatory proteins. Most of the DtxR proteins bind Fe, although they can be activated by Mn under some conditions. Surprisingly, MntR is highly selective for Mn. The basis of this selectivity appears to be the formation of novel dinuclear Mn active site,[10] in which the Mn are bridged by two carboxylates, one in a μ-1,3 geometry and one in a μ-1,1 geometry, with a third bridge provided by a solvent molecule. Although DtxR also binds two metal ions, the irons in DtxR are separated by 9 Å, in comparison with the 3.3 Å Mn–Mn separation in MntR. The presence of a dinuclear site in MntR may be responsible for its Mn selectivity; although it is certainly possible to form dinuclear Fe sites, one of the Mn ions in MntR appears to be 7-coordinate, a relatively uncommon structure for the smaller Fe^{II} ion.

Iron availability is known to limit the pathogenicity of many organisms. It appears that at least some microorganisms have responded to this limitation by evolving metabolic systems that can function with little or no Fe, but that, in many cases, have an absolute requirement for Mn. Examples include *Borrelia burgdorferi* (causative agent of Lyme disease) and *Mycoplasma pneumoniae*. The existence of a unique Mn requirement for some bacteria suggests that it may be possible to develop new drugs that attack selected microorganisms by limiting their Mn transport. For example, a virulence factor in *Enterococcus faecalis* (a cause of infective endocarditis) appears to be an (ABC)-type Mn transporter.

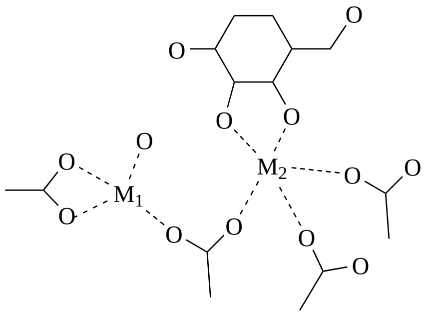
4 MANGANESE-ACTIVATED ENZYMES

Over 150 enzymes have been shown to contain Mn, and in many cases, it seems likely that Mn is the in vivo activator.[11] For example, enzymes that utilize nucleoside triphosphates (e.g. kinases, DNA polymerases) require divalent cations. Often Mn^{II} is just one of several divalent cations that can stimulate activity. In many cases, Mg^{II} is believed to be the physiologically relevant cation. There are, however, many cases in which Mn appears to be preferred, or even essential, for activity. Examples include L-threonine dehydrogenase, which has low basal activity that is significantly enhanced by Mn^{II} and Cd^{II}, but not by any other divalent cations and inorganic pyrophosphatase, which is specifically activated by Mn^{II} and more weakly by Co^{II}. In both cases, Mn^{II} almost certainly is the in vivo activator. Although no structural details are available for the former Mn site, the latter has recently been shown crystallographically to have a dinuclear Mn active site.[12]

Although there have been numerous studies of the interactions of substrates and inhibitors with the Mn^{II} ions in manganese-activated enzymes, structural details of the Mn sites in most Mn-activated enzymes are only beginning to be defined. However, with the growth of structural genomics initiatives, it is clear that the number of known Mn active sites will continue to grow rapidly – there are already over 1000 entries in the protein data bank containing bound Mn. Three Mn-activated enzymes in which the Mn site structure and function are relatively well-characterized are xylose isomerases, glutamine synthetase, and phosphoglycerate mutase.

4.1 Xylose Isomerase

D-Xylose isomerase catalyzes the isomerization of the five-carbon aldose D-xylose to the ketose D-xylulose. The enzyme has an absolute requirement for added divalent cations; however, Mg^{II}, Co^{II}, and Mn^{II} are all effective in stimulating activity. The enzyme has been the object of intensive scrutiny, including numerous crystal structures, because of its industrial importance in the production of fructose from glucose.[13] There are two adjacent metal-binding sites, with the metals sharing a carboxylate ligand. The structure (**1**) features a 1,3-bridging mode for the carboxylate. This gives a long metal–metal distance of ca. 5 Å, with some variation in this distance when substrate is bound. The first cation is believed to bind and orient the sugar, while the metal in the second site is believed to participate directly in the isomerization reaction. This second metal coordinates to O-1 and O-2 of the sugar and, by virtue of its electric field, facilitates hydride transfer between C-1 and C-2. Recently, it has been possible to engineer isomerases having modified metal ion specificity. In particular, modification of a carboxylate that is near, but not at, the cation sites gives a protein that is most active with Mn.



(**1**)

4.2 Glutamine Synthetase

Glutamine synthetase catalyzes the ATP-dependent biosynthesis of glutamine according to equation (1). This enzyme plays a central role in nitrogen metabolism. In mammalian brain tissue, glutamine synthetase converts the neurotransmitter glutamate into glutamine.

$$\text{L-Glutamate} + \text{ATP} + \text{NH}_3 \longrightarrow \text{L-Glutamine} + \text{ADP} + \text{P}_i \quad (1)$$

At one point, it appeared that the mammalian enzyme contained tightly bound Mn (i.e. was a manganoenzyme). More recently, however, it has been shown that both the mammalian and the bacterial enzyme are manganese-activated (i.e. Mn dissociation constants in the μM range). There are two cation binding sites. As with xylose isomerase, the first site is believed to be responsible for defining the orientation of the substrate binding while the second is directly involved in catalytic activity. Based on a dipolar relaxation mechanism, the EPR spectra of glutamine synthetase indicate a 6–10 Å distance between the two sites, depending on the state of the enzyme. The presence of at least one water in the coordination sphere of one site was inferred from NMR relaxation data. These spectroscopic interpretations were recently confirmed with the determination of the glutamine synthetase crystal structure.[14] Each Mn is coordinated by three or four protein ligands and two water molecules in an approximately octahedral geometry. There is a single bridging water molecule, giving a Mn–Mn distance of 5.8 Å.

4.3 Phosphoglycerate Mutase

Phosphoglycerate mutase (PGM) catalyzes the isomerization of 2- and 3-phosphoglycerate, and is essential for glucose metabolism. There are two major categories of PGM, one dependent on the cofactor 2,3-bisphosphoglycerate, and the other (*i*PGM) that is independent of organic cofactors, but that requires the presence of divalent metal cations. The *i*PGM from *Bacillus stearothermophilus* has an absolute requirement for Mn^{II} and shows dramatic pH sensitivity. Similar, albeit less well-characterized *i*PGMs are found in more dangerous pathogens, including *Bacillus anthracis* (the causative agent

of anthrax). Interestingly, the pH sensitivity is significantly enhanced by the presence of low levels of Mn; most likely this reflects the pH dependence of Mn binding, which in turn results from the fact that two protons are released when Mn binds. It is likely that this Mn-dependent pH sensitivity is physiologically important. The decrease in pH during sporulation inactivates *i*PGM and results in the accumulation of a reserve of 3-phosphoglycerate in the developing spore; on spore germination the pH rises, activating *i*PGM and allowing utilization of the 3-phosphoglycerate.[15] Given the large number of Mn-activated enzymes that are involved in the interconversion of phosphoglycerate, pyruvate, and oxaloacetate, it is possible that a mechanism similar to that found in *i*PGM could offer a way for Mn to play a central role in regulating cellular carbon metabolism.

The dramatic pH sensitivity requires that the available Mn concentration match the relatively weak-binding constant of *i*PGM for Mn. If higher Mn levels are present, the pH sensitivity is greatly attenuated. Crystallographic studies have shown that *i*PGM has a dinuclear Mn active site, with an oxygen of the phosphoglycerate forming a bridge between the two Mn, thus orienting the substrate for reaction.[16]

5 METALLOPROTEINS WITH MONONUCLEAR Mn SITES

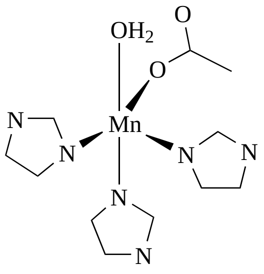
There are relatively few characterized metalloproteins having mononuclear Mn sites. By far the best characterized mononuclear Mn site is shown in *Superoxide Dismutase*, although there are several other proteins that appear to have tightly bound mononuclear sites, including an extradiol dioxygenase, and several members of the cupin family.

5.1 Superoxide Dismutase

Superoxide dismutase (SOD) catalyzes the disproportionation of superoxide to peroxide and oxygen according to equation (2). Four different types of SOD are known, containing either Cu and Zn (*see* ***Copper Proteins with Type 2 Sites***), Fe, Mn, or Ni (*see* ***Nickel Enzymes & Cofactors***). The Fe and Mn containing SODs have very similar structures and can be further subdivided into metal-specific (i.e. functioning only when the ‘correct’ metal is bound) and cambialistic (functioning with either Fe or Mn bound to the active site).

$$2O_2^- + 2H^+ \longrightarrow H_2O_2 + O_2 \qquad (2)$$

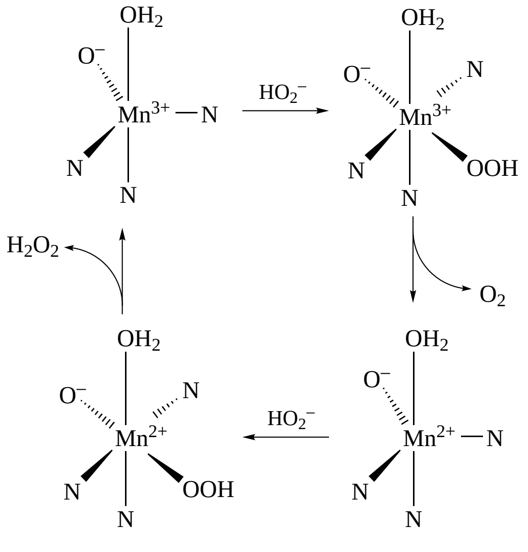
Crystal structures have been determined for both Fe and Mn SODs. These constitute a family of closely related proteins with homologous folding patterns. There is complete conservation of both the metal ligands and the aromatic residues surrounding the metal atom. The metal site has approximate trigonal bipyramidal structure (**2**) with an equatorial plane of two histidine imidazoles and one aspartate carboxylate, and axially coordinated solvent and imidazole.



(**2**)

In Mn-activated enzymes, the Mn appears either to play a structural role (e.g. defining the substrate orientation or stabilizing an active conformation of the protein) or to function as a Lewis acid (*see Lewis Acids & Bases*). In contrast, in extensive kinetic studies of Fe, and to a lesser extent Mn, SODs have shown unambiguously that the metal plays a redox role in these proteins, cycling between Mn^{II} and Mn^{III}. There is no significant change in the Mn structure when the metal is reduced; this is typical of redox-active metal sites, since any significant distortion will give rise to a kinetic barrier to reaction (*see* ***Long-range Electron Transfer in Biology***)

Azide is a competitive inhibitor of SOD and is believed to bind analogously to superoxide. The crystal structures of the azide derivative show that azide binding takes place without loss of protein ligands. A plausible kinetic mechanism, combining the kinetic and structural data for Fe and Mn SODs, is shown in Scheme 1. During steady-state turnover, the majority of Mn SOD appears to be present in an inactive



Scheme 1 Possible superoxide dismutase mechanism

dead-end complex that rapidly converts to the active enzyme once superoxide is consumed. Based on the observed *Ligand-to-Metal Charge Transfer* bands, the dead-end complex has been identified as a Mn^{III}−peroxo adduct.

One of the most intriguing questions about SOD is the structural basis of the metal specificity. Two limiting mechanisms have been suggested. One is based on redox potential. The midpoint potentials for oxidation and reduction of superoxide are −160 mV and +890 mV, respectively. In order to have maximum kinetic efficiency, the redox potential for SOD needs to be between these, and consistent with this, the redox potentials for the enzyme are around +300 mV. This is ca. 470 mV below the redox potential of aqueous Fe, but more than 1 V below the redox potential of aqueous Mn. The redox model then suggests that the Mn-specific protein must lower the reduction potential of the metal more than does the Fe-specific protein. Consequently, if Fe is substituted for Mn, the redox potential will be too low to oxidize superoxide. An alternative model is based on structural differences that are seen when Fe is substituted into the Mn site.[17] In this case, it appears that the Fe is 6-, rather than 5-coordinate, with the 6th coordination site being occupied by hydroxide, when Fe is substituted into Mn-specific superoxide dismutase. Hydroxide binding, like azide binding, would inhibit the enzyme by blocking access of the superoxide to the metal, and thus would account for the inactivity. Consistent with this, some activity is recovered at lower pH, where the hydroxide concentration is lower.

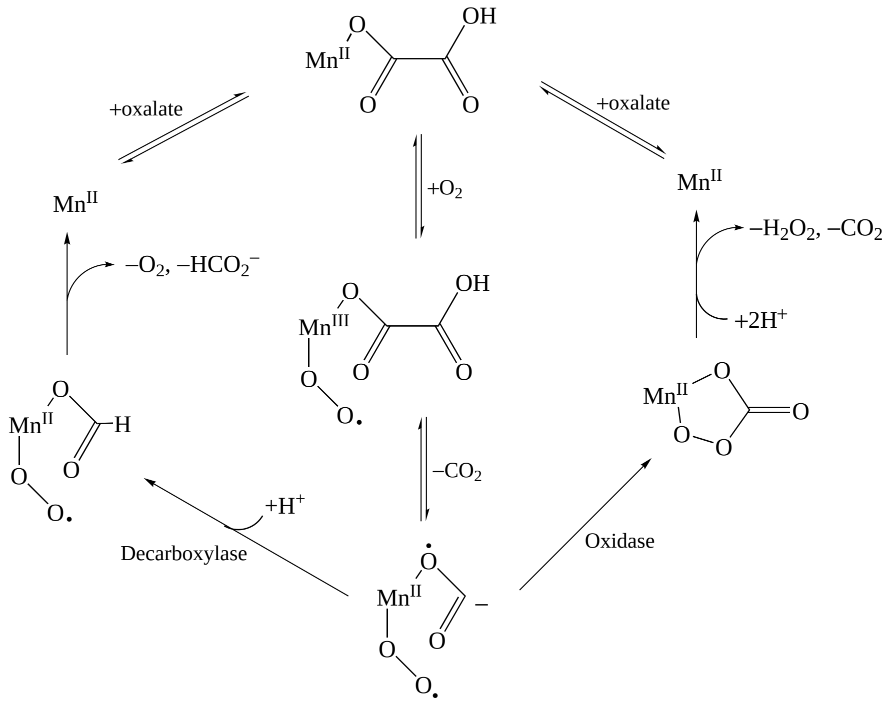
5.2 3,4-Dihydroxyphenylacetate 2,3-Dioxygenase

Iron-containing extradiol-cleaving dioxygenases are well known (*see* ***Iron Proteins with Mononuclear Active Sites***). These contain a loosely bound Fe^{II} and are readily inhibited by cyanide. In contrast, the dioxygenase from *Bacillus brevis* contains no Fe as-isolated, is not activated by Fe^{II}, and is not inhibited by cyanide. It does contain two tightly bound Mn ions per tetramer. EPR spectra show that the Mn environment changes when inhibitor is bound, thus suggesting a functional role for the Mn, and recent crystallographic studies confirm the presence of Mn rather than Fe.[18] For both the Fe and the Mn proteins, the metal is coordinated by two histidines, one glutamic acid, and solvent molecules completing the coordination sphere. The available structures are at fairly low resolution (2.5 Å or worse); thus it is not possible to define the metal ligation in detail; it is possible that Fe and Mn have different coordination numbers. Intriguingly, both the first and the second coordination spheres are essentially identical within the uncertainty of the data. Unlike SOD, it has not been possible to prepare metal substituted samples of the dioxygenases; thus it is not known whether the Fe-enzyme will function with Mn in the active site (and vice versa). The finding that the protein is either Fe-specific or Mn-specific, despite the identical structures and very similar sequences, suggests that metal selectivity may be due to changes in structure that occur during folding.

Since the proposed mechanism involves cycling of the metal between the M^{II} and M^{III} oxidation states, it is somewhat surprising that there is no apparent difference in structure between the Fe and Mn-specific enzymes. As discussed above, one would predict nearly a half-volt difference in reduction potential if Fe and Mn are bound in identical sites. This may mean metal oxidation is not rate limiting, and thus that the reaction can accommodate this shift in potential (in contrast with the case for SOD) or it may mean that there are structural changes (e.g. coordination number) that cannot be detected with the present crystallographic resolution.

5.3 Cupins

The cupin family of proteins form extremely stable beta-barrels. Recently, several cupins have been shown to bind Mn. The best characterized of these is oxalate decarboxylase, which has a $Mn(His)_3(Glu)(H_2O)_2$ binding site. The two water molecules are cis, thus providing a possible bidentate binding site for oxalate, or perhaps more realistically, binding sites for a monodentate oxalate and an O_2.[19] Oxalate metabolism is important for maintaining pH and ionic strength in plants, and oxalate production is believed to play an important role in biological defense. In addition to the decarboxylation reaction, in which oxalate is converted to CO_2 and formate, it is also possible to degrade oxalate by oxidation in an O_2-dependent process to give two moles of CO_2 and one mole of H_2O_2, a reaction catalyzed by oxalate oxidase. Recently, germin, a protein implicated in plant response to pathogens, was shown to be an oxalate oxidase, and was found crystallographically to have a structure very similar to that seen in oxalate decarboxylase.[20] Oxalate oxidase and oxalate decarboxylase have identical Mn active sites. Both enzymes require O_2 for activity, although only in the oxidase is O_2 consumed. One possible mechanism that could account for the reactivity is shown in Scheme 2. In this mechanism, O_2 binds to the Mn^{II} form of the enzyme, giving a Mn^{III} superoxide intermediate that acts as an electron sink to facilitate decarboxylation of the oxalate, producing a formyl radical-anion intermediate. In the decarboxylase (left-hand side of Scheme 2), the formyl carbon is protonated, while in oxalate oxidase (right-hand side), the intermediate decays with release of H_2O_2. Alternative schemes involving higher oxidation states of Mn have also been proposed,[21] but seem less likely given the known ability of histidine ligation to stabilize Mn^{II}. Recently, a new Mn-containing cupin was identified by structural genomics efforts.[22] This protein has a novel tetra-histidine Mn site, with two solvent molecules completing the octahedral site, but does not, as yet, have any known biological function. This ligation should significantly favor the Mn^{II} oxidation state, thus it is unlikely that this Mn is redox-active in vivo.



Scheme 2 Possible mechanisms for Mn-mediated oxalate metabolism

6 METALLOPROTEINS WITH DINUCLEAR Mn SITES

Several manganoproteins having dinuclear sites are now known. These include a large number of Mn-activated enzymes, such as phosphoglycerate mutase (discussed above), numerous hydrolytic enzymes, including inorganic pyrophosphatase (above) and arginase, and several proteins where the dinuclear site may play only a structural role, including concanavalin A and MntR (above). One enzyme in which the dimanganese site is unambiguously redox-active is Mn catalase. There are several other proteins that may have redox-active dinuclear sites; however, these have not, in general, been characterized structurally.

6.1 Mn Catalase

The catalases catalyze the disproportionation of hydrogen peroxide (equation 3). Most catalases contain the iron-protoporphyrin IX prosthetic group (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). However, some bacteria are able to synthesize catalases that are not inhibited even by millimolar concentrations of azide and cyanide,[23] suggesting that some catalases are nonheme enzymes; it is now known that these enzymes possess a dinuclear Mn active site.

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \qquad (3)$$

The nonheme catalases are sometimes referred to as pseudocatalases. However, this is inappropriate since there is nothing 'pseudo' about their catalase activity. They are better described as Mn catalases. Bacteria that lack Mn catalase (either genetically or through inactivation of the enzyme) show decreased viability, suggesting that Mn catalase does, in fact, play a physiological role in the detoxification of H_2O_2.

6.1.1 Characterization of Mn Catalase

Most of the work on Mn catalases has focused on the enzymes isolated from *Lactobacillus plantarum* and *Thermus thermophilus*. However, numerous putative Mn catalases have been identified from sequence comparisons. Most of these are from stress-tolerant bacteria (heat, salt, pH, etc.) consistent with the suggestion (above) that Mn proteins may be important in stress response. Intriguingly, at least three putative Mn catalases are found in pathogenic organisms: *E. coli* O157:H7, *Salmonella typhimurium*, and *Bacillus anthracis*.

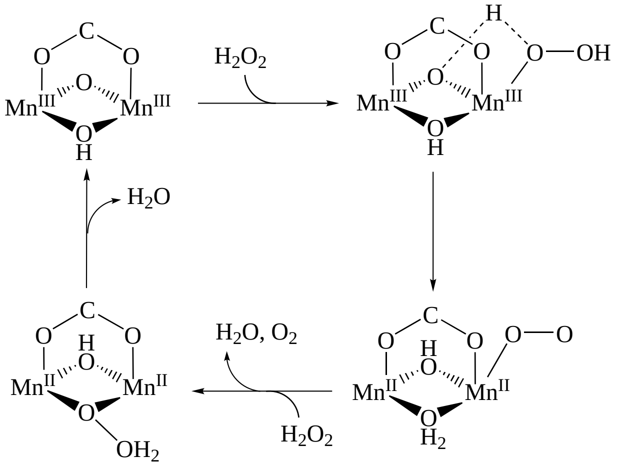
Three Mn catalases have been purified and characterized,[24] including crystals structures for two of the enzymes.[25] Each Mn catalase monomer has four parallel α-helices, similar to the structure found in hemerythrin (*see* ***Iron Proteins with Dinuclear Active Sites***). The crystallography demonstrates that the Mn site is bridged by a single μ-(1,3)-carboxylate ligand and two solvent molecules, and that there is a single histidine coordinated to each Mn. The remainder of the ligation sphere, to give 6-coordinate Mn, is completed by two additional glutamates (one monodentate and one

bidentate) together with a third solvent molecule. The Mn–Mn separations are relatively long (3.4–3.6 Å) suggesting that at least one of the bridging solvents must be protonated. One possible scheme invokes oxo, hydroxo bridging in the oxidized Mn^{III}_2 form and hydroxo, aquo bridging in the reduced Mn^{II}_2 form.[26] However, despite the availability of several crystal structures, questions remain regarding the structural details owing to the sensitivity of the enzyme to X-ray induced radiation damage, especially in the Mn^{III} oxidation state. Consistent with this, EXAFS (*see Extended X-ray Absorption Fine Structure*) spectra seem to show shorter Mn–Mn separations than are seen crystallographically.

The optical spectrum of as-isolated Mn catalase has a broad weak absorption band at ca. 450–550 nm, similar to the spectra seen for Mn^{III} superoxide dismutase and for a variety of Mn^{III} model complexes, thus suggesting that at least some of the Mn in Mn catalase is present as Mn^{III}. In particular, the absorption maximum at ca. 500 nm is similar in energy and intensity to the transitions seen for oxo-, carboxylato-bridged Mn dimers (see Section 9). The EPR spectrum of the as-isolated enzyme is a complex multicomponent signal. At 50 K, the EPR is dominated by a 16-line signal centered at ca. $g = 2.0$ that is ca. 1300 G wide. This signal is essentially identical to those observed for Mn^{III}/Mn^{IV} mixed-valence compounds (*see* ***Mixed Valence Compounds***). On treatment with NH_2OH, the Mn^{III}/Mn^{IV} signal disappears and a new, very broad signal, attributed to a Mn^{II}/Mn^{II} form of the enzyme, appears. This signal is quite sensitive to the buffer, the pH, and the anions that are present (i.e. SO_4^{2-}, N_3^-, F^-, CN^-). At temperatures below 50 K, a third EPR signal, attributed to a Mn^{II}/Mn^{III} derivative, is observed. All three signals contribute to the observed spectrum of the as-isolated enzyme but each can be enhanced by selective redox interconversions. Electron Spin Echo Envelope Modulation (ESEEM) (*see Electron Spin Echo Envelope Modulation Spectroscopy*) spectra for the Mn^{III}/Mn^{IV} enzyme show ^{14}N modulations, consistent with the nitrogen ligation seen crystallographically. Interestingly, only one of the two histidines is detectable by ESEEM.

The Mn catalases were originally identified on the basis of their insensitivity to azide and cyanide. However, kinetic studies have subsequently shown that all three Mn catalases are inhibited by azide and other anions, albeit at much higher concentrations than are required for inhibition of heme catalases. In the case of azide, the inhibition is competitive, suggesting that azide and peroxide bind at the same metal site. Azide binding to the reduced (Mn^{II}/Mn^{II}) enzyme appears to cause loss of a coordinated water molecule.

Mn catalase cycles between the Mn^{II}/Mn^{II} and the Mn^{III}/Mn^{III} oxidation states during catalysis and is thus, in some sense, the two-electron analog of Mn superoxide dismutase. One possible mechanistic model, based on the known coordination chemistry of Mn dimers and the crystal structures of Mn catalase, is shown in Scheme 3.[26] In this scheme, the bridging solvent molecules play a critical role in proton transfer, with the oxo bridge acting as a Lewis base, facilitating the oxidation of peroxide to dioxygen.



Scheme 3 Possible mechanism for Mn catalase peroxide disproportionation

6.1.2 *Possible Analogies to the Oxygen-Evolving Complex*

The best characterized of the Mn enzymes is the photosynthetic oxygen-evolving complex (OEC, *see* ***Manganese: The Oxygen-evolving Complex & Models***). On the surface, the OEC would appear to be quite different from any other Mn enzyme, since it contains four tightly bound Mn ions and appears to use only the Mn^{III} and Mn^{IV} oxidation states. However, if Mn catalase is inactivated by the simultaneous addition of μM concentrations of NH_2OH and H_2O_2, a Mn^{III}/Mn^{IV} mixed-valence derivative is formed. This superoxidized catalase has a $Mn^{III}(\mu\text{-}O)_2Mn^{IV}$ structure[27] and is spectroscopically (EPR) and structurally (EXAFS) similar to the Mn site in the OEC. With this in mind, it is intriguing to note that the OEC Mn site has been implicated both in the disproportionation of H_2O_2 and in the formation of H_2O_2. It thus seems that the OEC and Mn catalase may not be as different as they first appear.

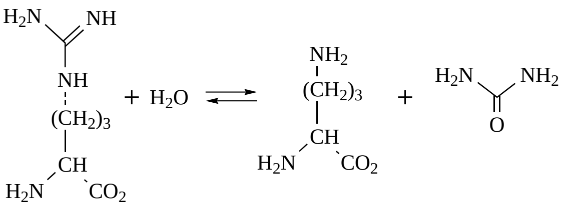
6.2 Concanavalin A

The lectins are saccharide-binding proteins that cause cell agglutination. The best characterized of the lectins is concanavalin A (Con A). Con A is devoid of carbohydrate binding activity in the absence of added metal. Each monomeric unit of Con A has two binding sites, named S1 (the transition metal site) and S2 (the calcium site). The S1 site binds a variety of divalent transition metals, including Mn, Ni, Co, Cd, Zn, Fe, and Cu, although Mn is probably the metal used in vivo. The S2 site is not formed until S1 is occupied. Both S1 and S2 must be occupied before saccharide will bind.

Crystallographic studies show that the S1 and S2 sites are ca. 4.2 Å apart and are bridged by two carboxylate residues. When Mn^{II} and Ca^{II} are added to the *Apoprotein*, Con A is initially in an inactive conformation. This slowly converts to an active, or 'locked', conformation. In the locked conformation, Mn is tightly bound. The Mn appears to play solely a structural role in Con A. The principal interest in Con A, in the context of understanding dinuclear Mn proteins, is that in the absence of Ca^{II}, two equivalents of Mn^{II} will bind to the apoprotein. This dimanganese protein has an EPR spectrum characteristic of an antiferromagnetically coupled (*see Antiferromagnetism*) Mn dimer. Although the dimanganese protein is active in saccharide binding, it is of particular interest as the first well-characterized spectroscopic model for exchange-coupled di-Mn^{II} sites.

6.3 Arginase

Arginase is the terminal enzyme in the urea cycle. It catalyzes the hydrolysis of L-arginine to L-ornithine and urea (equation 4). Preincubation with Mn^{II} is required for activation. However, in contrast to Mn-activated enzymes, free Mn^{II} is not required in the assay medium. That is, Mn^{II} is apparently lost during purification, but once the Mn site is reformed, the Mn is tightly bound. The EPR spectrum for Mn-saturated arginase is very similar to that for Mn_2Con A, indicating that there are two magnetically coupled Mn ions in the active site.



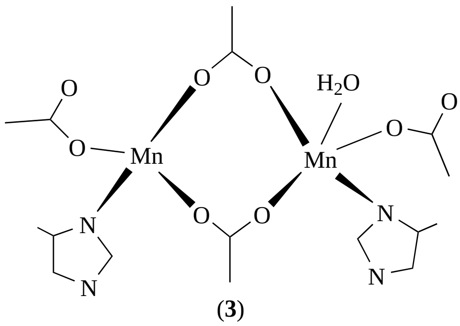
(4)

Crystallography has shown that arginase is structurally quite similar to Mn catalase. The protein provides similar ligands to the Mn: a μ-1,3-carboxylate, together with one histidine and one carboxylate per Mn (aspartates in arginase vs. glutamates in catalase). However, in contrast with the two bridging solvent molecules in catalase, arginase has one bridging solvent and a μ-1,1 bridging carboxylate. This difference in ligation is apparently responsible for the lack of catalase activity, despite the similar ligation. This is consistent with the critical role proposed for the bridging solvent in proton buffering during H_2O_2 disproportionation by Mn catalase.

The concentration of arginase in the liver greatly exceeds that necessary for the observed metabolic flux. For many years, this was taken to indicate that arginase could not be the rate-determining step in urea production, and thus that arginase regulation was unlikely to be important metabolically. Recently, however, it has been shown that, in vivo, arginase operates at well below its maximum capacity owing to subsaturation with Mn^{II}. Arginase has a strong pH dependence that appears to arise from the pH dependence of Mn binding, similar to that described previously for phosphoglycerate mutase, suggesting that arginase is a candidate to be another Mn-regulated enzyme.

6.4 Ribonucleotide Reductase

Ribonucleotide reductase catalyzes the reduction of ribonucleotide diphosphates to the corresponding deoxyribonucleotides and is thus an essential enzyme for all living organisms. The ribonucleotide reductase from *E. coli* has a dinuclear Fe site that has been characterized crystallographically (*see* ***Iron Proteins with Dinuclear Active Sites***). Mn competes with Fe in reconstitution of apo-ribonucleotide reductase and has been shown crystallographically to bind at the same site as Fe. The Mn_2 site in ribonucleotide reductase (**3**) is bridged by two carboxylate groups, giving it a relatively short Mn–Mn distance of 3.6 Å. This is essentially the same as that found in Mn catalase structure, despite the difference in bridging ligation. There is no EPR signal for Mn_2 ribonucleotide reductase at room temperature; however, at low temperature a broad signal consistent with an exchange-coupled Mn dimer is seen. Unlike the native Fe protein, in which the Fe is redox-active, the Mn^{II} in Mn_2 ribonucleotide reductase is not readily oxidized (thus explaining why the Mn-substituted enzyme is catalytically inactive).



(**3**)

It was suggested, based on UV-visible and EPR spectroscopy, that the ribonucleotide reductase from *Corynebacterium ammoniagenes* contains Mn rather than Fe in its native form. However, more recent crystallographic studies have shown that this protein is structurally identical to the native iron proteins and apparently does not contain a Mn active site.[28]

6.5 Other Dinuclear Mn proteins

A wide range of hydrolase enzymes contain dinuclear metal sites, and in many cases these can include dinuclear Mn sites. Phosphotriesterases catalyze the hydrolysis of a wide range of organophosphates and generally bind two divalent cations. The native enzyme typically contains Zn^{II}; however,

this can be replaced by Mn^{II} with no loss of activity. The EPR spectrum of the enzyme is typical of those found for antiferromagnetically coupled Mn^{II}/Mn^{II} sites with a broad feature near $g = 2$ that shows >26 lines with a hyperfine coupling of ca. 45 G, attributed to an $S = 1$ excited state. These data demonstrate that the two metal ions must be within 3–5 Å, thus indicating that phosphotriesterase is a dinuclear Mn enzyme. Similar behavior is found for glyoxylase II, a member of the metallo-β-lactamase superfamily. In this case, the enzyme is isolated with Zn, Fe, and Mn bound, all of which appear to be active.[29] Other, less well-characterized systems that may contain dinuclear Mn include an enzyme from *Thiobacillus versutus* that oxidizes thiosulfate to sulfate. One of the proteins in this system ('protein B') has an EPR spectrum indicative of an exchange-coupled Mn^{II} dimer. No structural information is available for this protein.

7 MANGANESE-SUBSTITUTED PROTEINS

Most of the enzymatic reactions that utilize the naturally occurring diamagnetic Mg^{II} ion still occur when the Mg^{II} is substituted by the paramagnetic Mn^{II} ion, often with little or no loss of activity. Since Mn^{II} is present at much lower concentrations than Mg^{II} in the cell, Mn^{II} does not play a role in vivo. The substitution studies are nonetheless useful, since Mn^{II} can be used as a probe for cation environment.[1] An important class of enzymes that have been studied in this way are those enzymes that utilize nucleoside triphosphates, including elongation factors and kinases.

Transferrin is a reversible iron-binding protein used in vertebrate iron-transport (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). Manganese will bind to transferrin in vitro to form a Mn^{III}–transferrin complex. Transferrin appears to bind the majority of the serum Mn and may be important in Mn transport.

8 SPECTROSCOPY

Magnetic resonance techniques (EPR, ESEEM, and NMR) have been among the most useful in characterizing Mn proteins. Other techniques, such as *X-Ray Absorption Spectroscopy* are also useful in special cases.

8.1 EPR

As described above, Mn^{II} is the most common oxidation state for Mn in proteins. In biological complexes, Mn^{II} is exclusively high-spin ($S = 5/2$) giving it a ^{6}S ground-state. This gives a total of 36 possible states, since m_S and m_I can both range from $-5/2$ to 5/2 (*see Electron Paramagnetic Resonance*). In the most general case, there are five EPR transitions, each split into a sextet by hyperfine coupling to the Mn nucleus. In reality, it is typical to observe only the central $\Delta M_S = \pm 1/2$ transitions since the other allowed transitions have pronounced orientational anistropy (and hence are often too broad to be detected). As a half-integral spin system, Mn^{II} is always EPR active (although this does not mean that the EPR spectrum is easily detectable). In general, the detectability and interpretability of Mn^{II} EPR spectra is improved by making measurements at higher fields. The so-called Q-band (35 GHz) is accessible to many investigators, and recent work has demonstrated the value of ultrahigh field EPR (up to ~300 GHz) for making subtle distinctions between different Mn sites. From the EPR spectrum, one can (at least in principle) extract the zero-field-splitting tensor for the Mn ion, and thus learn about the local symmetry of the site. This was shown in a recent ultrahigh field study of superoxide dismutase, where measurements at 285 GHz revealed subtle differences in Mn electronic structure that could be correlated with protein activity.[30]

By judicious use of spin-labeled substrates (often ^{17}O), it has proven possible to extract substantial information about the interactions between the Mn and various substrates.[2] As discussed above, EPR is also a powerful probe for determining the metal–metal distances in proteins having multiple metal sites. A variation on EPR is Electron Nuclear Double Resonance (ENDOR; *see Electron Nuclear Double Resonance Spectroscopy*), in which samples are irradiated by a combination of microwaves and radio waves. ENDOR allows identification of the nuclear spin transitions that are magnetically coupled to the unpaired electron spin, and thus has been extremely useful for identifying ligands to Mn sites (e.g. by identifying protons from solvent and/or nitrogens from histidine ligands).

8.2 ESEEM

ESEEM spectroscopy is a time-domain (i.e. pulsed) analog of EPR (*see Electron Spin Echo Envelope Modulation Spectroscopy*).[31] In principle, ESEEM contains the same information as is found in EPR and ENDOR, although in practice ESEEM is much more sensitive to weakly coupled nuclei that are not easily detected by ENDOR. On the other hand, strongly coupled nuclei can be undetectable by ESEEM, thus the combination of both techniques is often useful.

8.3 NMR

The proton spin–lattice relaxation times for solvent water are strongly perturbed if the water is in rapid exchange with a paramagnet. In particular, Mn^{II} is a strong relaxer for water protons and thus nuclear magnetic resonance (NMR) spectroscopy provides a sensitive probe for the presence of exchangeable water molecules bound to Mn in Mn proteins.

8.4 UV–Visible Spectroscopy

Since the ligand-field transitions (*see* ***Ligand Field Theory & Spectra***) for Mn^{II} are both spin and orbitally forbidden, Mn^{II} proteins seldom have detectable visible absorption bands. Proteins in which the Mn is oxidized, for example, Mn catalase or Mn transferrin, do have characteristic absorption features, as discussed above. As more Mn proteins are discovered, possibly with redox-active metals, visible spectroscopy may become more important. For paramagnetic species, which includes most Mn proteins, it is also possible to measure *Magnetic Circular Dichroism*. This provides sensitive insight into the electronic structure of the manganese site, and has been used, for example, to investigate the ligation changes that are responsible for the thermochromism in Mn superoxide dismutase.[32]

9 MODEL COMPOUNDS

Until relatively recently, little was known about the coordination chemistry of Mn, particularly in the higher oxidation states. In the last 2 decades, there has been an explosion of interest in synthesizing Mn model compounds (*see* ***Manganese: Inorganic & Coordination Chemistry***). Much of this effort has been devoted to synthesizing models for the oxygen-evolving complex; however, there also now exist a variety of well-characterized Mn dimers, including several Mn^{II} dimers that appear to be good models for the dinuclear sites in Mn catalase, glutamine synthetase, and ribonucleotide reductase. There are, in addition, several well-characterized reactivity models that carry out peroxide disproportionation.

Several conclusions can be drawn from the model studies. First, it is clear that Mn is just as versatile as Fe or Cu and that Mn complexes can, with appropriate design, be synthesized in a variety of oxidation states and coordination environments. A common feature of the model chemistry is the observation of $(\mu\text{-O})(\mu\text{-carboxylate})_2Mn_2$ and $(\mu\text{-O})_2(\mu\text{-carboxylate})Mn_2$ core structures similar to those suggested for Mn catalase. By judicious protonation of the oxo bridge(s), it is possible to vary the Mn reduction potential of these structures over a wide range.

1 INTRODUCTION

This chapter is an update of the chapter appearing in the first edition of the *Encyclopedia*. The literature has been surveyed up through June, 2003 with the intent of including studies that directly relate to the themes put forth in the original chapter.

Reactions of organometallic compounds are of interest because of their role in catalytic reactions and as models for catalytic reactions. An understanding of the chemical transformations that occur may lead to modifications of a catalyst to increase the activity (activity refers to the total amount of product formed) or the selectivity (selectivity refers to the formation of a specific product). Thus, a significant amount of effort has been devoted to understanding the mechanisms of organometallic reactions. In the following sections, the most important aspects of organometallic reactions will be examined.

A very important concept for the interpretation of organometallic reactions is counting electrons (*see Counting Electrons*). A number of years ago, it was suggested that most organometallic reactions occur through complexes that have 16 electrons ($16e^-$) or 18 electrons ($18e^-$).[1] This counting refers to the number of metal valence and ligand electrons (*see* ***Bonding Energetics of Organometallic Compounds***). Thus, 16-electron complexes would undergo associative reactions and 18-electron complexes would undergo dissociative reactions. Although exceptions to this scheme exist, it remains a valuable rule and will form the basis for this presentation.

2 16-ELECTRON COMPLEXES

16-electron organometallic complexes exist primarily as square-planar complexes involving Rh^I, Ir^I, Pd^{II}, Pt^{II}, Au^{III}, and Os^0. These d^8 metals coordinated to four $2e^-$ donor ligands give stable $16e^-$ complexes that provide excellent examples of associative reactions and oxidative addition (*see Oxidative Addition*).

2.1 Ligand Substitution

Ligand substitution reactions of square-planar complexes most often occur by associative reaction sequences.[2,3] An example of square-planar organometallic complexes that will illustrate this reactivity is *trans*-$Ir(Cl)(CO)(PPh_3)_2$ (frequently referred to as Vaska's Complex), (*see Vaska's Complex*).[4] This complex undergoes rapid ligand substitution with ^{13}CO, PR_3, and X^-:[5]

$$trans\text{-}Ir(Cl)(CO)(PPh_3)_2 \xrightarrow{PR_3} trans\text{-}Ir(Cl)(CO)(PR_3)_2 \quad (1)$$

These reactions are sufficiently rapid to preclude kinetic studies. However, the expected associative intermediates, $Ir(Cl)(CO)_2(PPh_3)_2$ and $Ir(Cl)(CO)(PR_3)_3$, can be spectroscopically identified in the presence of CO and PR_3, respectively.

Square-planar substitution reactions can be presented generically as:

$$Ir{-}X + Y \longrightarrow Ir{-}Y + X \quad (2)$$

where Ir represents an iridium(I) center, X is a leaving group, and Y is the incoming ligand. The rate law for such a reaction:

$$\text{rate} = k[\text{Ir}][\text{Y}] \quad (3)$$

is dependent on the concentration of the iridium complex and on the concentration of the incoming ligand. As for substitution reactions of other square-planar complexes, square-planar organometallic substitution reactions depend on the nucleophilicity of the entering ligand. Values for substitution of *trans*-$Pt(Cl)(Me)(PEt_3)_2$ are shown in Table 1.[6]

$$trans\text{-}Pt(Cl)(Me)(PEt_3)_2 + Y^- \longrightarrow trans\text{-}Pt(Me)(PEt_3)_2Y + Cl^-$$
$$Y = NO_2^-, N_3^-, Br^-, I^-, \text{ or thiourea} \quad (4)$$

More nucleophilic entering ligands react more readily. Solvent attack may also provide a route for ligand substitution, depending on the nature of Y and the solvent.

When a ligand substitution reaction is carried out in a coordinating solvent, such as methanol, the rate law becomes more complex and involves a first-order term involving only the metal complex, M and the second-order term usually

Table 1 Y group dependence for equation (4) in MeOH at 30 °C

Y	k_2 ($10^2\ M^{-1}\ s^{-1}$)
NO_2^-	1.6
N_3^-	7
Br^-	12
I^-	40
Thiourea	≥1500

associated with $16e^-$ complexes. This type of rate law is referred to as a compound rate law:

$$\text{rate} = k_1[M] + k_2[M][Y] \quad (5)$$

Experimental evidence for this type of rate law comes from a study of substitution in the presence of excess Y, when the rate law becomes pseudo–first order:

$$\text{rate} = k_{obs}[M] \qquad k_{obs} = k_1 + k_2[Y] \quad (6)$$

A plot of the observed pseudo-first-order rate constant versus [Y] gives k_2 as the slope of the line and k_1 as the intercept.[7]

Associative reactions of square-planar organometallic complexes are also important in the formation of $18e^-$ complexes. Some of the most valuable studies of unsaturated hydrocarbon binding to transition metal centers have centered on $16e^-$ organometallic complexes:[4,8,9]

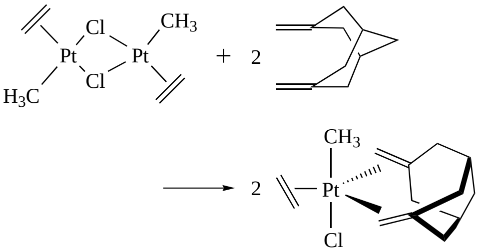
$$Ir(CO)(Cl)(PPh_3)_2 + \text{alkene} \rightleftharpoons Ir(\text{alkene})(CO)(Cl)(PPh_3)_2 \quad (7)$$

$$Ir(CO)(Cl)(PPh_3)_2 + \text{alkyne} \rightleftharpoons Ir(\text{alkyne})(CO)(Cl)(PPh_3)_2 \quad (8)$$

$$Ir(CO)(Cl)(PPh_3)_2 + C_{60} \longrightarrow Ir(C_{60})(CO)(Cl)(PPh_3)_2 \quad (9)$$

The stability of the five-coordinate adduct depends on the electron-withdrawing ability of the unsaturated hydrocarbon fragment.[4,9] The adducts are trigonal bipyramidal with the strongly π-accepting groups in equatorial positions.

Reactions of 16-electron *intermediates* with ligands occur very rapidly by an associative reaction. These reactions will be covered in Section 3.1 on dissociation from 18-electron complexes. Evidence for the trigonal bipyramidal complex as an intermediate and for the preference of π-acceptor ligands for the equatorial positions in this geometry comes from the work of Wing and Rettig.[10] A stable trigonal bipyramidal trisolefin complex of Pt(II) with all three olefins in the equatorial positions was isolated by using the chelating and sterically constrained diolefin, 3,7-dimethylene[3.3.1]nonane:[10]



(10)

2.2 Oxidative Addition Reactions

Oxidative addition (*see Oxidative Addition*) is a very important reaction for 16-electron complexes and is involved in many catalytic reactions.[2] Our examples will use stable 16-electron complexes, although in many catalytic reactions a five-coordinate, $18e^-$ complex undergoes ligand dissociation to form the $16e^-$, square-planar complex prior to oxidative addition. Several examples are shown here:

$$Ir(CO)(Cl)(PPh_3)_2 + Cl_2 \longrightarrow Ir(CO)(Cl)_3(PPh_3)_2 \quad (11)$$

$$Rh(Cl)(PPh_3)_3 + H_2 \longrightarrow Rh(Cl)(H)_2(PPh_3)_3 \quad (12)$$

$$Pt(I)(Me)(PPh_3)_2 + MeI \longrightarrow Pt(I)_2(Me)_2(PPh_3)_2 \quad (13)$$

In each of these examples, the metal oxidation state is increased by two, the formed complex contains $18e^-$, and the geometry is octahedral. For oxidative addition of nonpolar molecules, the adding groups occupy cis positions, while for polar molecules the adding groups adopt trans positions.[11] These different stereochemistries are related to mechanistic differences that will be described below.

In a number of cases, oxidative addition reactions are reversible:

$$\textit{trans}\text{-}Rh(CO)(Cl)(PPh_3)_2 + MeI \rightleftharpoons Rh(CO)(Cl)(I)(Me)(PPh_3)_2 \quad (14)$$

$$Rh(Cl)(PPh_3)_3 + H_2 \rightleftharpoons Rh(Cl)(H)_2(PPh_3)_3 \quad (15)$$

The reaction that is the reverse of the oxidative addition reaction is called reductive elimination (*see Reductive Elimination*). In reductive elimination, two ligands are removed from the metal and the metal undergoes a reduction in its oxidation state. Reductive elimination reactions of $18e^-$ complexes will be discussed in Section 3.2.

Enthalpy changes for oxidative addition of different RI groups to *trans*-$Ir(CO)(Cl)(PMe_3)_2$ have been reported:[11]

$$\textit{trans}\text{-}Ir(CO)(Cl)(PMe_3)_2 + RI \longrightarrow Ir(CO)(Cl)(I)(R)(PMe_3)_2$$
$$R = I, H, Me, Et, etc. \quad (16)$$

Values are given in Table 2.[11] The enthalpies suggest that the stronger bond of R to Ir gives the larger enthalpy for oxidative addition.

Table 2 Enthalpies[8] for oxidative addition reactions at Ir^{I}

RI	ΔH (kJ mol^{-1})
I_2	-185 ± 7
HI	-160 ± 3
MeI	-117 ± 7
EtI	-110 ± 3
PrI	-103 ± 4
$PhCH_2I$	-95 ± 7
i-PrI	-88 ± 10
MeC(O)I	-125 ± 4

Table 3 Rates of reaction of MeI with *trans*-$Ir(CO)(Cl)L_2$ for different L groups[a]

L	k (s^{-1} M^{-1})
P(*p*-tolyl)$_3$	3.3×10^{-2}
PPh_3	3.3×10^{-3}
P(*p*-$C_6H_4Cl)_3$	3.7×10^{-5}

[a]Rate $= k[Ir(CO)(Cl)L_2][MeI]$.[12]

Oxidative addition reactions of nonpolar molecules, such as H_2, show quite different characteristics from the oxidative addition reactions of polar molecules, such as MeI. For H_2 addition, the rate is relatively insensitive to the nature of the metal center, although a stable dihydride is formed only for very electron-rich metal centers. For *trans*-$Ir(CO)(X)(PPh_3)_2$, the rate depends on the X group (X = I > Br > Cl).[12] The very small deuterium isotope effect ($k_H/k_D = 1.22$) and calculations indicate only slight H–H bond weakening in the transition state.[13,14] Hydrogen addition is best considered as a donation of the H–H σ-bond electron density to the metal (as in molecular hydrogen complexes: *see* ***Hydride Complexes of the Transition Metals***), followed by simultaneous formation of two M–H bonds while the H–H bond weakens. This concerted addition leads to a cis stereochemistry.

Oxidative addition reactions of polar molecules show evidence for a nucleophilic attack mechanism in many cases. Methyl iodide is the most frequently used example. Metal complexes with more electron density react more rapidly with methyl iodide. This effect is shown by changes in the phosphine ligands for $Ir(CO)(Cl)L_2$ (Table 3).[15] For phosphines that only differ in the para substituents on the aryl groups and should be sterically very similar, the more-donating groups lead to appreciably faster reactions with MeI. Since the oxidative addition reaction leads to an increase in coordination number, an increase in steric congestion about the metal center causes a decrease in the rate, as expected. When an alkyl halide with a chiral carbon is used as the adding molecule, an inversion of configuration at carbon is observed,[16] consistent with the nucleophilic attack mechanism. The rate dependence on the alkyl halide is also consistent with nucleophilic attack by the metal on the alkyl halide RX (R = Me > Et > secondary > cyclohexyl; X = I > Br = tosylate > Cl).[17]

Alkyl halides that do not readily undergo nucleophilic attack may oxidatively add to a metal by radical mechanisms.[18] Oxidative addition reactions that occur by radical mechanisms show loss of stereochemistry, nonreproducible rates, inhibition by radical inhibitors, and acceleration by O_2 or light. Reactions of $Ir(Cl)(CO)(PMe_3)_2$ with methyl and benzyl halides showed no indication of radical behavior, but other saturated alkyl halides, vinyl, and aryl halides showed characteristics consistent with a radical-chain pathway.[18,19] The following scheme was suggested.

$$R\bullet + Ir(Cl)(CO)(PMe_3)_2 \longrightarrow Ir(Cl)(CO)(PMe_3)_2R \xrightarrow{RX} Ir(Cl)(CO)(PMe_3)_2(R)(X) + R\bullet \quad (17)$$

In other cases, non-chain radical reactions have been suggested (*see* ***Paramagnetic Organometallic Complexes***).

2.3 Dissociative Processes

Considerable data have now been obtained that show that dissociative processes are possible for square-planar, 16-electron, organometallic complexes.[20] Ligand substitution reactions of *cis*-PtR_2S_2 (R = Me, Ph; S = SMe_2, $S(O)Me_2$) use the strong labilizing effects of Me and Ph groups to proceed through 14e$^-$ intermediates.[20]

The primary evidence cited has been: (1) positive values for the volume of activation, (2) independence of the rate on the nature of the entering group, (3) saturation kinetics, (4) identical rates for dissociation and solvent exchange, and (5) positive values for the entropy of activation.[20]

Dissociative reactions for square-planar organometallic complexes may be more important than for square-planar coordination complexes because a strong donor ligand is important to facilitate dissociation. The characteristics of dissociative processes are quite different from associative reactions. Lack of dependence on the nature of the incoming ligand is shown in the replacement of DMSO from *cis*-$Pt(Ph)_2(DMSO)_2$ with chelating diphosphines.[21] For both dppe and *o*-phen, the rate constant is 2.0 s^{-1}. Such dissociative processes also have a very small solvent dependence.[21]

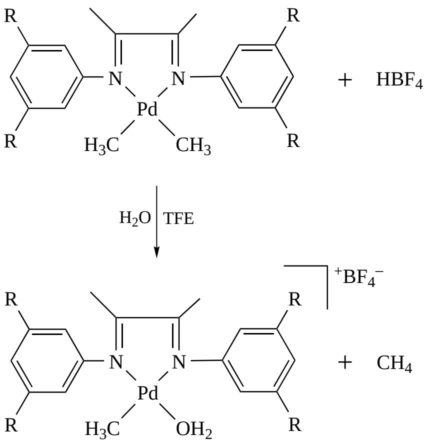
Dissociation of ligands from square-planar complexes is also important in ligand redistribution reactions of square-planar complexes:[22,23]

$$Ir(CO)(Cl)L_2 + Ir(CO)(Me)L'_2 \rightleftharpoons Ir(CO)(Cl)LL' + Ir(CO)(Cl)L'_2 + Ir(CO)(Me)LL' + Ir(CO)(Me)L_2 \quad L,L' = \text{phosphine ligands} \quad (18)$$

Phosphine ligand dissociation offers the most reasonable explanation for such redistribution reactions.

Most recently, square-planar organometallic complexes of Pd(II) and Pt(II) have been reported whose

reactivity incorporates almost all of the reaction pathways discussed in this section (i.e. associative and dissociative ligand exchange, oxidative addition, reductive elimination, and redistribution).[24] Thus, the N,N'-diaryl-α-diimine Pd(II)dimethyl complexes, $({}^{t\mathrm{Bu_2Ar}}\mathrm{DAB^{Me}})\mathrm{PdMe_2}$ and $({}^{\mathrm{(CF_3)_2Ar}}\mathrm{DAB^{Me}})\mathrm{PdMe_2}$ (${}^{t\mathrm{Bu_2Ar}}\mathrm{DAB^{Me}}$ = ArN=C(CH_3)-C(CH_3)=NAr, Ar = 3,5-di-*tert*-butylphenyl; ${}^{\mathrm{(CF_3)_2Ar}}\mathrm{DAB^{Me}}$, Ar = 3,5-bis(trifluoromethyl)phenyl) undergo protonolysis with HBF_4 in trifluoroethanol to form cationic complexes presumably via protonation at the metal followed by reductive elimination:



(19)

This complex then undergoes reaction with benzene and a second elimination of methane in a reaction where C–H bond cleavage is rate determining ($K_H/K_D = 4.1$) and which is inhibited by water. The final products are biphenyl and a bis-aquo complex presumably formed by a redistribution reaction of an aquo-phenyl complex followed by reductive elimination of biphenyl and by oxidation by O_2 of the resulting Pd^o complex (equation 20).

This chemistry not only illustrates the extension of the reactivity of $16e^-$ complexes but also represents an alternative to more conventional routes for catalytic C–H activation, where the more accessible Pd^o/Pd(II) couple replaces the Pt(II)/Pt(IV) couple.[24]

3 18-ELECTRON COMPLEXES

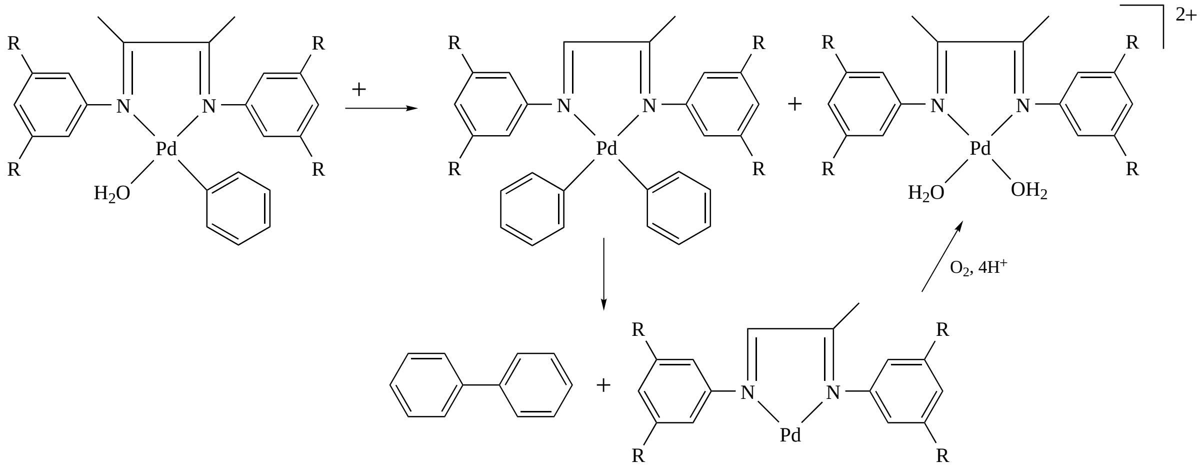
The majority of organometallic complexes contain 18 electrons (*see* ***Bonding Energetics of Organometallic Compounds***). These complexes undergo ligand substitution, reductive elimination, and electron-transfer reactions (*see* ***Electron Transfer in Coordination Compounds***). Each type of reaction will be covered in the following sections.

Understanding the reactivity of organometallic complexes requires an understanding of ligand bonding. While a full description of the bonding of organometallic ligands is inappropriate in this section, a summary of the σ donation, π acceptance, and size of typical ligands will be very useful to the discussion. There has been much discussion in the literature about the relative amounts of π- and σ-bonding in a given ligand. The separation of these two contributions is a daunting task but two recent studies have used computational and experimental techniques to help define the relative π- and σ-bonding parameters for phosphines and related ligands.[25,26] On the basis of the semi-empirical method known as QALE (Quantitative Analysis of Ligand Effects) the σ-donating abilities of phosphine and related ligands have been estimated:

$$\mathrm{P}(i\text{-Pr})_3 > \mathrm{P(Me)_3} > \mathrm{P(Ph)_3} > \mathrm{N(R)_3} > \mathrm{PH_3} > \mathrm{P(OMe)_3} > \mathrm{P(OPh)_3} > \mathrm{PF_3} > \mathrm{CO}$$

and for π acceptance:

$$\mathrm{PF_3} \gg \mathrm{PCl_3} > \mathrm{P(OPh)_3} > \mathrm{PH_3} > \mathrm{P(OMe)_3} > \mathrm{PPh_3} > \mathrm{P(Me)_3}$$



(20)

Table 4 Chromium–PPh_3 bond lengths for different trans ligands

Ligand trans	Cr–PPh_3 bond length (Å)
PBu_3	2.345(3)
$P(OMe)_3$	2.362(2)
$P(OPh)_3$	2.393(1)
CO	2.422(1)

On the basis of QALE alkyl phosphines, PR_3 function only as strong donors.[25] For these ligands, the most accurate statement is that alkyl phosphines have orbitals that may accept electron density. For aryl phosphines such as PPh_3, however, π acceptance may be significant. The most straightforward evidence is from the Cr–PPh_3 bond lengths of *trans*-$Cr(CO)_4LPPh_3$ [L = PBu_3, $P(OMe)_3$, $P(OPh)_3$, CO] (Table 4).[7] The shortening of the Cr–PPh_3 bond as the donor strength of the trans ligand increases is most easily accommodated in terms of π acceptance by PPh_3. However, it should be pointed out that DFT calculations have recently shown that there is no correlation between calculated bond dissociation energies and metal phosphorous bond lengths in this type of complex. Any discussion of the electronic binding of these ligands to an organometallic center is complicated by steric interactions of the rather bulky phosphine and phosphite ligands.[25] The relative size of the ligands is as follows:[25,27]

$$P(^tBu)_3 > P(Cy)_3 > P(^nBu)_3 > P(OPh)_3 > P(OMe)_3 > P(Me)_3 > CO$$

Each of these ligand parameters is important in discussing reactivity of organometallic compounds. As we investigate reactions of organometallic complexes, we shall often refer to σ-bonding ability, π-accepting ability, or size of the ligand.

3.1 Substitution Reactions

3.1.1 Mononuclear Metal Carbonyls

Most studies of organometallic substitution reactions have been accomplished on transition metal-carbonyl complexes (*see* ***Carbonyl Complexes of the Transition Metals***). These complexes are readily prepared and purified, are stable, and have very characteristic IR spectra that allow quantitative analysis. The reactions can be represented by

$$M(CO)_n + L \longrightarrow M(CO)_{n-1} + CO \qquad (21)$$

where M is a transition metal and L is an entering ligand, usually a phosphine or phosphite. Two examples among the first to be investigated kinetically were $Ni(CO)_4$ and $Mn(CO)_5Br$:[28,29]

$$Ni(CO)_4 + L \longrightarrow Ni(CO)_3L + CO \qquad (22)$$

$$Mn(CO)_5Br + L \longrightarrow cis\text{-}Mn(CO)_4LBr + CO \qquad (23)$$

Kinetic data indicate that the rate law is independent of the concentration of L and first order in metal-carbonyl complex:

$$\text{rate} = k_1[Ni(CO)_4] \qquad (24)$$

The accepted mechanism involves rate-determining CO dissociation from the 18-electron complex to form a 16-electron intermediate:

$$Ni(CO)_4 \xrightarrow{k_1} Ni(CO)_3 + CO \qquad (25)$$

$$Ni(CO)_3 + L \xrightarrow{\text{fast}} Ni(CO)_3L \qquad (26)$$

such that the substitution can be considered to be a two-step process. The second step (equation 26) is much more rapid, occurring at a rate of $10^6\,M^{-1}\,s^{-1}$, in contrast to the first step (equation 25), which occurs at a rate of $10^{-4}\,s^{-1}$.[12] The activation parameters are in agreement with a dissociative process that has a positive entropy of activation, as shown in Table 5.[28]

Substitution of several metal-carbonyl complexes $Cr(CO)_6$ and $Mn(CO)_5$(amine) show a small dependence on the nature and concentration of the entering ligand. Under pseudo-first-order conditions, the rate laws for these substitutions have two terms, as shown for $Cr(CO)_6$ (as for some substitution reactions with $16e^-$ complexes, see equation 5). The second-order term was always much smaller than the first-order term.[30,31] A mechanism that ascribes the second-order term to dissociative interchange (I_d) has been suggested for the $Mo(CO)_5Am$ system (Am = amine) and involves a solvent-encased substrate and a species occupying a favorable site for exchange.[31] Thus, the body of evidence for the simple metal carbonyls indicates that CO dissociation and is the mechanism of ligand substitution reactions.

Metal Effects on Metal-carbonyl Reactivity. The effect of the metal center on organometallic reactivity is not as clearly defined as for coordination complexes. We will examine: (a) the effect of charge, (b) first-row, second-row, and third-row effects and (c) the effect of d-electron count. As will be discussed in Section 4.1, the enhanced reactivity of odd-electron complexes is a major effect of the metal center.

(a) *Effect of Charge*. The effect of charge on metal–carbon monoxide bonding has been frequently examined, with the extent of π acceptance being greater as the charge on

Table 5 Activation parameters for the reaction of $Ni(CO)_4$ with nucleophiles

L	ΔH‡ (kcal mol^{-1})	ΔS‡ (cal K^{-1} mol^{-1})	k (10^{-4} s^{-1}) at 20 °C
PPh_3	24	13	50
$C^{18}O$	24	14	52

the metal is lowered. The effect of charge on reactivity is not as clear. $V(CO)_6^-$, $Cr(CO)_6$, and $Mn(CO)_6^+$ are relatively inert to CO dissociation. Similarly, $Mn(CO)_5^-$ and $Fe(CO)_5$ are relatively inert, though the fact that $Co(CO)_5^+$ is unknown may indicate that it would have considerable reactivity. The best indication of the expected effect of charge on reactivity is in the greater reactivity of $Ni(CO)_4$ than $Co(CO)_4^-$ (ready substitution versus no reaction in 48 h).[32]

The failure (in many cases) to see the expected large increase in rate of CO loss with increase in negative charge must indicate that the destabilization of the ground state is negated by a similar destabilization of the transition state. This suggests that the effect of charge on the bonding of CO in the 16-electron transition state for CO dissociation is similar to that for the 18-electron ground state.

(b) *Row Effects*. In general, the reactivity is greatest for the second-row metal and least for the third-row metal. This order is different from the order of reactivity observed for classical coordination complexes, for which the reactivity decreases down a row for analogous complexes. The change of reactivity across a row has not been examined to any significant extent. The order of reactivity, $Ni(CO)_2L_2 > Cr(CO)_4L_2 > Fe(CO)_3L_2$ (L = CO, phosphine base), does not correlate with effective nuclear charge or steric considerations.[33] Further, M–L distance does not correlate with the reactivity toward dissociative loss of L,[33] as shown in Table 4.

(c) *Electronic Effects*. The metal-carbonyl compounds offer the best comparative data on rates of reactions:[33]

$$\begin{array}{lcccc} \text{Complex} & Co(CO)_4, & Mn(CO)_5 > & V(CO)_6 > & Ni(CO)_4, \\ \text{d electrons} & d^9 & d^7 & d^5 & d^{10} \end{array}$$

$$\begin{array}{ccc} Ti(CO)_3(P\text{–}P)_2 > & Cr(CO)_6 > & Fe(CO)_5 \\ d^4 & d^6 & d^8 \end{array} \qquad (27)$$

Table 6 is composed of dissociative reactions for quite different classes of compounds. These data indicate several features, which appear to be general. (i) Organometallic complexes with a d^{10} configuration are relatively labile. (ii) Complexes with a d^6 configuration are relatively inert. (iii) Dissociative reactivity apparently follows the order $d^{10} > d^4 > d^6 > d^8$ for a homologous series.

A comparison of analogous compounds shows no evidence that the observed dependence of the rate on the metal center arises from ground-state properties. Thus, a primary factor in the metal center reactivity is the transition state. This is similar to the conclusions regarding substitutional reactivity of classical coordination complexes, suggesting that similar interpretations may be possible.

Table 6 Rates of reactions at 30 °C for different organometallic complexes compared to the number of d electrons[33]

Compound	Rate	d Electrons
$CpMn(CO)_3$	Very slow at 140 °C	6
$CpV(CO)_4$	$4.7 \times 10^{-13}\ s^{-1}$	4
$Cr(CO)_6$	$1 \times 10^{-12}\ s^{-1}$	6
$Fe(CO)_3(PPh_3)_2$	$1 \times 10^{-11}\ s^{-1}$	8
$Cr(CO)_4(PPh_3)_2$	$5 \times 10^{-11}\ s^{-1}$	6
$CpRu(CO)_3Br$	$3 \times 10^{-10}\ s^{-1}$	6
$CpFe(CO)_2I$	$5 \times 10^{-8}\ s^{-1}$	6
$CpMo(CO)_3I$	$6.2 \times 10^{-8}\ s^{-1}$	4
$Ni(P(OEt)_3)_4$	$1.0 \times 10^{-6}\ s^{-1}$	10
$Ti(CO)_3$		
$Ni(CO)_4$	$1 \times 10^{-2}\ s^{-1}$	10

Stereochemistry of CO Dissociation. If a complex has nonequivalent CO groups, the stereochemistry of the dissociative process can be defined. This has prompted many studies of exchange reactions with $Mn(CO)_5Br$.[34] Substitution reactions always lead to *cis*-$Mn(CO)_4LBr$,[29] but substitution products do not necessarily provide information on the site of CO dissociation. In an exchange reaction, the products must reflect the site of dissociation by the principle of microscopic reversibility. One would predict that the site of CO dissociation would be cis to the bromide in $Mn(CO)_5Br$ since each *cis*-CO (equatorial) is trans to CO and should not be as strongly π bonded as the axial CO, which is trans to Br. However, both the axial and equatorial positions were enriched when reacted with $C^{18}O$ or ^{13}CO:

$$Mn(CO)_5Br + {*CO} \longrightarrow Mn(CO)_n({*CO})_{5-n}Br + CO \qquad (28)$$

This rather surprising result is explained by recognizing that the 16-electron intermediate is five coordinate and could equilibrate the cis and trans carbonyls. A fluxional five-coordinate intermediate (*see Fluxional Molecule*) would allow for enrichment in the axial position without dissociation of the axial CO.[34] Thus, the stereochemistry of CO dissociation is consistent with expectations.

The extent of substitution depends on the size of the substituting ligand. A series of substitutions on $Mn(CO)_5Br$ have been studied for the effect of ligand size on the number of ligands that can be substituted and the geometry of substitution.[35] These data are shown in Table 7. The smaller ligands are able to substitute to a greater extent than the larger

Table 7 Complexes prepared by ligand substitution on $Mn(CO)_5Br$[35]

Complex	L
trans-$Mn(CO)_3L_2Br$	PPh_3, $P(OPh)_3$, $AsPh_3$
mer-$Mn(CO)_2L_3Br$	PMe_2Ph, PMe_3, $P(OMe)_2Ph$
trans-$Mn(CO)_2L_3Br$	$P(OMe)_3$, $P(OEt)_3$
trans-$Mn(CO)L_4Br$	$P(OMe)_3$

ones. Steric effects are certainly significant in complexes of this type.

Dissociation of Other Ligands. There have been relatively few studies of dissociation of ligands other than CO from organometallic complexes. Because many of the ligands are large, one must analyze the data in terms of size as well as σ- and π-bonding ability. Indeed, rates of L dissociation from NiL_4 correlate very nicely with ligand size, suggesting a dominant role for steric effects in dissociation of L from NiL_4:[36]

$$NiL_4 + L' \longrightarrow NiL_3L' + L \qquad (29)$$

This effect is readily understandable, because tetrasubstituted complexes should have very significant steric interactions. Steric interactions are also shown to be important in dissociations from *cis*-$Mo(CO)_4L_2$ complexes.[37]

A systematic investigation of ligand dissociation from chromium carbonyl complexes provided evidence regarding electronic effects. The complexes $Cr(CO)_5L$, *trans*-$Cr(CO)_4L_2$, and *trans*-$Cr(CO)_4LL'$ have been investigated for their reaction with carbon monoxide.[38] The order of Cr–L bond stabilities in $Cr(CO)_5L$ is:

$$\text{Cr–PBu}_3 \gg \text{Cr–P(OPh)}_3 > \text{PPh}_3 \approx \text{CO} > \text{AsPh}_3 > \text{py} \qquad (30)$$

which indicates that the strength of bonding ability is more significant than whether the bonding is σ or π in nature.[38] The order of bond energies for Cr–L bonds, where the ligand is bound to Cr^0 is remarkably similar to the order for *trans*-$MePt(PMe_2Ph)_2L^+$, where the ligand is bound to Pt^{II}.[39]

A trans effect (*see Trans Effect*) in octahedral metal-carbonyl substitution reactions was observed in the reactions of $Cr(CO)_4LL'$ with CO:[38]

$$trans\text{-Cr(CO)}_4\text{LL}' + \text{CO} \longrightarrow \text{Cr(CO)}_5\text{L} + \text{L}' \qquad (31)$$

The ordering of the trans effect on dissociation of PPh_3 and of $P(OPh)_3$ is identical: $PPh_3 > PBu_3 > P(OPh)_3 > P(OMe)_3 > CO$. Crystal-structure determinations showed no correlation between the Cr–PPh_3 or Cr–$P(OPh)_3$ bond lengths and rates of PPh_3 and $P(OPh)_3$ dissociation from *trans*-$Cr(CO)_4LL'$.[38] Thus, the rate acceleration by L from $Cr(CO)_4LL'$ does not arise by a ground-state destabilization, for that would be manifested by a lengthening of the Cr–L′ bonds. Rather, a transition state stabilization by L is indicated. A stabilization of the 16-electron intermediate $Cr(CO)_3$(*o*-phen) by electron-releasing *o*-phenanthroline ligands was noted a number of years ago.[40] This simple concept is also applicable to cis labilization of CO dissociation, to the trans effect noted for dissociation from $Cr(CO)_4LL'$, and probably generally to organometallic substitution reactions that proceed through unsaturated intermediates. To completely understand the effect of a ligand on either stereochemistry or reactivity for a given reaction, one must consider both ground and transition state effects. In cis labilization, the increased reactivity arises by stabilization of the 16-electron intermediate attributable to the presence of a donating ligand. The cis stereospecificity results from a stronger M–CO bond trans to the donor ligand (a ground-state effect). A complete interpretation of substitution reactions of metal-carbonyl complexes requires knowledge of site specificity, of steric effects in both the ground and transition states, and of the ground-state bond energies; but the gross effects, especially in a series of complexes, can be accounted for in terms of a stabilization of the electron-deficient transition state by electron-donating groups.

3.1.2 Ligand Substitution Reactions on Alkyl Complexes

Alkyl complexes (*see Alkyl Complexes*) undergo ligand substitution processes:

$$\text{MeMn(CO)}_5 + \text{L} \longrightarrow \text{MeMn(CO)}_4\text{L} + \text{CO} \qquad (32)$$

similar in stoichiometry to other substitution reactions. An important difference is that in many reactions of this type an acyl intermediate is observed:

$$\text{MeMn(CO)}_5 + \text{L} \longrightarrow \text{MeC(O)Mn(CO)}_4\text{L} \longrightarrow \text{MeMn(CO)}_4\text{L} + \text{CO} \qquad (33)$$

Reactions of this type are termed alkyl migration (*see Alkyl Migration*). These reactions are very important in several catalytic reactions, such as hydroformylation, methanol carbonylation, and homogeneous CO reduction (*see* ***Carbonylation Processes by Homogeneous Catalysis***).

Kinetics and Rate Law. The rate is dependent on the concentration of the metal complex and on the entering ligand.[2] The rate law that best accommodates the observations is

$$\text{rate} = \frac{k_1k_2[\text{L}][\text{RM}]}{k_{-1} + k_2[\text{L}]} \qquad (34)$$

The mechanism most consistent with this rate law involves a rapid preequilibrium as represented for $RMn(CO)_5$:

$$\text{RMn(CO)}_5 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{RC(O)Mn(CO)}_4]$$

$$\text{RC(O)Mn(CO)}_4 \xrightarrow[\text{L}]{k_2} \text{RC(O)Mn(CO)}_4\text{L} \qquad (35)$$

followed by the reaction of the 16-electron acyl intermediate with L.

The rate of carbonylation on the alkyl group has been shown to depend on the electron-withdrawing ability of the R group.[41] The results of the carbonylation of substituted methylmanganese pentacarbonyl complexes are shown in Table 8. The presence of an electron-withdrawing R group

Table 8 Rates of carbonylation for a series of substituted methylmanganese pentacarbonyl complexes at 30 °C in β,β'-diethoxydiethyl ether[42]

$RCH_2Mn(CO)_5 + CO \longrightarrow RCH_2C(O)Mn(CO)_5$

R	$10^5\,k$ ($M^{-1}\,s^{-1}$)
Et	14 000
Me	12 000
Cy	2500
H	1200
MeO	25
Ph	12
HOC(O)	<5

dramatically slows the rate, most likely by affecting the preequilibrium.

Stereochemical Considerations. Much attention has been directed toward the stereochemistry of substitution reactions of alkyl complexes. Substitution of $MeMn(CO)_5$ leads to *cis*-$MeC(O)Mn(CO)_4L$ initially, although the cis complex isomerizes to the trans eventually:

$$MeMn(CO)_5 + L \longrightarrow cis\text{-}MeC(O)Mn(CO)_4L \xrightarrow{\text{slow}} trans\text{-}MeC(O)Mn(CO)_4L \quad (36)$$

The stereochemistry of substitution reactions does not necessarily provide information on the stereochemistry of the intermediates. In this case, however, the formation of a kinetically stable product, *cis*-$MeC(O)Mn(CO)_4L$, indicates that the substitution reaction probably does provide stereochemical information. This is confirmed by carbonylation with ^{13}CO, which leads exclusively to *cis*-$MeC(O)Mn(CO)_4(^{13}CO)$. A more difficult question to answer is whether the methyl group migrates to a CO or whether a CO inserts into the Me–Mn bond. These processes are termed methyl migration and CO insertion (*see CO Insertion*), respectively. The distinction between these two is based on which group is moving during formation of the 16-electron acyl intermediate. The body of evidence shows that alkyl migration is the reaction occurring.[2]

Reaction of optically active alkyl groups shows that the carbonylation proceeds with retention of configuration at the carbon:[43]

$$Me_3CC(H)(D)C(H)(D)FeCp(CO)_2 + PPh_3 \longrightarrow Me_3CC(H)(D)C(H)(D)C(O)FeCp(CO)PPh_3$$

$$[threo\text{-}3,3\text{-dimethylbutyl-}1,2\text{-}d_2](Cp)\text{dicarbonyliron} + PPh_3 \longrightarrow [threo\text{-}4,4\text{-dimethylpentanoyl-}2,3\text{-}d_2](Cp)\text{carbonyltriphenylphosphineiron} \quad (37)$$

This suggests that the C–Fe bond remains intact as the C–C bond forms, consistent with the results of an extended Hückel calculation of the reaction coordinate for migration of Me in $MeMn(CO)_5$.[44]

Table 9 Kinetic data for alkyl migration reactions[44]

Lewis acid	k_{obs} (s^{-1})
None	2×10^{-6}
$AlClEt_2$	0.37
$AlCl_2Et$	10
$AlCl_3$	170

Alkyl migration is catalyzed by the presence of Lewis acids, such as $AlCl_3$. The effects of several Lewis acids are shown in Table 9.[44] As shown by the data, a Lewis acid can accelerate the methyl migration by a factor of 10^8.

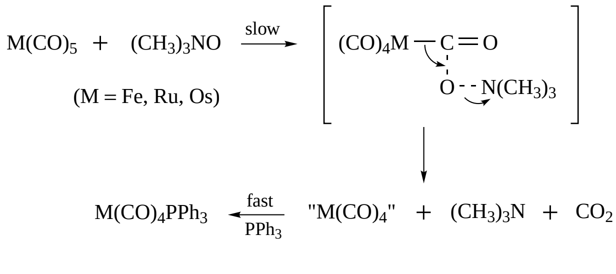
To summarize the results on substitution of alkyl complexes:

- A preequilibrium exists between the 18-electron alkyl carbonyl complex and a 16-electron acyl, which probably is solvent coordinated.
- The rate of migration depends on the electron-withdrawing ability of the alkyl group, with the more electron-withdrawing groups reacting more slowly.
- More nucleophilic entering ligands accelerate the reaction.
- The reaction proceeds by alkyl migration as the carbanion.
- The migration may be catalyzed by Lewis acids.

Recently, it has been shown that inclusion of (η^5-methylcyclopentadienyl)$Fe(CO)_2Me$ into cyclodextrins allows phosphine substitution to take place both thermally and photochemically without CO insertion/alkyl migration. This compound normally undergoes an irreversible alkyl migration to give the corresponding acyl derivative exclusively. The use of the cyclodextrin inclusion complexes may provide a general method circumventing the alkyl migration.[45]

3.1.3 *Ligand Substitution of Lightly Stabilized Ligands on Mononuclear Carbonyls*

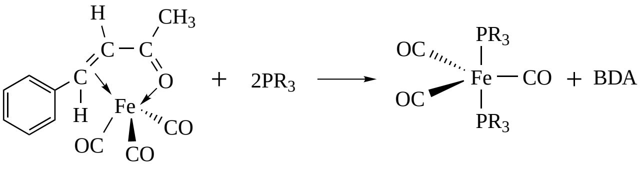
The importance of phosphine ligands to organometallic chemistry has prompted the development of synthetic methodologies that allow more precise control of the degree of substitution via the use of lightly stabilized or labile ligands rather than the direct thermal or photochemical substitution of phosphine for CO. These methods include the use of O-atom transfer reagents such as trimethylamine-N-oxide where one mole of CO is oxidized per mole O-atom transfer reagent and where a labile ligand such as acetonitrile replaces each oxidized CO prior to reaction with the phosphine or the other nucleophile (equation 54).[46] In the absence



(38)

of the intermediate labile ligand, the reaction is first order in the carbonyl complex, first order in amine oxide, and zero order in phosphine. The mechanism is thought to involve nucleophilic attack on the carbon of the coordinated carbonyl to create the good leaving group, CO_2, followed by rapid reaction of the phosphine or the labile ligand with the $16e^-$ complex (equation 38). The order of reactivity for mononuclear metal carbonyls is W > Mo > Cr and Os > Ru > Fe with the former triad being much less reactive than the latter. This general trend is in agreement with the overall trend that carbonyl complexes with higher infrared stretching frequencies are less reactive towards nucleophiles. The activation parameters for the iron triad all show negative entropies of activation and activation enthalpies in the range of 10–15 kcal mol^{-1}. As expected, good hydrogen bonding solvents, such as ethanol, tend to slow the reaction down by bonding to the negatively polarized oxygen on the O-atom transfer reagent.

The labile bidentate ligand, benzylidene acetone (BDA) has been extensively employed in substitution reactions for mononuclear carbonyl complexes. In particular, the reactions of (BDA)$Fe(CO)_3$ with trialkyl phosphines to give *trans*–$(PR_3)_2Fe(CO)_3$ have allowed detailed and quantitative investigations of the enthalpies of the reactions as a function of the steric and electronic nature of the phosphines employed (equation 39).[47,48]



(39)

The enthalpies of this reaction become more negative in the order PPh_3 < PCy2Ph < PCyPh2 < PCy3 < PiPr3 < PPh2Et < PBz3, suggesting that both steric and electronic factors play a role in the formation of these bis phosphines. A QALE treatment of the thermochemical data revealed that the electron-donating parameter, χ is generally dominant but that the reaction has a steric threshold where phosphines with cone angles >135° exhibit a significant steric effect on the thermodynamic stability of the disubstituted complex.[47] In a related study, using isosteric phosphines of the type $(p\text{-}XC_6H_4)_3P$ (X = H, CH_3O, CH_3, Cl, F, CF_3), it was shown that, indeed, the electronic factor is the more important factor in determining the enthalpy of this reaction (equation 39).[48]

3.1.4 Metal-carbonyl Dimers and Clusters

Substitution reactions on metal-carbonyl dimers (*see* ***Dinuclear Organometallic Cluster Complexes***) and clusters (*see* ***Polynuclear Organometallic Cluster Complexes***) occur by replacement of a CO with an entering ligand:

$$Mn_2(CO)_{10} \xrightarrow{+L,\ -CO} Mn_2(CO)_9L \xrightarrow{+L,\ -CO} Mn_2(CO)_8L_2 \qquad (40)$$

$$Fe_3(CO)_{12} \xrightarrow{+L,\ -CO} Fe_3(CO)_{11}L \qquad (41)$$

There are three features that are different for metal–metal bonded systems than for mononuclear complexes: possible substitution at different metals, fragmentation, and the effect of the metal–metal bond on reactivity.

Metal-carbonyl Dimers. The reactions that have been most often studied are those of the group 7 dimers, $Mn_2(CO)_{10}$, $Tc_2(CO)_{10}$, $Re_2(CO)_{10}$, and $MnRe(CO)_{10}$. Kinetic studies on these dimers show the rate law:

$$\text{rate} = (k_1 + k_2[L])[M_2(CO)_{10}] \qquad (42)$$

where the k_2 term is much smaller than the k_1 term. This rate law is identical to that seen for substitution at $Cr(CO)_6$ and is best ascribed to a dissociative interchange mechanism. Considerable controversy has existed over whether the mechanism involves CO dissociation or homolytic cleavage of the metal–metal bond. The ability to distinguish between the two metal centers in $MnRe(CO)_{10}$ added mechanistic information that ruled out Mn–Re bond homolysis for substitutions on this complex.[49]

The ultimate experiment to differentiate between metal–metal bond homolysis and other routes was performed for $Re_2(CO)_{10}$.[50] Two complexes with different rhenium isotopes were prepared ($^{185}Re_2(CO)_{10}$ and $^{187}Re_2(CO)_{10}$) for use in substitution and exchange reactions. No mixed-isotopic species were observed after several half-lives under the reaction conditions, ruling out the metal–metal bond homolysis mechanism in thermal substitution and CO exchange reactions of $Re_2(CO)_{10}$. The metal isotopes are not available for manganese, but similar reactions of $Mn_2(CO)_{10}$ and $Mn_2(^{13}CO)_{10}$ are fully consistent with CO dissociation and inconsistent with metal–metal bond cleavage. Substitution of $MnRe(CO)_{10}$ leads to predominantly the rhenium isomer $(CO)_5MnRe(CO)_4L$. Comparing the reactivities of $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$ and analogous mononuclear complexes of manganese and rhenium, one would anticipate that CO dissociation from manganese would occur at a rate about 100 times greater than from rhenium.[49] It has been suggested that CO dissociates from the manganese and that the intermediate/transition state contained a bridging CO such that the unsaturation at one metal center was shared by the other metal. The incoming ligand would then attack at the most favorable site, which for steric reasons would be the rhenium. A mass spectral study of $(CO)_5MnRe(^{13}CO)_5$ has shown preferential loss of CO from manganese.[51]

Substitution reactions of $Co_2(CO)_8$ show more variation than the group 7 dimers. Reaction with ^{13}CO, $AsPh_3$, and H_2 show a rate law that is independent of the concentration of the incoming nucleophile at temperatures from −15 to 30 °C.[52] The activation parameters ($\Delta H\ddagger = 22$ kcal mol^{-1} and $\Delta S\ddagger = 10$ cal K^{-1} mol^{-1}) and the lack of dependence on

the incoming ligand are consistent with CO dissociation:

$$Co_2(CO)_8 \longrightarrow Co_2(CO)_7 + CO \xrightarrow{AsPh_3,\ rapid} Co_2(CO)_7AsPh_3 \quad (43)$$

Substitution of $Co_2(CO)_8$ by phosphines is quite different:

$$Co_2(CO)_8 + 2PR_3 \longrightarrow [Co(CO)_3(PR_3)_2]^+[Co(CO)_4]^- + CO \quad (44)$$

leading to ionic products at rates that are more rapid than CO dissociation and that depend on the concentration and the nucleophilicity of the entering ligand. In addition, the apparent order with respect to $Co_2(CO)_8$ varies within the range 1.0–1.5, depending on the reaction conditions. A radical-chain mechanism has been suggested to account for these observations in the substitution of phosphine bases on $Co_2(CO)_8$.[52] Thus, two distinct mechanisms exist for $Co_2(CO)_8$: a CO dissociative route for reaction with weak nucleophiles and a radical-chain pathway for reaction with strong nucleophiles.

Transition Metal Clusters. Reactions of Lewis bases with metal clusters may yield either mononuclear or polynuclear products. Substitution reactions on $Fe_3(CO)_{12}$ represent the features that may be seen. Reaction with L at 50 °C leads to substituted metal clusters, but reaction at 80 °C produces substituted mononuclear fragments:[2]

$$Fe_3(CO)_{12} + nL \xrightarrow{50\,^\circ C} Fe_3(CO)_{12-n}L_n + nCO \quad (45)$$

$$Fe_3(CO)_{12} + L \xrightarrow{80\,^\circ C} Fe(CO)_4L + Fe(CO)_3L_2 \quad (46)$$

The ruthenium and osmium analogs have less tendency to fragment, presumably because of the stronger metal–metal bonds.

Substitutions on $Ir_4(CO)_{12}$ and derivatives have been thoroughly studied cluster reactions:[53–59]

$$Ir_4(CO)_{12} + nL \longrightarrow Ir_4(CO)_{12-n}L_n + nCO \quad (47)$$

The product observed depends on the reaction conditions and on the ligand L. The rate law observed has two terms:

$$\text{rate} = (k_1 + k_2[L])[Ir_4(CO)_{12}] \quad (48)$$

This rate law is of the same form as that seen for substitutions on other metal-carbonyl complexes, but the relative values of the two terms are very different from those observed in other systems. The ligand-dependent term predominates for ligands that are reasonably good nucleophiles, such as CNR, PBu_3, PPh_3, and $P(OPh)_3$. The relative values of k_2 show a strong dependence on the nucleophilicity of the entering ligand, indicating nucleophilic attack on the metal complex.

As the tetrairidium cluster is substituted, some changes are noted. Substitution on $Ir_4(CO)_{11}L$ (L = PPh_3, $P(OPh)_3$, and $AsPh_3$) occurs by a primarily ligand-independent mechanism, probably CO dissociation. For more nucleophilic entering ligands (PBu_3, CN-*t*-Bu), the ligand-dependent path still predominates. The CO dissociation rates from $Ir_4(CO)_{11}L$ show the same trends with changes in L as mononuclear complexes and metal-carbonyl dimers.

In metal clusters that are more highly substituted with phosphines, ligand steric effects may be significant. The rates of phosphine dissociation from $Ir_4(CO)_8L_4$ show evidence of a steric effect:[58,59]

$$Ir_4(CO)_8L_4 + CO \longrightarrow Ir_4(CO)_9L_3 + L \qquad L = PMe_3, PEt_3, PBu_3 \quad (49)$$

The steric interactions in $Ir_4(CO)_8(PMe_3)_4$ are sufficient to cause an elongated Ir–Ir bond.[59]

Mixed metal clusters (clusters containing two different metals) have considerable potential for mechanistic studies. Three separate studies on iron–ruthenium clusters show the possibilities.[60–62] Reactions of $FeRu_2(CO)_{12}$ and $Fe_2Ru(CO)_{12}$ in comparison to $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ show a very interesting activation of the iron center towards CO dissociation by ruthenium centers in the mixed metal-cluster system.[60] Such an activation of the iron center by ruthenium has also been demonstrated for (μ-H)$FeRu_2$(μ-COMe)$(CO)_{10}$.[61] The presence of different metal centers for $H_2FeRu_3(CO)_{12}$ allowed unusually detailed interpretation of the isomerization, substitution, and CO exchange reactions.[62,63]

It is rather surprising that the clusters thus far investigated show the same basic mechanistic features as mononuclear complexes. The primary reaction mode seen is CO dissociation, although large metals are susceptible to nucleophilic attack at the metal.

An interesting case in point where a high nuclearity cluster shows a distinct change in mechanism depending on the steric requirements of the incoming ligand is $Ru_5C(CO)_{15}$.[64] Phosphine ligands with cone angles of <133° show a two-step reaction mechanism, where an intermediate adduct can be detected spectroscopically:

$$Ru_5C(CO)_{15} + L \xrightarrow{k_{+L}} Ru_5C(CO)_{15}L$$

$$Ru_5C(CO)_{15}L \xrightarrow{k_{-CO}} Ru_5C(CO)_{14}L + CO \quad (50)$$

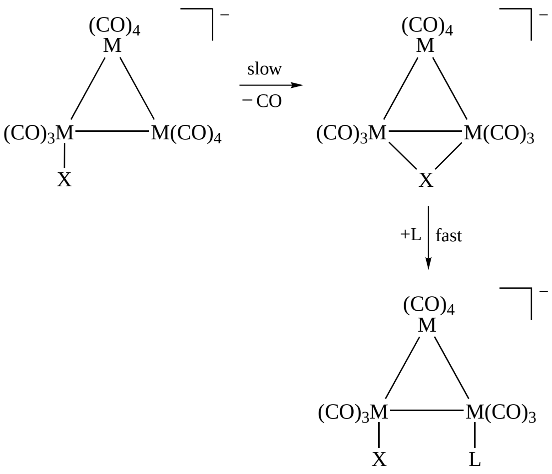
Ligands with cone angles >136° show a single-step reaction mechanism:

$$Ru_5C(CO)_{15} + L \xrightarrow{k_2} Ru_5C(CO)_{14}L \quad (51)$$

This distinct switch in the intimate mechanism in response to the steric requirements of the incoming ligand represents a more extreme example of the earlier studies with the tetrairidium clusters and is thought to arise from the ability of this cluster to open to a bridged butterfly structure on adduct formation with the sterically less-demanding ligands.

Coordinately Unsaturated Clusters and Clusters with Hemilabile Ligands. As for mononuclear complexes, the use of lightly stabilized ligand–cluster complexes to afford more control over ligand substitution reactions under milder conditions is widespread.[65,66] For example, a huge literature exists on the use of $M_3(CO)_{10}L_2$ (M = Ru, Os, L = CH_3CN, cyclooctene) for ligand substitution reactions with phosphines as well as alkynes amines and nitrogen heterocycles.[65,66] Recent kinetic studies on the cluster $Rh_6(CO)_{15}L$, where L = the 'lightly bonded ligands' CH_3CN, THF, DMSO, cyclooctene, and ethanol revealed that the reactions of these complexes are primarily dissociative in nature (I_d) and in some cases require stabilization of the intermediate $Rh_6(CO)_{15}$ by solvent or additional CO bridging.[67]

A distinctly different method of activating metal clusters towards precise ligand substitution is illustrated by the complexes $M_3(CO)_{11}X^-$ (M = Ru, Os, X = NCO, Cl, Br, I). Here, intramolecular nucleophilic attack by the metal coordinated halide or psuedohalide on a neighboring metal atom of the metal cluster promotes CO dissociation forming a bridged chloride intermediate, which then undergoes rapid reaction with the incoming ligand:[65,66]



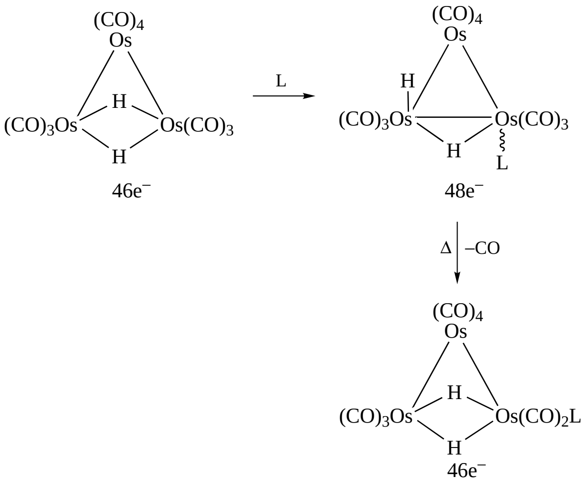
(52)

Kinetic studies have shown that the reaction is first order in cluster and zero order in incoming ligand.[68] The reaction can be carried out catalytically starting with the parent carbonyl cluster and [PPN]X and gives the monosubstituted cluster exclusively.[65,66] The intermediate bridging halide species has been isolated. An alternative catalytic path for obtaining the monosubstituted cluster is the electron-transfer-induced substitution using sodium benzophenone ketyl as the electron-transfer agent.[69]

Coordinately unsaturated clusters are defined as those species that do not obey the effective atomic number rule (EAN) according to the relationship:

$$\text{\# Electrons Required for an EAN Cluster} = 18(\text{\# Metal Atoms}) - 2(\text{\#M–M Bonds}) \qquad (53)$$

Thus, for a trinuclear cluster with three metal–metal bonds 48 electrons are required. By far the most well-studied group of coordinately unsaturated clusters are the trinuclear 46 electron species of which $Os_3(CO)_{10}(\mu\text{-}H)_2$ is the best-known example.[65] This complex undergoes facile ligand addition reactions with a wide variety of two-electron donors by an associative mechanism and subsequent thermolysis can result in reformation of the 46-electron cluster:



(54)

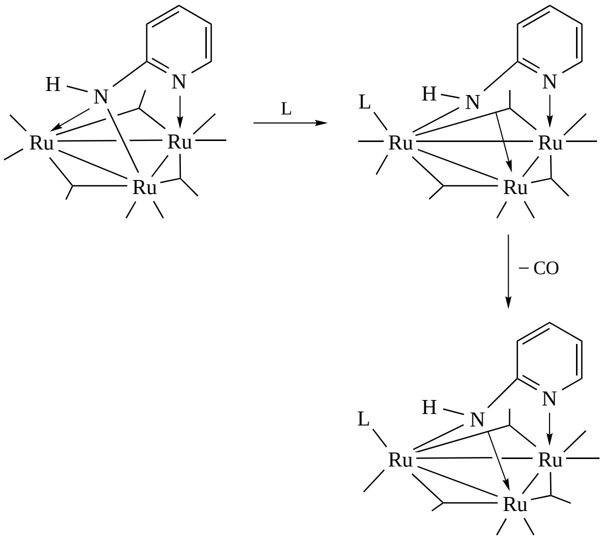
The mechanism of the ligand addition reactions are associative and a detailed kinetic study of the $Os_3(CO)_{10}(\mu\text{-}H)_2 + CO$ system revealed that both the addition of CO and its loss are both single-step concerted processes with the observed rate constant for the system as it approaches equilibrium being:[70]

$$Os_3(CO)_{10}(\mu\text{-}H)_2 + CO \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Os_3(CO)_{11}(\mu\text{-}H)H; \quad k_{obs} = k_{-1} + k_1[CO] \qquad (55)$$

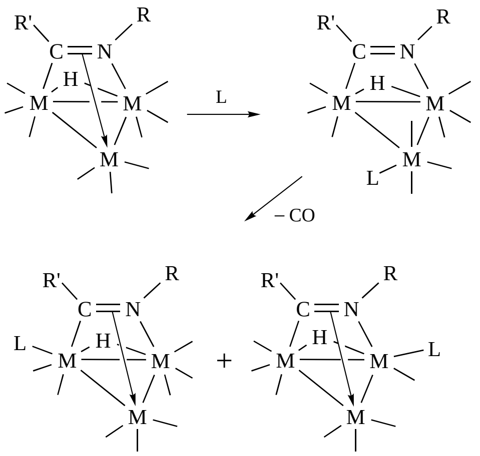
Unsaturated trinuclear clusters that undergo similar addition reactions are now known for diphosphine hydride and alkyne clusters of ruthenium[65,66] as well as for triosmium clusters containing nitrogen heterocycles.[71] In the case of the latter systems, the electronic unsaturation is communicated to the heterocycle and completely changes the regiochemistry of the organic ligand, a feature unique to this class of molecules. Coordinately unsaturated clusters that undergo ligand addition reactions are well known for higher nuclearity clusters[72,73] as well as for mixed metal clusters and binuclear clusters.[74]

Electron-precise (*see Electron Precise Compound*) metal clusters that undergo concerted associative ligand addition reactions have become increasingly common in metal-cluster chemistry. A common feature in many of these systems is a hemilabile face-capping ligand whose coordination is partially displaced by the incoming ligand and then recoordinates with loss of CO on subsequent thermolysis to give a substituted product. Two well-studied examples of trinuclear clusters containing ancillary hemilabile ligands

are $Ru_3(CO)_9(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-2-amino-pyridyl})$ and $M_3(CO)_9(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-imidoyl})$ (M = Ru, Os):[65,75]



(56)



(57)

Kinetic studies on the imidoyl complexes reveal strict second-order rate laws where the observed rate is related to the donor properties of the incoming ligand.[76]

3.1.5 Hydride Complexes

Hydride complexes (*see* ***Hydride Complexes of the Transition Metals***) are important in many reactions catalyzed by organometallic complexes, yet understanding of substitution reactions of hydrides is limited. Metal hydrides are quite sensitive to oxygen, and therefore difficult to study quantitatively. Another difficulty is that the presence of trace impurities leads to rapid reactions by radical-chain mechanisms. Most hydride complexes have been observed to undergo facile ligand substitution reactions, probably by radical reactions like those studied for $HRe(CO)_5$.[2] Under rigorously pure conditions, with the exclusion of light, $HRe(CO)_5$ showed no reaction with PBu_3 in 60 days at 25 °C.[77] When such care was not taken, the reaction yielded $HRe(CO)_4PBu_3$ and $HRe(CO)_3(PBu_3)_2$ at variable rates, and this was explained by a radical-chain process where hydrogen atom abstraction by an initiator produces the $Re(CO)_5{\bullet}$ radical that acts as a chain carrier. The latter undergoes rapid ligand substitution for CO and then abstracts a hydrogen.

Thus, the substitution reaction is catalyzed by trace impurities ($R^{\bullet}$), which initiate a self-perpetuating chain mechanism for substitution. Mechanisms of radical reactions will be discussed in Section 4.1.

Metal hydride complexes might undergo substitution by dissociative, associative, or hydride migration processes. Very few studies have been accomplished under conditions that clearly rule out radical mechanisms. The reactions of $HMn(CO)_5$ with L (L = ^{13}CO, $AsPh_3$, PPh_3, and PBu_3) have been carefully investigated and show dependence of the rate on the nature and concentration of the entering ligand.[78] The rates for different ligands are shown in Table 10. The dependence on the nature of the entering ligand is considerably greater than that observed for alkyl migration. At this point, there is no evidence favoring hydride migration over direct nucleophilic attack on the complex in substitution reactions of $HMn(CO)_5$.

The very rapid substitution reactions of hydride complexes $H_2Fe(CO)_4$ and $H_2Ru(CO)_4$ at −70 °C are interpreted in terms of hydride migration.[79]

More recently, the reactions of the of anionic carbonyl hydrides $HFe(CO)_4^-$, $HCr(CO)_5^-$, and $H(Cr(CO)_5)_2^-$ with phosphines and phosphites have been studied over a wide range of conditions.[80,81] Although no kinetic studies have been done, the reactions show significant sensitivity to the stereoelectronic properties of the incoming ligand and also to the nature of the anion. Thus, ligand substitution reactions are much slower when the cation is PPN^+ than with Na^+, and this is thought to be the result of an interaction between the Na^+ and a radial carbonyl (based on infrared studies) that labilizes the axial carbonyl. For the iron complexes in protic solvents, the major product of the reactions is *trans*-$H_2Fe(CO)_4(PR_3)_2$ (*trans*-referring to the phosphine ligands), while in aprotic solvents the major product is $Fe(CO)_3(PR_3)_2$. In the case of the chromium complexes, the major product is *trans*-$Cr(CO)_4(PR_3)_2$ under both photochemical and thermal activation along with the corresponding metal hydride salt. The reactions have been shown to proceed through the anionic monophosphine hydride derivatives in all cases and the most likely mechanism is proposed to involve an associative pathway. Substitution of the first phosphine is thought to

Table 10 Variation in the rate of substitution on $HMn(CO)_5$ with L = ^{13}CO, $AsPh_3$, PPh_3, and PBu_3 at 20 °C[78]

L	Rate ($M^{-1}\ s^{-1}$)
$^{13}CO^a$	1.2×10^{-3}
$AsPh_3{}^b$	3×10^{-4}
PPh_3	1.4×10^{-2}
PBu_3	Fast

^{a}At 26 °C. ^{b}At 28 °C.

weaken the hydride-transition metal interaction and to increase the counter ion hydride interaction, thus favoring hydride loss from the salt.[81]

3.2 Reductive Elimination

Reductive elimination (*see Reductive Elimination*) from an 18-electron complex is the reverse of oxidative addition to a 16-electron complex:

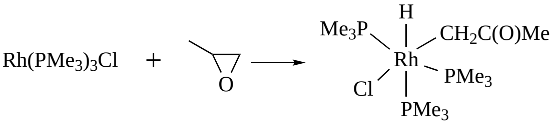
$$\text{CpIr(L)(R)(H)} \longrightarrow [\text{CpIrL}] + \text{R–H} \quad L = \text{CO, PMe}_3 \tag{58}$$

These reactions involve a decrease in the oxidation number of the metal (in this case Ir^{III} to Ir^{I}), and a decrease in coordination number for the metal. Reductive elimination reactions are very important in catalysis as the product-removing step. Frequently, the reductive elimination reactions are rapid, making detailed study difficult.

Our examples will first center on the complexes $Ir(CO)(R)(R')L_2X$ (R and R′ = H, alkyl, or alkoxy; L = PPh_3 or $P(p\text{-tolyl})_3$; X = halide or H), which reductively eliminate a number of different products. The reactions are summarized in Table 11. The reactions described in Table 11 show that reductive elimination from Ir^{III} results in formation of different types of bonds. These reductive elimination reactions occur under very similar conditions, indicating that the nature of R and R′ does not significantly affect the rate.[82–86] However, the coupling of two sp^3 carbon centers does not occur. Theoretical studies have suggested that the directionality of the sp^3 hybrid inhibits bond formation.[87,88]

Despite the fact that a coordination site is not formally required for reductive elimination reactions, ligand dissociation from the metal center apparently facilitates reductive elimination.[2] In the iridium examples described in Table 11, halide dissociation is important; in other examples, phosphine ligand dissociation is important.

Until recently, reductive elimination of alkanes from $18e^-$ complexes was not well studied. The reaction of $Rh(PMe_3)_3Cl$ with propylene oxide provides an early example:[89]



(59)

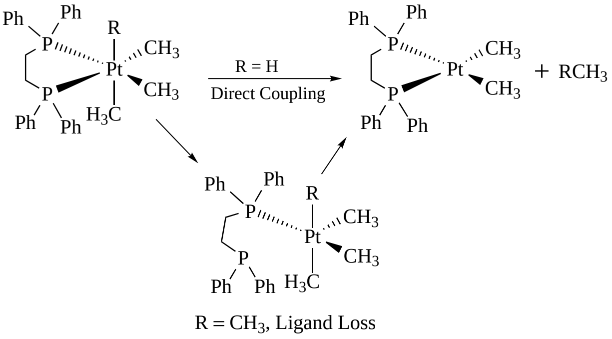
The stereochemistry was assigned from the ^1H and ^{31}P NMR spectra. Reductive elimination of acetone showed first-order kinetics, with $\Delta H‡ = 25.0\,\text{kcal mol}^{-1}$ and $\Delta S‡ = 5.3\,\text{cal K}^{-1}\,\text{mol}^{-1}$.[89]

$$cis\text{-RhH[CH}_2\text{C(O)Me](PMe}_3)_3\text{Cl} \longrightarrow \text{RhCl(PMe}_3)_3 + \text{MeC(O)Me} \tag{60}$$

The presence of PMe_3 inhibits the reaction. Mixtures of *cis*-$RhH(CH_2C(O)CH_3)(PMe_3)_3Cl$ and *cis*-$RhD(CD_2C(O)CD_3)(PMe_3)_3Cl$ led to only $CH_3C(O)CH_3$ and $CD_3C(O)CD_3$, showing that the elimination was intramolecular, which involved reversible dissociation of phosphine followed by an irreversible reductive elimination and reassociation of phosphine.[89]

More recently, the reductive elimination of alkanes from Pt(IV) complexes has become an intense area of investigation as it represents the reverse of the C–H oxidative addition reaction that has been shown to be catalytic in the presence of the Pt(II)/Pt(IV) couple.[90]

The mechanism of ethane and methane reductive elimination from the Pt (IV) complexes P_2PtMe_3R (P_2 = $Ph_2(CH_2)_2Ph_2$, *o*-$Ph_2C_6H_4Ph_2$, R = Me, H) has been thoroughly investigated and these studies revealed that ethane elimination occurs from a five-coordinate intermediate formed by partial dissociation of the chelating phosphine, while methane elimination occurs by the direct coupling without ligand loss:[91]



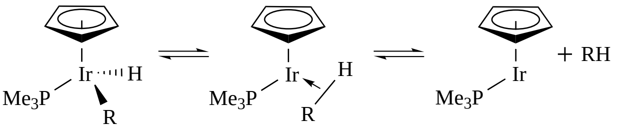
(61)

In a related study, the complex $Tp^{Me_2}Pt^{IV}(CH_3)_2H$ (Tp^{Me_2} = hydridotris(3,5-dimethyl pyrazolyl)borate) undergoes reductive elimination of methane, but here labeling studies revealed that the rate-determining step is loss of methane from an intermediate methane σ complex.[92] Following loss of methane, the $16e^-$ intermediate complex can be

Table 11 Reductive elimination reactions from $Ir(CO)(R)(R')L_2X$[82–86]

R	R′	X	Product (R–R′)
Me	H	H	CH_4
Me	H	Cl	CH_4
Ph	H	Cl	C_6H_6
OMe	H	H	MeOH
OMe	H	Cl	MeOH
Me	H	$Si(OMe)_3$	CH_4
OMe	$SiPh_3$	H	$Si(OMe)Ph_3$
Me	$SiMe_3$	I	$SiMe_4$
Me	C(O)Me	Cl	MeC(O)Me
OMe	C(O)Me	Cl	MeC(O)OMe
OH	Me	I	MeOH
OH	H	H	H_2O

trapped with R-D or with CD_3CN to give the corresponding alkyl-deuteride or nitrile complex respectively. The methane reductive elimination is reversible in this Pt(IV) system and an inverse isotope, which is characteristic for a reversible C–H activation, is observed. These results parallel the earlier work of Bergman *et al.* with Ir(III) aryl and alkyl complexes, which also exhibit first-order kinetics in complex and an inverse isotope effect:[93]



(62)

In a number of cases, dinuclear (*see Dinuclear* and ***Dinuclear Organometallic Cluster Complexes***) reductive elimination, in which two metal centers participate in the reaction, has been observed:[2]

$$Cp_2MH_2 + MeMn(CO)_5 \longrightarrow H_2 + CH_4 + Cp(CO)M[\mu\text{-}\eta^5, \eta^1\text{-}C_5H_4)]Mn(CO)_4 \qquad M = Mo, W \qquad (63)$$

$$CpMo(CO)_3H + CpMo(CO)_3R \longrightarrow RCHO + Cp_2Mo_2(CO)_4 + Cp_2Mo_2(CO)_6 \qquad (64)$$

The mechanism for the latter reaction was suggested to be:

$$RMoCp(CO)_3 \rightleftharpoons RC(O)MoCp(CO)_2 \xrightarrow{HMoCp(CO)_3}$$

$$RC(O){-}MoCp(CO)_2 \backslash H / Cp{-}Mo(CO)_3 \longrightarrow [CpMo(CO)_3]_2 + [CpMo(CO)_2]_2 + RCHO \qquad (65)$$

The reaction sequence is an alkyl migration that opens a coordination site for the bridging hydride, reductive elimination of aldehyde, and the combination of metal-carbonyl fragments to give the products, which have a metal single and triple bond, respectively, $Cp_2Mo_2(CO)_6$ and $Cp_2Mo_2(CO)_4$. The reactions of *cis*-$RMn(CO)_4L$ and *cis*-$HMn(CO)_4L$, where R = benzoyl derivatives and L = CO or $P(p\text{-}MeOC_6H_4)_3$, have been investigated.[94] Four distinct pathways have been identified for this dinuclear reductive elimination: (1) CO dissociation from the manganese alkyl followed by a concerted binuclear reductive elimination; (2) the same process but involving solvent displacement of CO by a coordinating solvent; (3) homolysis of the metal alkyl bond followed by H atom abstraction; (4) associative CO insertion followed by reductive elimination to give benzaldehyde instead of toluene. The relatively minor changes involved in the completely different mechanisms for dinuclear reductive eliminations from these manganese systems suggest that reductive elimination reactions may not be easily generalized.

3.3 Electron-transfer Reactions

Electron-transfer reactions of 18-electron organometallic complexes have received growing attention (*see* ***Paramagnetic Organometallic Complexes***). The field of electron-transfer catalysis where an organometallic complex is activated by oxidation or reduction provides the impetus for such studies (*see* section *Coordinately Unsaturated Clusters and Clusters with Hemilabile Ligands*). Organometallic complexes lie on the border between the fields of inorganic and organic chemistry. The terminology for electron-transfer reactions of organometallic complexes demonstrates the influence of organic (single-electron transfer (SET) and nucleophilic reactions) and inorganic outer and inner sphere (*see Outer-sphere Reaction* and *Inner-sphere Reaction*) electron-transfer nomenclature. For the metal-carbonyl anions whose reactions dominate the electron-transfer reactions of 18-electron organometallic complexes, SET, and outer-sphere terms are equivalent and nucleophilic and inner-sphere reactions are frequently equivalent.

Electron transfer has been frequently observed in catalytic and synthetic reactions of organometallic complexes. Simple reduction:

$$Fe(CO)_5 + 2Na(Hg) \longrightarrow Na_2Fe(CO)_4 + CO \qquad (66)$$

$$Cp_2Fe_2(CO)_4 + Mg \longrightarrow Mg[CpFe(CO)_2]_2 \qquad (67)$$

and oxidation:

$$2Ni(CO)_4 + CS_2 \longrightarrow 2NiS + C + 8CO \qquad (68)$$

$$Fe(CO)_5 + 2CuCl_2 \longrightarrow Cu_2Cl_2 + FeCl_2 + 5CO \qquad (69)$$

reactions are commonly observed and utilized. Disproportionation reactions provide another example of electron transfer.[95]

$$Co_2(CO)_8 + 2L \longrightarrow [Co_2(CO)_3L_2][Co(CO)_4] + CO \qquad L = \text{phosphine} \qquad (70)$$

$$3V(CO)_6 + 6L \longrightarrow [VL_6][V(CO)_6]_2 + 6CO \qquad L = \text{oxygen or nitrogen base} \qquad (71)$$

Reactions between cationic and anionic carbonyls to form metal–metal bonds also involve a formal electron transfer:[96,97]

$$[Mn(CO)_6]^+ + [Mn(CO)_5]^- \longrightarrow Mn_2(CO)_{10} + CO \qquad (72)$$

$$[Co(CO)_3(PPh_3)_2][Co(CO)_4] \xrightarrow{\Delta} Co_2(CO)_6(PPh_3)_2 + CO \qquad (73)$$

The primary method of synthesis of heterobimetallic complexes may involve electron transfer between metal halides and metal-carbonyl anions:[98–101]

$$CpFe(CO)_2I + NaMn(CO)_5 \longrightarrow Cp(CO)_2FeMn(CO)_5 + NaI \qquad (74)$$

$$Re(CO)_5Cl + NaMn(CO)_5 \longrightarrow MnRe(CO)_{10} + NaCl \qquad (75)$$

$$Mn(CO)_5Cl + NaCo(CO)_4 \longrightarrow MnCo(CO)_9 + NaCl \qquad (76)$$

Table 12 Half-reaction reduction potentials for one-electron and two-electron transitions of metal-carbonyl species[103]

[a]Values from Pugh and Meyer,[65] which are probably more accurate and are systematically 0.25 V more negative.

This type of reaction sometimes leads to formation of homobimetallic complexes.

An interesting example of electron transfer from $Mn(CO)_5^-$ to $Cr(\eta^6\text{-}C_6H_6)_2^+$ is shown below:[102]

$$2\,[Cr(\eta^6\text{-}C_6H_6)_2][Mn(CO)_5] \longrightarrow 2Cr(\eta^6\text{-}C_6H_6)_2 + Mn_2(CO)_{10} \quad (77)$$

This reaction occurs at reasonable rates just above ambient temperatures. The one- and two-electron transitions for many neutral carbonyl species have been measured (Table 12).[103]

3.3.1 *Metal-carbonyl Anions*

The electron-transfer reactions of metal-carbonyl anions have been reviewed.[103] Metal-carbonyl anions exhibit one- and two-electron reactions. The two-electron processes involving transfer of groups such as hydrogen, alkyl, and halogen between metal centers are related to the nucleophilicity of the anion involved. The one-electron processes are primarily outer-sphere electron transfers. However, in contrast to organic reactions, the metal-carbonyl anions can also undergo inner-sphere electron transfers. This is usually the case when an anion of low nucleophilicity transfers an electron to a metal-carbonyl cation or halide.

Recently, the thermally and photochemically induced one-electron transfers from the metal-carbonyl anions $A[Mn(CO)_5]$, $A[Co(CO)_4]$, and $A[Re(CO)_5]$ (A = Na and PPN) to fullerene have been studied.[104] In the case of the thermal reactions of the Mn and Re anions, initial electron transfer to form C_{60}^- and the corresponding $17e^-$ $M(CO)_5$ radical is followed by the competitive collapse to the metal dimer and formation of the η^2-C_{60} complexes $A[Mn(CO)_4(\eta^2\text{-}C_{60})]$. Under photochemical conditions, redissociation of the dimer results in exclusive formation of the η^2-complexes, which are thought to be formed by nucleophilic displacement of CO on the substitution labile $M(CO)_5$ fragment by C_{60}^-:

$$Mn(CO)_5^- + CO_{60} \xrightarrow{\Delta \text{ or } h\nu} Mn(CO)_5 + C_{60}^- \longrightarrow [(CO)_4Mn(\eta^2 - C_{60})]^- + CO \quad (78)$$

The kinetics of accumulation and consumption of the iron carbonyl radical anions, $Fe_3(CO)_{12}^{\bullet-}$ and $Fe_3(CO)_{11}^{\bullet-}$ formed by one-electron transfer from (NH_4)SEt have been studied using stopped-flow techniques.[105] The kinetic measurements reveal that initial formation of a thioacetyl adduct is followed by electron transfer to $Fe_3(CO)_{12}$ forming the radical anion, $Fe_3(CO)_{12}^{\bullet-}$, which then undergoes CO loss to give the other spectroscopically characterized radical anion, $Fe_3(CO)_{11}^{\bullet-}$. The formation of these radical anions is followed by a series of reactions involving radical-chain electron transfers and ligand exchange reactions where the main chain carriers are the trimetallic radical anions and where the final major product is the salt $NH_4[Fe_2(CO)_7]$. The significance of this work is that it supports the idea that chain radical processes including preliminary complex formation followed by redox initiation lies at the heart of the interaction of iron carbonyls with Lewis bases, and that ligand substitution takes place via the coordinately unsaturated species created by the radical-chain processes.

4 17-ELECTRON COMPLEXES

17-electron complexes are inherently unstable. However, the huge increase in reactivity for 17-electron complexes offers possibilities for activation of 18-electron complexes through a process called electron-transfer catalysis (*see* ***Paramagnetic Organometallic Complexes***). 17-electron complexes are formed by oxidation of 18-electron complexes, by reduction of 18-electron complexes accompanied by ligand dissociation, and by homolytic cleavage of the metal–metal bond of dimers. The reactions of 17- and 18-electron complexes have recently been reviewed.[106] The two most common reaction pathways for the 17-electron species are ligand substitution and electron transfer. However, some recent work illustrates that 17-electron complexes can undergo other types of reactions as well.

4.1 Ligand Substitution

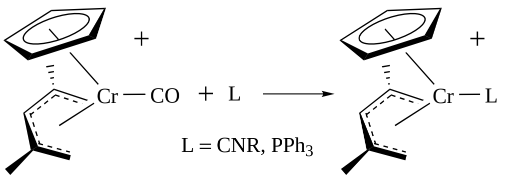
17-electron complexes undergo ligand substitution through an associative reaction and a 19-electron intermediate.[106,107] This can be illustrated by the reactions of $[V(CO)_6]^\bullet$:

$$[V(CO)_6]^\bullet + L \longrightarrow [V(CO)_6L]^\bullet \xrightarrow{-CO} [V(CO)_5L]^\bullet + CO \quad (79)$$

The activation parameters and dependence on L are shown in Table 13.[108] These data are fully consistent with an associative reaction. The 17-electron complex $V(CO)_6$ has an associative substitution reaction rate that is $>10^{10}$ more facile than for the 18-electron $Cr(CO)_6$ complex. The vanadium complexes are among the most inert of the 17-electron complexes. Table 14 shows the rate constants for substitution of several complexes.[107] As expected from size considerations, substituting a phosphine ligand for a CO decreases the rate for an associative reaction.

The two dominant characteristics for substitution reactions of 17-electron complexes are very rapid reactions and associative mechanisms. Each of these features is in contrast to reactions of 18-electron complexes. The reactivity has been attributed to the formation of a three-electron bond between the entering nucleophile and the 17-electron complex.[109] Electron density analysis supports stabilization of the 19-electron transition state as the primary source for the labilization.[110]

The arene complexes of the early transition metals represent recent extensions 17-electron class of compounds. Thus, the 18-electron half open chromocene carbonyl complexes, (2, 4-dimethylpentadienyl)CpCrCO and the analogous Cp* complex undergo one-electron oxidation with $NOBF_4$ to provide the corresponding cationic 17-electron complexes.[111] These complexes undergo ligand substitution processes:[111]



(80)

Table 13 Rate constants and activation parameters for substitution of $V(CO)_6$[108]

L	k ($M^{-1}\,s^{-1}$)	ΔH‡ (kcal mol^{-1})	ΔS‡ (cal $K^{-1}\,mol^{-1}$)
PMe_3	132	7	−23
PBu_3	50	7	−25
$PMePh_2$	4	9	−26
$P(OMe)_3$	0.7	11	−23
PPh_3	0.2	10	−28
$AsPh_3$	0.02	–	–

Table 14 Rate constants for substitution of 17-electron complexes[107,a]

Complex	k ($M^{-1}\,s^{-1}$)
$[V(CO)_6]^{\bullet}$	100
$[V(CO)_5PBu_3]^{\bullet}$	5×10^{-4}
$[Re(CO)_5]^{\bullet}$	2×10^{9}
$[Mn(CO)_5]^{\bullet}$	1×10^{9}
$[Mn(CO)_4PPh_3]^{\bullet}$	7×10^{2}

[a]The entering ligand is an alkyl phosphine.

The reactions exhibit second-order kinetics with rate constants on the order of $2.0 \times 10^{-4}\,M^{-1}\,s^{-1}$. This rate of substitution is 6 to 9 orders of magnitude slower than 17-electron binary metal carbonyls but is similar to that observed for phosphine substituted vanadium carbonyls (Table 14). When t-butyl isocyanide is the incoming ligand, the initial slow substitution for CO is followed by rapid displacement of the of the pentadienyl ligand to yield the complex, $CpCr(CN^tBu)_4^+$. This is presumably caused by a pentadienyl slippage after the first rate-determining associative ligand addition. Reaction with more electron-donating phosphines results in nucleophilic addition to the C(1) of the pentadienyl ligand by an associative pathway. Interestingly, the CO exchange rate for the cationic 17-electron complex is about the same as for the 18-electron precursor. Taken together, these data indicate that electron count may control reaction pathway (i.e. associative versus dissociative) but steric factors have a dominant influence on rate and on the nature of the product obtained. This steric dependence is exemplified by the different cone angle limits for phosphine substitution on the more sterically encumbered 17-electron systems $Cp^*Cr(CO)_3$ and $(Tp)Mo(CO)_3$ (Tp = hydridotris(pyrazolyl)borate, cone angle limit = 140°) relative to $CpCr(CO)_3$ (cone angle limit = 170°).[112]

An exception to the general rule that 17-electron complexes react by strictly associative mechanisms has been reported.[113] The alkyl for iodide metathesis in the 17-electron complex $CpCr(NO)(PPh_3)I$ is inhibited by excess phosphine. The reaction requires formation of a THF solvate CpCr(NO)(THF)I, which has been characterized. Although the formation of this intermediate takes place by an associative pathway, the requirement that a two-electron ligand dissociate prior to the replacement of iodide by the alkyl group puts this transformation of a 17-electron complex into a different mechanistic class.

The gas-phase reactions of the 17-electron radical anions $Cr(CO)_5^-$, $Fe(CO)_4^-$, and $Ni(CO)_3^-$ with organic electrophiles have been examined.[114] Here, CO substitution takes place by initial charge transfer to the organic electrophile (e. g. maleic anhydride) followed by addition of the resulting anion to the $16e^-$ metal center. The efficiency of the reaction correlates with the electron affinity of the organic ligand. This mechanism is also thought to be operative in the condensed phase reactions of $Fe(CO)_4^-$ with similar ligands studied earlier and represents an alternative to the formation of the usual 19-electron intermediate.[115]

4.2 Electron-transfer Reactions

17-electron complexes undergo facile oxidation, reduction, and atom-transfer reactions. The rapidity of these reactions has made the study difficult, but their importance in radical-chain processes warrants discussion. The speed of atom-transfer reactions can be illustrated by the reactions of 17-electron metal-carbonyl complexes with halide complexes.[107] A few

reactions with CCl_4 are shown in Table 15.[107]

$$M^{\bullet} + CCl_4 \longrightarrow M\text{–}Cl + [CCl_3]^{\bullet} \quad (81)$$

Hydrogen-transfer reactions have also been reported. 17-electron complexes may be oxidized or reduced:

$$M^{\bullet} + e^- \longrightarrow M^- \quad (82)$$

$$M^{\bullet} \xrightarrow{S} [M - S]^+ + e^- \quad (83)$$

S = solvent

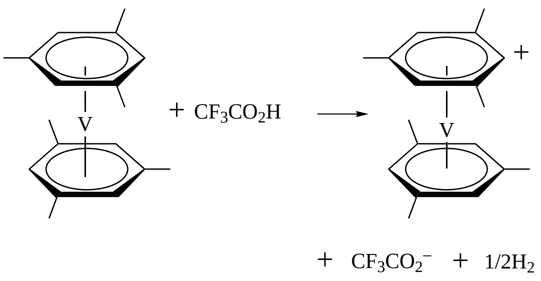
$M^{\bullet}$ = a 17-electron complex

Burke and Brown examined reactions of $[Re(CO)_4L]^{\bullet}$, L = PMe_3, $P(O\text{-}i\text{-}Pr)_3$, with *N*-methylpyridinium salts.[116] These reactions occur with electron-transfer rate constants in the 10^6–$10^9\,M^{-1}\,s^{-1}$ range. From Marcus-type (*see Marcus Equation*) analysis, an intrinsic barrier of $\sim$3 kcal mol^{-1} was obtained for the 17-electron rhenium complexes.[116] The facile oxidation and reduction of 17-electron complexes makes them quite susceptible to disproportionation reactions:

$$3V(CO)_6 \xrightarrow{MeC(O)Me} [V(MeC(O)Me)_6][V(CO)_6]_2 \quad (84)$$

Such reactions are probably quite important in the disproportionation of dimers. Disproportionation of $V(CO)_6$ was interpreted as an inner-sphere reaction with transfer of an electron through an isocarbonyl (*see Isocarbonyl Complexes*).[117] The observation that $V(CO)_5PBu_3$ disproportionates 10^5 times more slowly than $V(CO)_6$ suggests large ligand effects are possible for such reactions. Atom-transfer and electron-transfer reactions of 17-electron complexes are very important in radical-chain processes. Thus, the radical-initiated substitution of $HRe(CO)_5$ involves the 17-electron electron $Re(CO)_5{}^{\bullet}$ as the chain propagating intermediate.[95] Chain reactions take advantage of the very rapid atom transfer (in other cases electron transfer) and ligand substitution of 17-electron complexes.

The 17-electron bis(mesitylene)vanadium(0) undergoes a one-electron transfer when reacted with difluoro- or trifluoroacetic acid to give the vanadium(I) salt $[V(mes)_2][CF_3CO_2]$ with the liberation of a half mole of hydrogen:[118]



(85)

Table 15 Rate constants for equation (81)[107]

$M^{\bullet}$	k ($M^{-1}\,s^{-1}$)
$Mn(CO)_5$	1×10^6
$Re(CO)_5$	3×10^7
$Re(CO)_4PMe_3$	2×10^9
$CpMo(CO)_3$	2×10^4
$CpW(CO)_3$	1×10^4

This species is stable in THF but reacts with excess trifluoroacetic acid to give the protonated vanadium(II) complex $[H(THF)_n][V(CF_3CO_2)_3]$. Similarly, the reaction of $V(mes)_2$ with triphenyl methyl halides in DME gives the vanadium (II) complexes $VX_2(DME)_n$ (X = Cl, n = 1.1, X = Br or I, n = 2).

5 CONCLUSION

The reaction mechanism expected for an organometallic complex is closely correlated with the electron count at the metal center. This has been recognized for many years as the 16e$^-$ and 18e$^-$ rule for organometallic reactions. 18-electron complexes usually undergo transformations (ligand dissociation, alkyl migration, or reductive elimination) that result in a 16e$^-$ intermediate. 16-electron complexes usually undergo transformations (ligand addition or oxidative addition) that result in 18-electron complexes. However, some very interesting exceptions to this rule now exist. Generation of 14-electron intermediates by ligand dissociation from 16-electron complexes now appears to be a viable alternative for complexes containing very strongly donating ligands. Single-electron transfer reactions of 18-electron complexes can generate 17e$^-$ and 19e$^-$ complexes, which are very reactive for a number of reaction types. Such transformations allow the use of electron-transfer catalysis with organometallic complexes.

Furthermore, although electron count can by used to anticipate a mechanistic type for a given complex, the rate of the reaction is strongly influenced by the stereoelectronic factors associated with the complex. Thus, although 17-electron complexes usually react by an associative pathway, the rate of the reaction may be as slow or even slower than the primarily dissociative reactions of their 18-electron counterparts depending on the overall charge, the nature of the incoming ligand, and the nature of the ancillary ligands on the metal(s).

In many respects, the reactivities of organometallic complexes are similar to organic complexes (high reactivity of

odd-electron complexes, single-electron transfer, and nucleophilic displacement) and in other respects organometallic complexes are very similar to coordination complexes (ligand substitution and metal effects).

1 INTRODUCTION

Mercury has been known for over 4000 years. Its chemistry has many unusual aspects that have resulted in extensive usage by mankind. Mercury is the only common metal that is liquid at room temperature. It is also one of the very few elements that is monoatomic in its vapor phase at low temperatures, an indication of the weak *Intermolecular* forces that are present in mercury. The element exhibits surprisingly different chemistry from its congeners zinc and cadmium, a feature that is probably a consequence of the poor shielding by electrons in the completely filled 4f and 5d sublevels. The metal is used in a number of applications, including thermometers, amalgams, and production of chlor–alkali.

Mercury is the only group 12 member to have a substantial chemistry in the +1 oxidation state, in which Hg_2^{2+}, the most common of all metal polycations, is formed. This ion was the first one known to exhibit metal–metal bonding. Its chloride salt is the material present in the standard calomel reference electrode. In addition to halides and oxy salts, nitrogen and oxygen-donor ligand complexes of mercury(I) are known, but far fewer than of mercury(II).

In the divalent state, mercury forms compounds and complexes with many different CN and geometries. Since Hg^{2+} is a d^{10} metal ion lacking strong coordination geometry preferences, crystallography is critical to definitive structural characterization. Although Hg^{2+} typically makes stronger bonds with S, N, and P donors than any other divalent metal ion, rapid ligand exchange is common for simple complexes. Recent studies with multidentate ligands have revealed slowed exchange and stimulated development of ^{199}Hg NMR methods.

Although mercury has been used medicinally, the element and its compounds are generally very toxic (*see* ***Metal Ion Toxicity***). For reasons of economy, conservation, and public health, mercury use is gradually falling back to instances where no substitute can be found and recovery efforts are becoming more scrupulous.

2 GENERAL ASPECTS OF THE CHEMISTRY OF MERCURY

2.1 Prevalence and Applications

Mercury is the sixty-second most abundant element, with a terrestrial abundance of 5×10^{-5}%. Its abundance is comparable to silver and much less than either zinc or cadmium. Cinnabar (HgS) serves as the only important mercury ore, and droplets of liquid mercury are frequently found in cinnabar veins. The chloride and oxide are also found in nature, and mercury is a by-product from mining of other metals (e.g. copper, zinc, gold, silver). Volcanic activity produces mercury vapor, and the liquid condensate can sometimes be found in association with volcanic flows. Degassing of the earth's crust and oceans places thousands of tons of elemental mercury into the atmosphere each year. Coal-burning power plants, crematoria, and waste incinerators burden the atmosphere with additional elemental mercury. With an estimated residence time of at least one year in the atmosphere, Hg^0 is widely dissipated before deposition as a nonbiodegradable environmental toxin. In the oceans, Hg^{II} is the prevalent form of mercury, but it can be converted to methylmercury (CH_3Hg^+) and dimethylmercury by microorganisms. These lipid soluble compounds are biomagnified in aquatic food chains. All forms of mercury are toxic and the magnitude of the public health risk presented by mercury has spurred development of alternatives to many Hg-containing products.

Mercury and its compounds have a long and rich history. Its atomic symbol is derived from the Greek name *Hydragyrum* meaning watery silver. The English word for the element comes from the name of the Roman messenger god because of mercury's liquid mobility and 'quickness'. As early as the second millennium B.C., mercury may have been recovered and used in Egypt. Recovery of the element from

its principal ore, cinnabar (HgS), by smelting in air was known in the Mediterranean region during the fifth century B.C.[1] As early as the second century B.C., alchemists are believed to have used mercury in attempts to convert base metals to gold. In the ancient world, the ink and cosmetic pigment known as vermilion came from the red color of cinnabar. Pharmaceuticals containing mercury have included diuretics, antibacterial agents, antiseptics, and laxatives. Mercury containing treatments for syphilis in the 1500 s led to the discovery of the important toxicological principle, usually credited to Paracelsus, that 'the dose makes the poison'.

Large-scale release of mercury from the earth's crust began about 500 years ago for the mining of gold and silver from Spanish America by a mercury amalgamation process.[2] Historically, the cinnabar mine near the town of Almadén in Spain has dominated global production from the mercuriferous belt between the Western Mediterranean and Central Asia. Mercury was originally smelted by placing cinnabar in a pile of brushwood and burning the wood. Modern smelting techniques (*see Extraction of the Elements*) are still based upon the same chemical reaction (equation 1). The cinnabar ore is concentrated by flotation before smelting. Mercury may also be obtained from cinnabar by roasting the ore in the presence of iron metal or calcium oxide (equations 2 and 3). The initial purification of the crude metal is by filtration, followed by oxidation using dilute nitric acid or air. This removes contaminants of more easily oxidized metals. The final step is usually distillation, taking advantage of the relatively low boiling point of the metal.

$$\mathrm{HgS(s)} + \mathrm{O_2(g)} \xrightarrow{600\,^\circ\mathrm{C}} \mathrm{Hg(g)} + \mathrm{SO_2(g)} \quad (1)$$

$$\mathrm{HgS(s)} + \mathrm{Fe(s)} \longrightarrow \mathrm{Hg(g)} + \mathrm{FeS(s)} \quad (2)$$

$$\mathrm{4HgS(s)} + \mathrm{4CaO(s)} \longrightarrow \mathrm{Hg(g)} + \mathrm{3CaS(s)} + \mathrm{CaSO_4(s)} \quad (3)$$

The industrial age prompted further increases in mercury mining. Cumulative industrial age anthropogenic global production of Hg is estimated at 0.64 million tons through 2000.[3] Diverse applications have been found for metallic mercury in the electrical industry including lamps, switches, relays, and batteries. Control instruments including thermometers, manometers, barometers, and other pressure sensing devices often use mercury in the metal form. Mercurous chloride is a component of the calomel electrode used in pH measurement and mercury cadmium telluride (MCT) (*see* ***Semiconductor Interfaces***) has become the material of choice for a broad range of infrared applications. Inorganic mercury compounds are catalysts for a variety of industrially important processes. Mercury production spiked to approximately 10 000 tons per year during World War II, in part because mercury fulminate was used as a component of detonating devices. Production peaked again in the 1960s and 1970s with discovery of the Castner–Kellner process for production of chlor–alkali (chlorine–NaOH). This process, in which liquid mercury serves as the cathode for electrolysis of brine solutions, remains the

Cathode:

$$\mathrm{HgO} + \mathrm{H_2O} + 2e^- \longrightarrow \mathrm{Hg} + 2\mathrm{OH}^-$$

Anode:

$$\mathrm{Zn} + 2\mathrm{OH}^- \longrightarrow \mathrm{ZnO} + \mathrm{H_2O} + 2e^-$$

Net:

$$\mathrm{Zn} + \mathrm{HgO} \longrightarrow \mathrm{ZnO} + \mathrm{Hg}$$

$$E^\circ = +1.3\ \mathrm{V}$$

Scheme 1

largest industrial use of mercury. During this time, mercury batteries were prevalent in which mercury (II) oxide (HgO) served as the cathode and a zinc–mercury amalgam as the anode (only Zn reacts) with a KOH electrolyte. The cell voltage is about +1.3 V, and the overall cell reaction is shown in Scheme 1. The battery has a high conversion of mass of the composite materials to energy, and there are no concentration changes during discharge since the reaction does not involve ions in solution.

Mercury production has declined to 2000 tons annually in recent years reflecting conversion of many products and processes to less toxic Hg-free alternatives.[4] For example, the major battery manufacturers have developed mercury-free formulations for nearly every application, decreasing their mercury consumption by 99% since 1985. Pacemaker batteries are notable exceptions that, along with amalgam fillings, contribute mercury to crematoria efflux. Mercury-free membrane and diaphragm processes are available for the production of chlor–alkali, and are economically viable for new units. Mercury compounds are no longer used as antifoulants in paints, seed grain fungicides, nor slimicides in paper pulp factories. In general, mercury-free alternatives for most electromechanical applications of mercury are well established. For products dependent on the unique photoelectronic properties of mercury, designs minimizing mercury use are under development as well as recycling infrastructures.

In spite of the trend toward minimizing mercury use, novel applications are still being discovered. For example, the landmark synthesis of mercury cuprates with superconducting transition onset (T_C) higher than the boiling point of liquid nitrogen was reported in 1993 (*see* ***Superconductivity***).[5] The family of ceramic copper oxide materials based on single mercury-oxide layers in rock salt–like blocks (BaO-HgO_δ-BaO) and variable perovskite type blocks ($\mathrm{CuO_2}$-$(\mathrm{Ca}$-$\mathrm{CuO_2})_{n-1}$) have a general formula $\mathrm{HgBa_2Ca}_{n-1}\mathrm{Cu}_n\mathrm{O}_{2n+2+\delta}$. The material with $n = 3$ has the record-high T_C (onset) > 133 K, which can be raised above 160 K by the application of external pressure. Furthermore, mercury-based films are good candidates for applications demanding high current density since their single blocking layer structure promotes stronger coupling between adjacent

CuO_2 layers. Reviews of the challenging issues relevant to the synthesis, structural chemistry, and properties of critical importance for these superconducting materials have been published.[6]

2.2 Chemical Properties

The properties of elemental mercury are summarized in Table 1. Mercury has a *Ground State* configuration of $[Xe]4f^{14}5d^{10}6s^2$ (Ground-state term: $^1S_0$), and its first three ionization energies are 1007, 1809, and 3300 kJ mol^{-1}; it does not commonly form an oxidation state (*see Oxidation Number*) higher than +2 because of its large third ionization potential. In the solid phase, Hg^0 adopts a distorted hexagonal close-packed structure (*see Close Packing*) with significant distortion. The six hexagonal coplanar mercury atoms are at a 16% greater distance than the six proximate, noncoplanar mercury atoms. This distortion from normal hexagonal close packing is the opposite of what is observed for zinc and cadmium. The metal shows limited solubility in both polar and nonpolar solvents, with a solubility in water of 6.1×10^{-6} g per 100 g at 25 °C, and a solubility in n-hexane of 2.7×10^{-7} g per 100 g at 40 °C.

It has been proposed that the contraction of the electron orbitals in mercury due to *Relativistic Effects* are important contributors to the element's unusual physical, chemical, and spectroscopic properties.[7–9] Some of these properties include the so-called *Inert Pair Effect*, the difficulty of oxidation of the metal, its unusually low-melting point and electrical conductivity, and the low *Enthalpy* of vaporization, which at 59.1 kJ mol^{-1} is about one-half those of cadmium (100 kJ mol^{-1}) and zinc (114 kJ mol^{-1}). Both NMR shieldings and spin–spin coupling constants with ^{199}Hg are significantly impacted by relativistic effects.[9]

Table 1 Properties of elemental mercury

Atomic weight	200.59
Number of natural isotopes	7
Valence configuration and ground-state term	$5d^{10}6s^2$, $^1S_0$
Ionization energies (kJ mol^{-1})	
1st	1007
2nd	1809
3rd	3300
Melting point (°C)	−38.9
Boiling point (°C)	357
Heat of vaporization (kJ mol^{-1})	59.1
Heat of fusion (kJ mol^{-1})	2.30
E°_{red} for Hg^{II}/Hg	+0.854
Radius (pm)	
Hg^{II} (6-coordinate)	116
Hg^{I} (6-coordinate)	133
Hg (12-coordinate)	151
Density (g cm^{-3} at 20 °C)	13.546
Vapor pressure (mm Hg at 20 °C)	2×10^{-3}
Solubility (g per 100 g H_2O at 25 °C)	6×10^{-6}
Pauling electronegativity	2.00
Ohmic resistance (μΩ cm at 20 °C)	95.8
Crystal structure	hcp (distorted)

Mercury has a high density (13.546 g cm^{-3} at 20 °C) and a wide liquid range (mp −38.9 °C; bp 357) over most of which its volume expands uniformly. In addition, the high surface tension of mercury keeps it from sticking to glass surfaces. These properties have contributed to its use in an impressive number of laboratory applications. For a metal, mercury has an unusually high electrical resistivity or specific resistance (95.8 μΩ cm), and this property enables it to be used as an electrical standard. Of all the common metals, only bismuth has a higher resistivity.

Mercury readily dissolves or forms alloys (*see* ***Alloys***) with many metals, including Ag, Au, Na, and Zn, a process known as amalgamation. Mercury amalgams find applications as reducing agents in chemical synthesis (usually Zn or Na amalgam) and in the recovery of Au and Ag from their ores in metallurgy. Perhaps, the most famous historical case is Spain's use of its cinnabar deposits to extract silver from New World mines in the 1500 s. Amalgamation is presently used in the Amazon basin for what has been described as the largest gold rush of the twentieth century.[10] Alchemists used amalgams in their search for the transmission of base metals to Au and Ag. Since mercury does not amalgamate iron, iron flasks can be used to store the metal or amalgams. Some amalgams (Hg_2Au, Na_2Hg) exist as stoichiometric compounds with discrete crystalline structures. The solid-state chemical aspects of the six thermodynamically stable binary Na–Hg solids has been reviewed recently with an emphasis on the temperature-dependent polymorphic transitions and their thermodynamics.[11]

Mercury is a relatively nonreactive metal and is nobler than its lighter congeners zinc and cadmium; this is reflected in its positive reduction potential. It does not react with HCl under any conditions, but it is oxidized to Hg^{II} by concentrated HNO_3 or hot concentrated H_2SO_4 with production of nitrogen and sulfur oxides, respectively. Cold dilute HNO_3 reacts slowly with Hg^0 to form mercury(I) nitrate, $Hg_2(NO_3)_2$. The metal does not generally react with bases, but does react with aqueous ammonia in the presence of O_2 to form Millon's base, $Hg_2NOH{\cdot}2H_2O$.

2.3 Spectroscopic Properties

Traditionally, spectroscopic studies of mercury compounds have been limited. As a d^{10} metal ion, Hg(II) lacks any *Crystal Field Stabilization Energy*, *Paramagnetism* or d–d absorption spectra (*see d–d Transitions*). Similarly, the Hg_2^{2+} ion can be fingerprinted by *Infrared Spectroscopy*, but other spectroscopic methods commonly used to characterize metals are inapplicable. However, since mercury is diamagnetic (*see Diamagnetism*) in the most common oxidation states, its complexes with organic ligands are readily characterized by multinuclear magnetic resonance.[12]

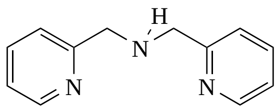
Table 2 NMR properties of the magnetic isotopes of mercury

Isotope	Natural abundance (%)	Spin, I	Magnetic moment, μ/μ_N	Magnetogyric ratio, γ	Quadrupole moment, Q (10^7 rad T^{-1} s^{-1})	NMR frequency, Ξ (MHz)	Relative receptivity, D^c
^{199}Hg	16.87	1/2	0.87621937	4.8457916	–	17.910323	5.73
^{201}Hg	13.18	3/2	−0.7232483	−1.788769	0.385	6.611400	1.13

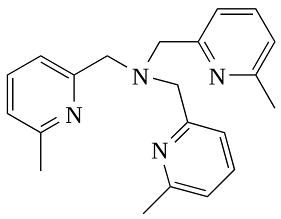
Furthermore, over the last decade, considerable advances in the characterization of mercury compounds by mercury NMR have been made. The properties of the two naturally occurring NMR-active isotopes of mercury, ^{199}Hg and ^{201}Hg, are listed in Table 2.[13] Since ^{201}Hg has a large quadrupole coupling constant, efficient relaxation mechanisms leading to severe broadening of NMR transitions and averaging of spin–spin couplings to zero make it generally unsuitable for NMR studies. For example, even though mercury occupies a site of *Tetrahedral* symmetry in $K_4[Hg(CN)_4]$, its solid-state ^{201}Hg NMR signal linewidth was three times larger than the ^{199}Hg signal.[14] On the other hand, ^{199}Hg is one of the relatively few metals with a high natural abundance (16.87%) spin $I = 1/2$ isotope that can be exploited for compound characterization. The sensitivity of this nucleus is five times higher than ^{13}C. ^{199}Hg has a relative frequency of 17.9 MHz when ^{1}H has a frequency of 100 MHz. Thus, ^{199}Hg is a very accessible nucleus on most NMR spectrometers. The chemical shift range for ^{199}Hg extends over 5000 ppm, exhibiting extraordinary sensitivity to changes in the coordination environment. The ^{199}Hg chemical shift associated with coordination environments composed of a single ligand type can range more than 1000 ppm.[15] In the spectra of other nuclei, satellite peaks reflecting spin–spin coupling to one ^{199}Hg nucleus are 1/5 the size of the main resonance. Coupling to the mercurous ion or any other pair of magnetically inequivalent ^{199}Hg nuclei produces satellites that are each one-quarter the size of the main resonance. Several reviews of the ranges of observed mercury chemical shifts and ^{199}Hg–^{1}H coupling constants have been published.[15–18]

The primary reference material for ^{199}Hg NMR spectroscopy is dimethylmercury(II). However, a lethal accident caused by the cutaneous absorption of a few drops of this substance in 1996 cautions against its routine experimental use.[19] Calculation of the frequency at 0 ppm for ^{199}Hg from the measured frequency of 0 ppm for protons in the sample is a prudent alternative with modern spectrometers.[20] For solid-state NMR, hexakis(dimethylsulphoxide)mercury(II) trifluoromethanesulphonate, $\delta(^{199}\text{Hg}) = -2313$ ppm,[21] is a suitable secondary standard. Its high symmetry *Octahedral* coordination environment results in small chemical shift anisotropy and short H–Hg separations lead to high $^1\text{H} \rightarrow {}^{199}\text{Hg}$ polarization transfer efficiency.

Solution-state NMR studies of mercury complexes are most meaningful when taken under slow-exchange conditions. Fast-exchange spectra involving equilibria between several species in solution are common due to the relatively high lability of ligands in mercury complexes. Tridentate coordination appears to be necessary but not sufficient for slow ligand exchange in solution. Furthermore, isolation of a bis-tridentate chelate of (**1**) and $Hg(ClO_2)_4$ that had C_2 symmetry in the solid-state but a single environment for each ligand proton when dissolved in the recrystallization solvent indicates the occurrence of dynamic racemization processes.[22] This process was *Intramolecular* since most of the ligand protons remained ^{199}Hg-coupled. The stereochemical nonrigidity of tetrahedral Hg^{II} complexes has also been reviewed.[23] In the most spectacular demonstration of slow ligand exchange for Hg^{II} yet reported, as many as five complexes of the sterically demanding multidentate ligand (**2**) were shown to coexist in slow-exchange on the proton chemical shift timescale in acetonitrile-d_3.[24]

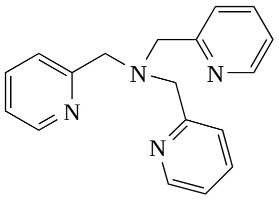


(**1**)



(**2**)

Although the majority of the reported values for heteronuclear coupling with ^{199}Hg are associated with alkylmercurials,[15] (**2**) has been used to detect $J(^{199}\text{Hg}^1\text{H})$ between nuclei as many as five bonds apart[24] and $J(^{199}\text{Hg}^{13}\text{C})$ over as many as three bonds were detected in the Hg^{2+} complexes of (**3**).[25] Indirect nuclear spin–spin coupling constants $^nJ(^{199}\text{Hg-X})$ were reviewed in 1992.[15] The additivity of coupling constants is generally accepted, and chelate rings provide multiple coupling paths with the possibility of significant enhancements if contributions are of the same sign. Solution-state proton NMR of isostructural Cd^{II} and Hg^{II} complexes of (**1**) and (**3**) revealed larger and longer-range couplings in Hg^{II} complexes,[26] consistent with significant relativistic effects.[9] Spin–spin coupling has also been reported for mercurous complexes, with $^1J(^{199}\text{Hg-}^{199}\text{Hg}) > 200\,000$ for asymmetric coordination by *Crown Ethers*, the largest scalar couplings ever recorded.[27] The first example of slow-exchange on the $J(^{199}\text{Hg}^1\text{H})$ timescale for a mercurous complex was recently reported for $[Hg_2(\mathbf{2})_2](ClO_4)_2$ in acetonitrile-d_3 solution.[28] The methylene



(**3**)

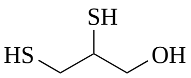
protons of (**2**) were coupled to both metal centers with $^{3,5}J(^{199}Hg^1H) = 22$ Hz and $^{4,6}J(^{199}Hg^1H) = 13$ Hz.

Over the last decade, developments in high-resolution NMR techniques for solids have been extended to mercury nuclei.[29] Solid-state NMR studies provide more definitive characterization of mercury complexes since their interpretation is not compromised by exchange processes or solvent coordination. While medium effects on spectra are not absent in the solid-state, they are generally more defined and therefore studied more readily. Furthermore, the chemical shift anisotropy, coupling constant anisotropy, and dipolar coupling constants obtained by solid-state NMR provide an additional probes into structure and bonding. Comparison of solid-state NMR spectra of structurally characterized complexes with solution-state NMR spectra promises to reveal significant differences between the solution and solid-state structures.

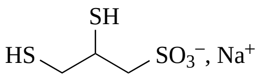
2.4 Biological Properties

Mercury is the only group 12 member without a known beneficial biological role.[30] Several references discuss the safety precautions and hazards of working with the various forms of mercury.[31,32] The vapor pressure of Hg at 25 °C is high, 1.9×10^{-3} mm; since this is many times the LD_{50}, air saturated with mercury vapor is highly toxic and liquid mercury must only be used in a well-ventilated area and stoppered when not in use. Spills must be collected and removed immediately to prevent prolonged exposure. A common procedure involves the absorption of mercury by a small quantity of elemental sulfur. Even small amounts of mercury can exert potent, detrimental effects. The use of slaves and criminals to mine mercury in ancient times indicates that the toxic properties of mercury were already known. Historically, mercury was used in the production of felt hats, causing hatters of the nineteenth century to exhibit the effects of inorganic mercury poisoning: nervous tremors, loosening of the teeth, mouth soreness, and neurological disorders. The expression ‘mad as a hatter’ is said to have come from the effects of acute mercury poisoning. Alfred Stock, a noted chemist, was a temporary victim of mercury poisoning from the pools of mercury often present around his laboratory vacuum lines. Over 50 fatalities and numerous neurological impairments in a small fishing village on the Minamata Bay of Japan have been attributed to the biotransformation of Hg^{II} in industrial effluent to methylmercury (CH_3Hg^+). Bioaccumulation of alkyl mercurials in the aquatic food chain presents a serious risk to the world’s food supply.

Mercury forms strong *Covalent Bonds* in biological systems and competes with physiologically essential metals for binding to organic molecules, resulting in high toxicity. In all its forms, mercury is a cumulative poison because of its slow elimination from the body. While metals cannot be destroyed metabolically, many bacteria are able to convert organomercurials and Hg^{II} to less deleterious and volatile Hg^0.[33] The most common bacterial resistance mechanism uses specific proteins for mercuric ion transport (MerT and MerP), organomercurial cleavage (MerB or organomercurial lyase) and mercuric ion reduction (MerA or mercuric ion reductase), which are transcriptionally regulated by a Hg^{II}-activated metalloregulatory switch (MerR). In eukaryotic organisms, sequestration by specific, cysteine-rich enzymes (phytochelatins in plants and metallothioneins in animals), and excretion are the dominant routes for heavy metal removal. The oxidation of elemental mercury to Hg^{II} in animals is mediated by catalase. Brain uptake of elemental mercury and subsequent oxidation can lead to mercury accumulation since Hg^{II} does not readily cross the blood–brain barrier. Mercury(I) salts disproportionate into Hg^0 and Hg^{II} within organisms. Furthermore, Hg^{II} can be reduced to Hg^0 internally. Treatment for mercury poisoning first involves removal from the exposure source. Metal-mobilizing chelating agents with greater affinity than endogenous ligands may be used to increase water solubility and excretion by the kidney. Standard treatment for mercury poisoning has been dimercaprol (British Antilewisite, BAL, (**4**)). Recently, a challenge test with Dimaval (2,3-dimercapto-1-propane sulfonic acid, sodium salt, DMPS, (**5**)) was found to have high sensitivity for low level mercurialism.[34] DMPS is used for treatment of mercury poisoning by physicians in Europe but is not FDA approved for use in the United States even though it is 300 times less toxic and neither crosses the blood–brain barrier nor redistributes mercury to the brain like BAL.



(**4**)

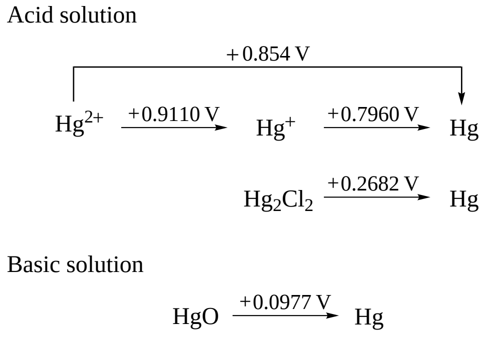


(**5**)

3 MERCURY(I): COMPOUNDS AND COORDINATION CHEMISTRY

3.1 General Aspects

In contrast to zinc and cadmium, mercury has a stable monovalent state, and thus exhibits an appreciable chemistry as Hg^I. Both Hg^I and Hg^{II} are stable in aqueous environments, and Hg^I can be prepared by the reduction of Hg^{II} in



Scheme 2

an aqueous acidic environment. The Latimer diagram (*see Latimer Diagrams*) for mercury is shown in Scheme 2.

A summary of the thermodynamic properties of elemental mercury and its compounds has appeared.[35] Although Hg^I is considered a class b or 'soft' metal ion (*see Class A & Class B Behavior* and ***Hard & Soft Acids and Bases***), its coordination behavior suggests that it functions as a harder acid than the divalent ion. Advanced texts have discussed the chemistry of the element and its compounds.[36,37]

There are no compounds containing the simple Hg^I ion. Instead, a metal-to-metal σ-bond produces the $Hg_2{}^{2+}$ *Cation* through the overlap of the 6s orbitals of two Hg^I ions and occupation of the bonding MO by two electrons. *Disproportionation* of the mercurous ion into Hg^0 and Hg^{II}, as shown in equation (4), has an *Equilibrium Constant* of 1.14×10^{-2} based on standard potentials. Hence, the mercurous ion is stable, but depletion of free Hg^{2+} by complexation or precipitation will result in disproportionation.

$$Hg_2{}^{2+} \rightleftharpoons Hg\,(1) + Hg^{2+} \qquad (4)$$

$$E^\circ = -0.115\text{V};\ K = \frac{Hg^{2+}}{Hg_2{}^{2+}} = 1.14 \times 10^{-2}$$

Reviews listing tables of Hg–Hg bond lengths[38–40] (*see Bond Length*) and Hg–Hg stretching frequencies in a series of mercurous compounds have appeared, from which selected values are given in Table 3. The bond distances fall in the range of 245 to 269 pm, while the stretching frequencies range from 113 to 207 cm^{-1}. For the mercury (I) halides, there is an inverse correlation between bond length and stretching frequency, which has been related to the *Electronegativity* of the halogen.

Table 3 Hg–Hg bond lengths and Hg–Hg stretching frequencies in selected mercury(I) compounds

Compound	Hg–Hg (pm)	Hg–Hg (cm^{-1})
Hg_2F_2	251	185.9
Hg_2Cl_2	253	166.5
Hg_2Br_2	249	132.2
Hg_2I_2	269	112.5
$Hg_2(NO_3)_2{\cdot}2H_2O$	254	179.8
$Hg_2(CIO_4)_2{\cdot}2H_2O$	250	181.6
Hg_2SO_4	250	172.2
$Hg_2(BrO_3)_2$	251	183

3.2 Mercury(I) Halides

The four mercury(I) halides have a linear structure X–Hg–Hg–X, the two most common being Hg_2Cl_2 and Hg_2F_2. All the halides are somewhat light sensitive, especially the iodide. The chloride, bromide, and iodide have very low solubility in water, but the fluoride decomposes upon contact with water. Reaction of mercury(I) halides with halogens or oxidizing acids leads to the oxidation of the metal to Hg^{II}. All four halides are oxidized to form mercury(II) oxyhalides. The addition of aqueous ammonia leads to the formation of a black solid, which contains finely divided elemental mercury and a complex mixture of mercury(II) compounds including $HgNH_2Cl$, $Hg_2NCl{\cdot}H_2O$, and $HgCl_2{\cdot}2\,NH_3$. The properties of the four mercury(I) halides are summarized in Table 4.

The chemistry of mercury(I) fluoride, Hg_2F_2, has been reviewed.[41] This yellow solid is prepared by the reaction of Hg_2CO_3 (itself precipitated from aqueous $NaHCO_3$ and $Hg_2(NO_3)_2$) with 40% aqueous HF. It decomposes in water to produce Hg^0 and HgO, and heating of the compound above 570 °C results in a disproportionation to Hg^0 and HgF_2. The higher melting point relative to the other halides indicates a greater *Ionic Character*.

Even though Hg_2Cl_2 is white, its trivial name of calomel is derived from two Greek words meaning 'beautiful' and 'black'. It is possible that the name comes from the black color of elemental mercury formed by the reaction of Hg_2Cl_2 with ammonia. Calomel has been known for many centuries, and it was the first compound known to have a metal−metal bond. It is precipitated from aqueous solutions containing $Hg_2(NO_3)_2$ and chloride ions. All other mercury(I) halides can be prepared similarly, except the fluoride. The Hg–Hg bond length in the compound is 253 pm, with an Hg–Hg stretching frequency of 166.5 cm^{-1}. It was used as a treatment for syphilis before the advent of penicillin, and is the material present in the standard calomel reference electrode.

The bromide and iodide, as well as pseudohalides (*see Pseudohalide*) such as the thiocyanate and azide, all have the general formula Hg_2X_2. Mercury(I) bromide is a white solid that sublimes at 345 °C, while mercury(I) iodide is a yellow solid that sublimes at 140 °C. The crude iodide

Table 4 Halides of mercury(I)

Compound	Color	Mp (°C)	K_{sp}
Hg_2F_2	Yellow	d > 570	Decomposes in water
Hg_2Cl_2	White	383, sublimes	1.1×10^{-18}
Hg_2Br_2	White	345, sublimes	1.3×10^{-22}
Hg_2I_2	Yellow	140, sublimes	4.5×10^{-29}

sometimes appears green because of the presence of fine particles of Hg^0. Mercury(I) iodide reacts with excess iodide ion to disproportionate into Hg^0 and $[HgI_4]^{2-}$. The S-bound mercury (I) thiocyanate, $Hg_2(SCN)_2$, formed by *Metathesis* between mercury(I) nitrate and thiocyanate ion, is very light sensitive (*see Ambidentate Ligand*). The azide can be prepared by a similar metathesis reaction using aqueous azide or HN_3. The colorless crystalline material is very shock sensitive and heat sensitive and explodes violently. The reaction between cyanide ions and mercury(I) results in a disproportionation, forming $Hg(CN)_2$ and Hg^0.

3.3 Mercury(I) Oxy Salts

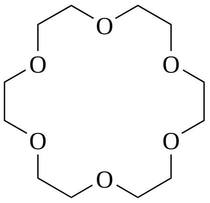
Numerous salts containing oxoanions (*see Oxoanion*), including the nitrate, perchlorate, chlorate, bromate, iodate, and sulfate, are known. Of these, only the nitrate, chlorate, and perchlorate demonstrate a fair degree of water solubility and these serve as a source of insoluble mercury(I) salts through metathesis reactions in water. The nitrate crystallizes as a dihydrate, $Hg_2(NO_3)_2{\cdot}2H_2O$ (*see Hydrates*), which contains linear O–Hg–Hg–O linkages. The nitrate is stable in acid solution; at higher pH it precipitates as $Hg(OH)(NO_3)$.

Mercury(I) is assumed to be of minor importance as an environmental contaminant due to the instability of Hg^I complexes with common atmospheric ligands (e.g. OH^- and SO_3^{2-}, etc.). However, reliable trace analytical techniques for Hg^I in the gaseous or aqueous phase are unavailable.

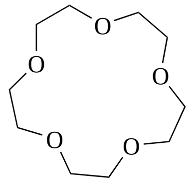
3.4 Mercury(I) Complexes

Complexes of Hg^I are considerably fewer than those of Hg^{II}; the tendency of the ion to disproportionate leads to difficulties in preparation. Decreasing the concentration of Hg^{II} by complexation or precipitation favors disproportionation, as is the case for ligands such as S^{2-}, OH^-, CN^-, NH_3, acac, and thioethers; very few mercury(I) complexes containing these species have been isolated. Similarly, bulky ligands that thwart intermolecular disproportionation processes and form low solubility Hg^I complexes of type $[Hg_2L_2]^{2+}$ can be prepared from Hg^{II}.[28,42] The Latimer diagram for mercury (Scheme 2) reveals that very few oxidizing agents are capable of oxidizing Hg^0 only to Hg^I.

A review of 30 structurally characterized complexes of mercury(I) with organic ligands has been published.[39] Complexes containing nitrogen-donor ligands (*see* ***Ammonia & N-donor Ligands***), principally weakly basic heterocyclic amines (anilines, pyridines, and phenanthroline), commonly have the compositions $[Hg_2L_2]X_2$ or $[Hg_2L_4]X_2$ with mercury coordination numbers of two and three, respectively. Asymmetric coordination is also possible as in $[Hg_2(phen)](NO_3)_2$, where both nitrogens of phenanthroline are bound to one mercury atom. Oxygen-donor complexes are also known with DMSO, polyphosphates, dicarboxylates, and group 15 oxides, including Ph_3PO and Ph_3AsO (*see* ***Water & O-donor Ligands***). These complexes exhibit a linear O-Hg-Hg-O structure. Recently, complexes $[Hg_2(\mathbf{6})_2(Me_2SO)(\mu\text{-}Me_2SO)](O_3SCF_3)_2$ and $[Hg_2(\mathbf{6})(\mathbf{7})(Me_2SO)](O_3SCF_3)_2$ were characterized by X-ray crystallography and ^{199}Hg NMR.[27] Asymmetric coordination permitted detection of $^1J(^{199}Hg^{199}Hg) = 220\,300$ and $284\,100$ Hz, respectively, the largest scalar couplings ever reported.



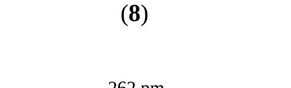
(**6**)



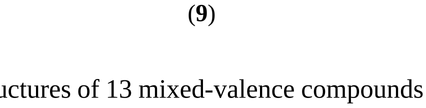
(**7**)

3.5 Mercury Polycations of Lower Oxidation States

A number of salts that contain polycations of mercury in oxidation states less than +1 are known. These lower oxidation state cations are typically generated in molten salt media but are also found in natural minerals. For example, salts containing the polycation Hg_3^{2+} (**8**) in the salt $Hg_3(AlCl_4)_2$ can be prepared in molten salt media (Hg, $HgCl_2$, $AlCl_3$). Here, the oxidation state of the mercury is +2/3. The same cation, as well as Hg_4^{2+} (Hg = +1/2) (**9**), can be generated using the correct stoichiometric equivalents of AsF_5 in liquid SO_2. The compound $Hg_4(AsF_6)_2$ is red while $Hg_2(AsF_6)_3$ is orange. A third compound, $Hg_2(AsF_6)_2$, can also be isolated from these reactions. Not surprisingly, it contains the Hg_2^{2+} cation and is colorless. Some of these cations can also be prepared in HSO_3F *Superacid* media. Under certain conditions, the reaction of Hg and AsF_5 in liquid SO_2 can also produce a nonstoichiometric compound (*see Nonstoichiometric Compounds*) of the formula $Hg_{2.82}(AsF_6)_{0.94}$, which consists of a ccp array of fluoride ions with infinite chains of mercury atoms. The compound is an anisotropic superconductor. Mercury NMR has proven useful in the study of the previously mentioned mercury polycations in low oxidation states.



(**8**)



(**9**)

The structures of 13 mixed-valence compounds containing Hg_n groups ($n = 2$ or 3), in which the oxidation state of

the mercury atoms is lower than +2, and Hg^{2+} cations have been reviewed.[39] Most of these compounds contain the mercurous ion. However, the first mixed-valence compound characterized by X-ray diffraction was the synthetic analog of the rare mineral terlinguaite $Hg_4O_2Cl_2$. Unusual triangular Hg_3 clusters with Hg–Hg bond lengths of 253 pm and mercury atoms with a formal oxidation state +4/3 were observed. A limited variety of additional compounds containing Hg triangles are known, with Hg–Hg distances of 261–344 pm.[40]

4 MERCURY(II): COMPOUNDS AND COORDINATION CHEMISTRY

4.1 General Aspects

Motivations to investigate the coordination chemistry of Hg(II) include improved understanding of its interactions in physiological systems and development of ligands with potential for selective coordination. Solvent extraction is potentially an effective and energy-saving technique for the recovery of mercury from industrial wastes; however, the complex syntheses of selective extractants and recoverability issues have thus far restricted commercial viability. Recent efforts relying on novel structural modifications of calixarene and crown ether, thiaether and azaether macrocycles have been reviewed.[43] Structural comparisons with other members of the group 12 triad are also common.

Hg^{2+} is about the same size as Ca^{2+}, but it is a much more strongly polarizing ion, which results in greater covalency. Interestingly, Hg^{2+} generally forms stronger bonds with S-, N- and P-ligands than any other divalent metal ion, yet undergoes extraordinarily rapid ligand exchange. The large diameter of Hg^{II}, its ability to form complexes of several different coordination numbers with the same ligand type, and its lack of strong coordination geometry preferences favor associative exchange processes. Although complexes of Hg(II) with monodentate ligands seem to favor linear and tetrahedral geometries, the binding constraints of multidentate ligands have expanded the number of accessible geometries. The coordination chemistry of the group 12 triad has been reviewed annually since 1994.[44–52]

The softness of Hg^{2+} makes it a prototypical class b acceptor. As noted, the ion has a strong tendency to form covalent bonds rather than ionic bonds. Its complexes can be highly colored owing to the presence of *Charge Transfer* bands because of the highly polarizing Hg^{2+} cation. The decreased shielding power of the 14 4f electrons and relativistic effects are the source of the large polarizing ability of Hg^{2+}.

A collection of well-proven syntheses for standard mercury compounds in general use synthetically has been published.[53] Mercury(II) forms both a hydride, HgH_2, and a carbide, HgC_2. These compounds are not stable and decompose rapidly, the carbide explosively.

4.2 Mercury(II) Halide and Pseudohalide Complexes

All four mercury(II) halides are known, and their properties are listed in Table 5. All can be prepared by the direct combination of the appropriate halogen with mercury metal. Except for the fluoride, which has bonds that are predominantly ionic in character, they are characterized by relatively low-melting and boiling points and display surprising solubility in organic solvents such as acetone. Their coordination chemistry has been reviewed.[54] A summary of the structural features of the crystalline mercury(II) halides is given in Table 6.

Mercury(II) fluoride, HgF_2, has the highest melting and boiling point of the mercury(II) halides due to the high degree of ionic character in the Hg–F bonds. It is prepared by the reaction of fluorine gas and Hg^0, and readily hydrolyzes into HgO and HF. It exists in the cubic fluorite structure with Hg–F distances of 240 pm.

Mercury(II) chloride, $HgCl_2$, has a linear structure with significant covalent character. It has a much higher solubility in organic solvents such as methanol (50 g per 100 g at 25 °C)

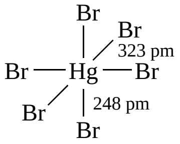
Table 5 Halides of mercury(II)

Compound	Color	Mp(°C)	Bp(°C)	Solubility (g per 100 g H_2O at 20 °C)
HgF_2	White	d > 645	–	Decomposes
$HgCl_2$	White	280	303	6.6
$HgBr_2$	White as solid, Yellow as liquid	238	318	0.62
HgI_2	Red, yellow	257	351	6×10^{-3}

Table 6 Structural information on crystalline mercury(II) halides

Compound	Crystalline structure, description	Distances of X atoms around Hg
HgF_2	Cubic, fluorite	8 F at 240 pm
$HgCl_2$	Orthorhombic, linear	2 Cl at 225 pm; 2 Cl at 338 pm; 2 Cl at 346 pm
$HgBr_2$	Orthorhombic, distorted O_h	2 Br at 248 pm; 4 Br at 323 pm
HgI_2 (red)	Tetragonal, distorted tetrahedral	4 I at 278 pm
HgI_2 (yellow)	Orthorhombic, distorted O_h	2 I at 262 pm; 4 I at 351 pm

and acetone (55 g per 100 g at 25 °C) than in water. In the solid-state, the Hg–Cl bond length is 225 pm. Historically, $HgCl_2$ has been referred to as 'corrosive sublimate', and small quantities have been used as an antiseptic. However, it is also highly toxic because of its large water solubility.



(**10**)

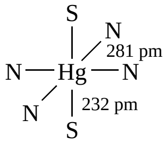
The heavier halides (X = Cl, Br, I) can also be prepared by precipitation from aqueous $Hg(NO_3)_2$ and the halide. The solubility of the mercury(II) halides decreases with increasing molecular weight, and the iodide is highly insoluble. Although the crystalline bromide is colorless, it produces a yellow liquid upon melting. Crystalline $HgBr_2$ (**10**) contains two short Hg–Br distances (248 pm) and four long distances (323 pm). This distortion from octahedral stereochemistry is observed in many mercury(II) compounds. In the vapor phase, the three heavier halides exist as discrete linear molecules with the following bond lengths: Hg–Cl, 228 pm; Hg–Br, 240 pm; Hg–I, 257 pm.

Two mercury(II) iodides exist: the yellow form is the kinetic product and the red is the thermodynamic product from the reaction between Hg^{II} and I^-. Both iodides have very low solubility in water. The red form consists of Hg^{2+} ions in tetrahedral holes in a ccp array of iodide ions with Hg–I distances of 278 pm. The red HgI_2 consists of a layer structure with HgI tetrahedral linked at the apex. Progress in growing single crystals of this form for use at room temperature as X-ray and gamma-ray detectors, as well as photocells with a wide variety of uses, has been reviewed.[55] The yellow HgI_2 is octahedrally coordinated with two short Hg–I distances (262 pm) and four longer ones (351 pm), similar to the observed $HgBr_2$ structure. Reaction of mercury with excess KI forms K_2HgI_4, and reaction of the metal with zinc(II) iodide forms the red HgI_2. Above 126 °C, the red form converts to the less dense yellow form. Evidence for a third metastable form, an orange HgI_2 with Hg–I distances of 268 pm, has been presented.[56]

Addition of excess iodide to the insoluble HgI_2 results in the formation of soluble mercury iodo complex $[HgI_3]^-$, with a trigonal planar structure. The ion is solvated in water and converts to a tetrahedral structure. Further, addition of I^- leads to tetrahedral $[HgI_4]^{2-}$. Reaction of iodide salts with Hg^0 can be used to produce mercury iodo complexes. Other halide and pseudohalides also form $[HgX_3]^-$ and $[HgX_4]^{-2}$. The tetrahalo anions (*see Anion*) are usually tetrahedral, while the trihalo ions readily add solvent molecules to form distorted tetrahedral or *Trigonal Bipyramidal* structures.

The 17 known chloromercury anions of form $Hg_xCl_y{}^{n-}$ ($x = 1-6$; $y = 2-10$; $n = 1-6$) have been reviewed.[57] These anions exhibit diverse configurations that cannot be determined from the analytical stoichiometry, and in many cases multianion combinations are observed. As a result, single-crystal diffraction studies are critical to definitive structural assignment. Many chloro complexes of mercury(II) are based upon distorted $HgCl_6$ units. These units are then linked into chains or layers by sharing edges or corners.

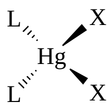
Mercury(II) cyanide, which exists as discrete linear $Hg(CN)_2$ molecules, forms 1:2 and 1:1 adducts (*see Addition Compound*) with soft ligands such as phosphines and thioethers. The cobalt(II) complex $CoHg(SCN)_4$, commonly used as a calibrant in *Magnetic Susceptibility* studies, exhibits a diamond-like structure in which the thiocyanate ligands link the Co and Hg ions into a three-dimensional framework. Furthermore, the Co ion is surrounded by a tetrahedron of four nitrogen atoms while the Hg ion is surrounded by a tetrahedron of four sulfur atoms. Mercury fulminate, $Hg(ONC)_2$, is used as a detonator. The principal component of a child's toy dating from 1865, 'Pharaoh's serpent eggs', is $Hg(SCN)_2$. When the $Hg(SCN)_2$ pellet is ignited, an ash is produced, which curves up into the air as it expands, resembling the movements of a snake. The structure of $Hg(SCN)_2$ (**11**) consists of two short Hg–S bonds (232 pm) and four long Hg–N bonds (281 pm) in a distorted octahedral arrangement around the central metal atom. All the thiocyanate ligands bridge mercury atoms (*see Bridging Ligand*). A highly sensitive spectrophotometric method for the measurement of trace amounts of mercury in solution based upon a colored complex of mercury(II), thiocyanate, and Rhodamine B has recently been reported.[58] Mixed halide and pseudohalide complexes such as [HgCl(SCN)] are known; typically they have linear structures.



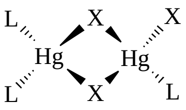
(**11**)

Mercury(II) halides form solvate complexes with a large number of polar organic solvents including methanol, pyridine, acetonitrile, and 1,4-dioxane. These complexes are usually polymeric and octahedral with doubly bridging halides. There are also adducts of the general formula HgX_2L, where X is typically Cl, Br, or I, and L is a soft ligand such as a phosphine, dithiocarbamate, or thioether, a heterocyclic amine, or an As, Se or Te donor. Compounds such as $HgI_2(PPh_3)_2$ display tetrahedral structures with the general formula ML_2X_2 (**12**). Some monomeric and polymeric complexes that do not contain bridging halide groups are also observed, as well as dimeric halogen bridged tetrahedral complexes of the general type $LXHgX_2HgLX$ (**13**). Additionally, some five-coordinate species of the type HgX_2L,

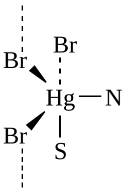
where L is a polydentate amine such as dien, are known. Most of these, such as $HgBr_2\cdot$ bipy (**14**), are trigonal bipyramidal, but a few, such as $HgCl_2\cdot$ diphenyl sulfoxide (**15**), are *Square Pyramidal*. Mercury(II) forms some six-coordinate halide complexes with distorted octahedral structures having short axial and long equatorial bonds.



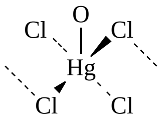
(**12**)



(**13**)



(**14**)

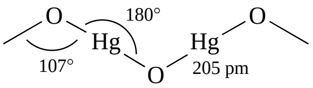


(**15**)

Mercury(II) is known to accelerate *Ligand Substitution* reactions of complexes of formula ML_5X (M = Rh, Cr, Co, Ru; L = H_2O or NH_3; X = bridging halide or pseudohalide), probably by forming an intermediate with a halide bridge between Hg^{II} and M.

4.3 Mercury(II) Oxides, Sulfides, and Other Chalcogenides

Mercury(II) oxide, HgO, is of historical significance since its pyrolysis by Priestley in 1774 led to the discovery of oxygen. Crystalline HgO is orthothombic, and the structure of HgO consists of almost linear O–Hg–O bonds (Hg–O bond length = 205 pm; O–Hg–O bond angle = 180°; Hg–O–Hg bond angle = 107°). These linear Hg–O bonds form a zigzag chain structure (**16**). Like HgI_2, HgO exists in both a red and a yellow form. In this case, however, the red form is prepared by the pyrolysis of $Hg(NO_3)_2$ or by the oxidation of Hg^0 by O_2 at elevated temperatures. The yellow form is precipitated from Hg^{2+} solution by aqueous OH^-. The color difference between the two mercury oxides is due to particle size and not a structural difference. The hydroxide, $Hg(OH)_2$, has never been isolated. The reaction between Hg metal and oxygen is kinetically slow and is usually carried out at 300 to 350 °C. Above 400 °C, however, HgO decomposes into Hg^0 and oxygen. As seen from the reduction potentials (Scheme 2), the reduction of mercury(II) in base, in the form of HgO, occurs less readily than in acidic solutions. Basic solutions therefore stabilize mercury(II) more than acidic solutions do. A less common hexagonal form of HgO that is isostructural with red HgS is known; it is obtained by heating K_2HgI_4 in aqueous NaOH at 50 °C. Mixed metal oxides of mercury(II), such as



(**16**)

$Hg_2Nb_2O_7$, also contain linear O–Hg–O linkages, and many have pyrochlore structures.[59]

The first systematic structure analysis of mercury oxosalts, salts containing oxygen atoms that are not part of an acid residue, was recently published.[60] Structural description in terms of oxocentered $[OHg_4]$ tetrahedra with nonequivalent Hg–O bonds linked by both vertices and edges efficiently illustrated the unique structures and interrelationships of these compounds.

Mercury(II) suflide, HgS, exists in both zinc blende and rock salt structures. The red cinnabar ore exhibits the rock salt form, which consists of Hg–S helical chains, resulting in a very large optical rotatory power for the crystal. There are three pairs of Hg–S bond distances: 236, 301, and 330 pm. The S–Hg–S bond angles are 172°, and the Hg–S–Hg bond angles are 105°. A less common zinc blende form, the black metacinnabar, is converted to the more stable rock salt structure upon heating. The denser red form is favored at higher pressures. A black precipitate of HgS is produced by the addition of H_2S or sulfide ion to a solution containing Hg^{2+} ions. This compound is highly insoluble ($K_{sp} = 1 \times 10^{-52}$), but the chemistry involved is more complex than a simple ionic precipitation since substantial hydrolysis of both mercury(II) and sulfide ion occurs, and complex polysulfides are formed.[61] Black HgS is an inert material that only very strong concentrated acids such as HBr, HI, and aqua regia will dissolve.

The other chalcogenides (*see Chalcogens*) mercury(II) selenide, HgSe and telluride, HgTe, can be synthesized directly from the elements. Both compounds have a zinc blende structure and function as semiconductors. The selenide is violet–black, and the telluride is black.

4.4 Mercury(II) Oxy Salts

The nitrate, perchlorate, and sulfate salts of mercury(II) are all known. Since mercury(II) is a weak acid, hydrolysis of the ion to form hydroxo-bridged polycations is strongly favored but is inhibited at low pH. In acidic solutions, species such as hydrated mercury(II) and $[Hg(NO_3)]^+$ are formed. The reaction of mercury(II) with excess nitrate leads to the formation of the complex anion $[Hg(NO_3)_4]^{2-}$. This complex is formally eight-coordinate with each nitrate ion coordinating in bidentate fashion through two O donors (*see Bidentate Ligand*). The average Hg–O bond distance in this complex is 240 pm.

Reaction of mercury(II) with carbonate ion produces the insoluble carbonate, $HgCO_3$, in addition to species such as $[Hg(OH)]^+$ and $[Hg(OH)(CO_3)]^-$. The oxalate and phosphate salts are also known, both of low solubility. Mercury forms

compounds with a variety of organic carboxylates, and many of these compounds are used as specific reagents or catalysts (*see Catalysis*) in organic reactions. Many of these oxo salts have two short Hg–O bonds and four longer Hg–O bonds, as is typical of mercury(II) coordination in general. When hydroxide is the coordinating ligand, zigzag chains of Hg–(OH)–Hg linkages are formed, similar to what is observed in the structure of HgO.

4.5 Other Complexes of Mercury(II)

The coordination chemistry of mercury has been reviewed.[44–52,62–64] Tolerance for different coordination numbers and coordination geometries, even with the same ligand type, is typical of the coordination chemistry of Hg(II) (Table 7). Two coordination is more common for mercury(II) than for any other cation. Tetrahedral mercury(II) complexes are usually more covalent in nature and contain less polar Hg–I or Hg–S bonds as opposed to the more ionic character observed in Hg–O bonds. Monodentate ligands tend to form either linear two-coordinate or tetrahedral four-coordinate complexes. Six coordination is less common than for Zn(II) or Cd(II), but reports of octahedral and higher CN complexes of mercury(II) are increasing in number. Frequently, the otherwise equal bond lengths in six-coordinate complexes are distorted into two short and four long bonds, analogous to linear coordination. Multidentate ligands have permitted isolation of numerous complexes with less common stereochemistry and high coordination numbers. Crystallographic and structural data for mercury coordination compounds have been classified in terms of nuclearity and CN with analysis of isomerism and correlations between ligand donor atoms, bond lengths, and bond angles.[65]

4.5.1 Complexes with Sulfur Donor Ligands

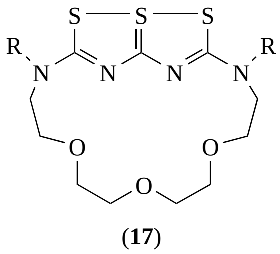
Mercury has a strong affinity for sulfur, so it is not surprising that a large number of mercury(II) complexes contain S-donor ligands (*see* ***S-donor Ligands***). In fact, the word 'mercaptan' is derived from 'mercury capturer' because of the ability of mercury to react readily with thiols. Organic thiols react with HgO to form mercury mercaptides, which are characterized by low-melting points and high solubility in solvents of low polarity such as toluene. The structure and spectroscopy of Hg^{II}–thiolates has been reviewed.[18] In physiological systems, proteins with high sulfur content called metallothioneins are responsible for scavenging Hg^{II} and transporting it to the kidney for excretion. The metalloregulatory protein MerR, which regulates metallothionein synthesis at the transcriptional level, is believed to have a trigonal planar sulfur-binding site that exhibits both high affinity and selectivity toward mercury.[17,18]

Table 7 Stereochemistries of selected mercury(II) complexes

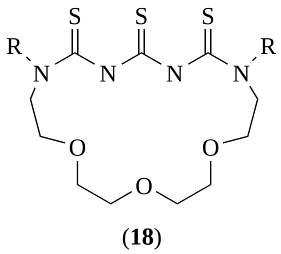
Coordination number	Stereochemistry	Complex
2	Linear	$[Hg(NH_3)_2]^{2+}$, $HgCl_2$
3	Trigonal planar	$[HgI_3]^-$
	T-shaped	$[Hg(SC_6H_2Bu^t_3)_2(py)]$
4	Tetrahedral	$[Hg(SCN)_4]^{2-}$, $[HgI_2{\cdot}2PPh_3]$
	Square planar	*trans*-$[Hg\{Ph_2PNP(O)Ph_2\text{-}P,O\}_2]$
5	Trigonal bipyramidal	$[Hg(dien)Cl_2]$, $[HgCl_5]^{3-}$
	Square pyramidal	$[Hg(15S5)]^{2+}$, $[HgCl_2{\cdot}$diphenyl sulfoxide$]$
6	Octahedral	$[Hg(en)_3]^{2+}$, $[Hg(9S3)_2]^{2+}$
	Trigonal prism	$[Hg\{Pt(2,6\text{-}Me_2C_6H_3NC)\}_6]$
8	Distorted square antiprism	$[Hg(NO_2)_4]^{2-}$

A number of sulfur containing ligands have been found to complex mercury(II), including thiourea, thiocarboxylic acids, thiocarboxylates, mercaptides, thiones, and thioethers. The remarkable structural diversity of the mercury(II) bis xanthates (S_2COR) and bis dithiocarbamates has been reviewed.[66] Dithiolates can function as monodentate, chelating, and bidentate bridging binding ligands of Hg(II), and more than one of these modes can be found in a single structure. Structurally characterized $[Hg(S_2COR)_2]$ complexes have a one-dimensional chain structure (R = Me), a two-dimensional layer structure (R = Et), and a three-dimensional network structure (R = *i*Pr). Variation of remote organic substituents also leads to an intriguing array of five distinct structural motifs for the $[Hg(S_2CNR_2)_2]$ system. The delicate balance between satisfaction of the bonding requirements of the mercury atom and optimization of intermolecular interactions is especially apparent in the existence of two forms of $[Hg(S_2CNEt_2)_2]$, one dimeric and the other essentially monomeric. Interestingly, eight distinct structural motifs have been observed for bis dithiolates of group 12 metals, of which three have only been observed with Hg and three have yet to be observed with Hg.[67] Structural assignments for this class of compounds obviously requires definitive crystallographic evidence.

The host–guest chemistry of crown ethers continues to be exploited for the development of new ionophores for the selective recovery of Hg(II). A novel crown ring system containing a redox switchable trithiadiazapentalene/trithiotriuret unit (**17**/**18**) allows control of Hg(II) in solvent extraction experiments between chloroform and water.[68] The thiocarbonyl sulfur donor sites outside the macrocyclic cavity of (**18**) are responsible for strong complexation and extractability into chloroform.

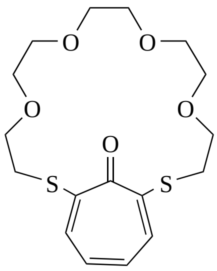


(**17**)

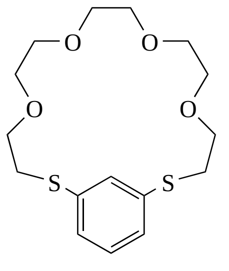


(**18**)

Selective transport of Hg(II) over Cu(II) through chloroform from a solution of these metal ions to an aqueous HCl solution was demonstrated for the troponoid dithiocrown ether (**19**).[69] The benzenoid dithiocrown ether (**20**) was a much less effective transporter in spite of similar cavity size, suggesting protonation of the tropone ring assisted release of the Hg(II) from the complex.

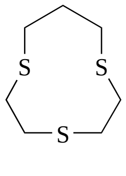


(**19**)



(**20**)

Related complexes containing several cyclic or crown thioethers are known, and the thioether ligands may bind through three, four, or even five sulfur donor sites. For example, unusual octahedral hexakis(thioether) coordination was observed in the single-crystal *X-ray diffraction* structure of $[Hg(\mathbf{21})_2](ClO_4)_2$.[70] Interestingly, no macrocyclic effect is observed for mercury(II) complexes with the two crown tetrathioether ligands (**22**) and (**23**).[71] Indeed, acyclic tetrathioethers such as (**24**) actually have a greater affinity for mercury(II) than do the cyclic thioethers, the converse of what is observed for other transition metal ions. This observation has been attributed to the large size of the mercury(II) ion and the need of a larger and more flexible ligand for better coordination. The stability constants (*see* ***Stability Constants & their Determination***) of many mercury(II) complexes of thioethers have been reported.[72]



(**21**)

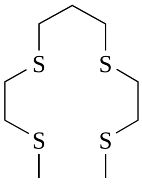
(**23**)



(**24**)

4.5.2 Complexes with Oxygen-donor Ligands

A series of octahedral complex ions with monodentate O-donor ligands, such as $[Hg(H_2O)_6]^{2+}$ and $[Hg(DMSO)_6]^{2+}$, are known, but only in the presence of poorly coordinating *Counter Ions* such as perchlorate or triflate. The Hg–O bond lengths in these complexes average about 234 pm. Related complexes with bidentate O-donor ligands such as oxalate are also known. The ophthalmic preservative known as thimerosal is actually the sodium salt of an anionic mercury complex, which contains a mercury(II) ion center chelated (*see Chelating Ligands*) by a bidentate mixed O,S– donor ligand.

4.5.3 Complexes with Nitrogen-donor Ligands

Alchemists performed reactions between ammonia and mercury compounds, to some of which they gave descriptive names. However, the complex nature of the products prevented their full characterization until more recently. Mercury(II) chloride or bromide reacts with ammonia under differing reaction conditions to form three types of complexes: $Hg(NH_3)_2X_2$, diammine halides; $HgNH_2X$, amidohalides or aminohalides; and Hg_2NHX, iminohaides (equations 5–7). The complex $Hg(NH_3)_2Cl_2$, known as 'fusible white precipitate', consists of a fcc lattice of chloride ions with linear N–Hg–N linkages. The observed Hg–N distance is 203 pm, and the observed Hg–Cl distance is 287 pm. The compound is isolated from the reaction of $HgCl_2$ and a mixture of aqueous ammonia and ammonium ions when a high concentration of ammonium ion and/or nonpolar solvents are present. The amidochloride, $HgNH_2Cl$, 'infusible white precipitate', can be isolated under conditions of low ammonia concentration and without NH_4^+ present. $HgNH_2Cl$ has a structure of zigzag chains of Hg–N bonds. In addition, complexation to mercury(II) can activate N–H bonds in these amine halides to form iminohalides (e.g. HgNHCl) (equation 7).

$$HgCl_2(s) + 2NH_3(aq) \rightleftharpoons [Hg(NH_3)_2Cl_2] \quad (5)$$

$$[Hg(NH_3)_2Cl_2] \rightleftharpoons [Hg(NH_2)Cl] + NH_4Cl \quad (6)$$

$$2[Hg(NH_2)Cl] + H_2O \rightleftharpoons [Hg_2NCl(H_2O)] + NH_4Cl \quad (7)$$

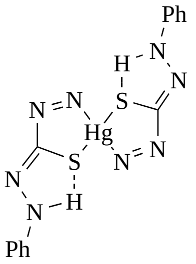
$$Hg^{2+} + 2NH_3 \rightleftharpoons [Hg\text{-}NH_2]^+ + NH_4^+ \quad (8)$$

The compound $[Hg_2NCl(H_2O)]$ is the chloride salt of the dihydrate of Millon's base, $[Hg_2NOH{\cdot}2H_2O]$ (see Section 2). Besides air oxidation of Hg^0 in ammonia, Millon's base can also be prepared by the reaction of yellow HgO with ammonia. The bright yellow product can be converted to $[Hg_2NCl(H_2O)]$ with HCl. Many salts, called imino derivatives, are known with the general formula $[Hg_2NX(H_2O)]$. These compounds have a structure consisting of $[Hg_2N]^+$ units with tetrahedra of four Hg^{II} ions linked to each nitrogen atom, and two nitrogen atoms linearly linked to each Hg^{II} ion. The structure has open channels and cavities to accommodate anions and water molecules in interstitial sites, and the compounds resemble

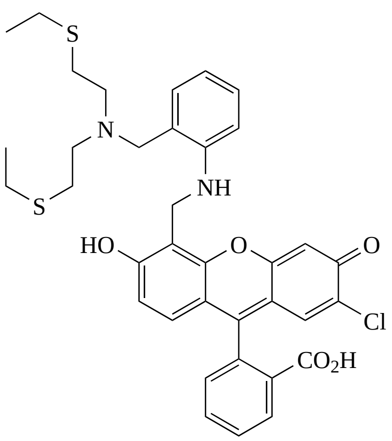
zeolites (*see* ***Zeolites***) in their ability to function as anion exchangers (*see Ion Exchange*).

Additionally, octahedral tris bidentate complexes of mercury(II) with ligands such as en, bipy, and phen have also been reported. Typically, these must be formed in the presence of excess ligand and must contain poorly coordinating anions such as perchlorate to minimize the formation of amino and imino compounds. Complexes of mercury(II) with aromatic amines, heterocyclic amines, and macrocyclic amines including porphyrins (*see Porphyrin*) are also known. Recent studies with dipodal and tripodal amines bearing pyridyl and imidazoyl appendages (e.g. **1**, **2**, **3**) have provided opportunities to correlate NMR spectra taken under slow-exchange conditions with crystallographically determined structures.[22,24,25,73] With (**2**), it was even possible to monitor changing from a tridentate binding mode with pendant lutidyl in [Hg(**2**)Cl_2] to a tetradentate binding mode in [Hg(**2**)Cl]$^+$ through changes in proton chemical shifts and $J(^{199}Hg^1H)$.[73]

Mercury(II) reacts with dithizone to form the mixed N,S-donor complex mercury dithizonate (**25**).[74] This complex has interesting photochromic properties (*see Photochromism*). For example, its solutions in a variety of organic solvents are orange in weak illumination, but they turn dark blue in sunlight or intense artificial light. The water-soluble, turn-on florescein-based sensor (**26**) that exhibits environmentally relevant selectivity and sensitivity for Hg was recently reported.[75]



(**25**)



(**26**)

4.5.4 Complexes with Phosphorus Donor Ligands

Mercury(II) reacts with phosphines to form 1:1 or 1:2 complexes of the general type $HgLX_2$, where X is an anionic ligand such as halide or nitrate. The values of the $^{31}P-^{199}Hg$ coupling constants are useful in elucidating the structures of these compounds. Complexes with bidentate ligands that contain phosphorous and group 16 donor atoms (S, Se) are also known.[76] These have been characterized by ^{31}P, ^{77}Se, and ^{199}Se, and ^{199}Hg NMR spectroscopy and by electrochemical studies. Recently, the first true square-planar Hg(II) compound *trans*-[Hg{$Ph_2PNP(O)Ph_2$-P, O}$_2$] was synthesized and fully characterized.[77] Charge delocalization in the ligand appeared to be key to the observed geometry.

4.5.5 Complexes with Other Donors

As observed previously for soft donor ligands such as thioethers and phosphines, mercury(II) reacts with selenoethers and telluroethers to form complexes of the general type $HgLX_2$, where X is a halide or pseudohalide. In addition, mercury(II) forms complexes with various Se-donor ligands such as diethylselenocarbamate and selenourea.

Tellurium coordination is seen in a series of acyclic bidentate ligands that coordinate through Te–N donor atoms or Te–O donor atoms.[78] An interesting series of adamantane-like cage complex cations that contain mercury(II) have been prepared and have the general formula $[\mu\text{-}ER_2(HgL)_4]^{2+}$ (E = S, Se, or Te; L = phosphine or arsine).[79,80] These cations contain a variety of Hg–L bonds and have been characterized using heteronuclear NMR (^{31}P, ^{125}Te, ^{199}Hg).

4.6 Mercury(III) Complexes

There is potentiometric evidence for the formation of a mercury(III) complex by the oxidation of the mercury(II) complex of the cyclam macrocycle 1,4,8,11-tetraazacyclotetradecane.[81] There is also some evidence for the biological oxidation of mercury to Hg^{III}.

4.7 Compounds with Metal–Mercury Bonds

Mercury will bond directly to certain metal atoms including Co, Ru, Rh, Fe, Pt, and Mn. Such Hg–metal bonds are usually part of linear M–Hg–M or M–Hg–X linkages, and some clusters containing mercury–metal bonds are also known. These compounds are prepared by the reaction of mercury(II) halides with carbonylmetallates. A rare example of trigonal prismatic (*see Trigonal Prism*) coordination in a mercury complex is exhibited by [Hg{Pt_3(2, 6-$Me_2C_6H_3NC)_6$}$_2$], which contains Pt–Hg bonds.[82] These types of compound have been reviewed.[83]

1 INTRODUCTION

In spite of their early discovery by Frankland in 1852, organomercurials have found relatively limited applications with respect to other organometallic compounds. The reason for this can be traced back to their high toxicity, which causes damage to the central nervous system and induces neuropsychiatric disorders in humans.[1] Since the publication of the first edition of EIC,[2] the chemistry of organomercurials has focused more on development than on innovation. New compounds have been prepared using the general synthetic procedures that had previously been described. The reactivity of organomercurials has been further explored – using established methodologies – leading to interesting applications in organic synthesis. The solvomercuration of alkenes is still the most widely employed organometallic reaction of mercury, although there have been important advances in the use of the mercury-mediated ring opening of cyclopropanes. Structural investigations of organomercurials have received considerable attention over the past 10 years. Several new structures have been crystallographically elucidated providing detailed information on the connectivity of a wide range of mono- and polymercuric complexes. Furthermore, there has been considerable interest in understanding the supramolecular interactions displayed by several organomercurials in the solid state and in solution.

This entry will provide an overview of the most important advances on the organometallic chemistry of mercury between 1993 and 2003. During the past 10 years, several reviews and books on this topic have appeared.[3–13] Annual updates can be found in the Specialist Periodical Reports on Organometallic Chemistry published by the Royal Society of Chemistry.[14–17]

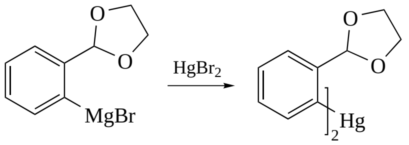
2 SYNTHESIS OF ORGANOMERCURIALS

2.1 Transmetallation

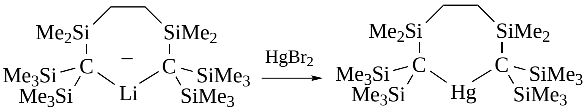
A general method for the synthesis of organomercurials is the transmetallation of mercury(II) salts with other organometallic species. Organolithium and -magnesium compounds continue to be widely employed for the preparation of complexes with formula RHgX or HgR_2 (see equation 1).

$$HgX_2 \xrightarrow{RM} RHgX \xrightarrow{RM} HgR_2 \qquad M = Li, MgX \qquad X = Cl, Br, I \tag{1}$$

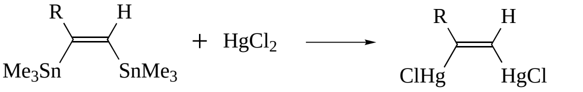
Selected recent examples of the applicability of this synthetic procedure are shown in equations (2–4).[18–20]



(2)



(3)



(4)

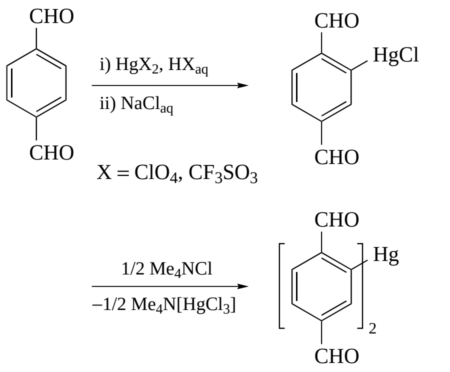
Organoboranes (such as aryl and vinyl boronic acids) have also demonstrated to be valuable reagents for the synthesis of organomercurials, particularly in the presence of functional groups that are not compatible with the more reactive organolithium or -magnesium reagents.

2.2 Mercuration of C–H Bonds

Mercury salts can react directly with hydrocarbons exchanging hydrogen for mercury. This reaction is an electrophilic substitution (equation 5) and hence can take place with arenes, cyclopentadienyls, terminal alkynes, and also with aliphatic hydrocarbons that contain activated carbon–hydrogen bonds (e.g. carbonyl or nitrile compounds). When the hydrocarbon contains several equivalent hydrogen atoms, polymercuration is often observed.

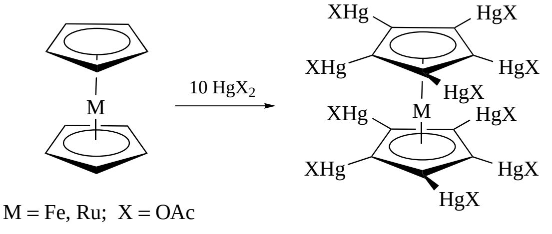
$$R\text{–}H + HgX_2 \longrightarrow RHgX + HX \tag{5}$$

The direct mercuration of arenes is widely used for the synthesis of arylmercurials. The reaction is particularly efficient for activated arenes (such as phenols, anilines, and aryl ethers), while deactivated arenes require the use of stronger electrophiles and higher reaction temperatures. A recent example of the latter is the mercuration of terephthaldehyde reported by Vicente (equation 6).[21]



(6)

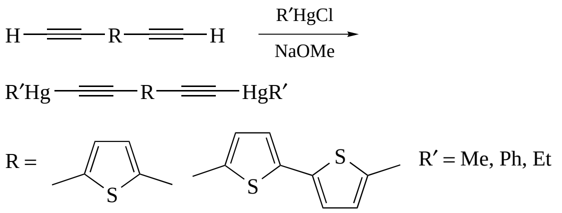
The mercuration of metallocenes has continued to attract interest due to the potential use of the mercurated species in the synthesis of different metallocene derivatives. New mercurometallocenes, together with some mechanistic studies on their formation,[22] have been reported over the past few years. Besides the monomercurated species, a detailed study has appeared on the permercuration of ferrocene and ruthenocene.[23] For both metallocenes, the decamercurated species shown in equation (7) have been obtained in high yields.



(7)

Direct mercuration of alkynes has also been achieved.[24] The interest in mercury alkynyls stems from their documented applications in the rapid separation and detection of toxic organomercurials (particularly, methylmercury derivatives). Upon reaction with alkynes, samples containing methylmercury salts yield $Hg(C{\equiv}CR)_2$ or $Hg(Me)(C{\equiv}CR)$ species that can then be analyzed using chromatographic techniques.

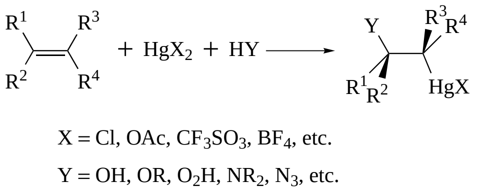
A series of luminescent mercury(II) bis(alkynyl) complexes containing oligothiophenes have been synthesized by Wong via direct mercuration of the corresponding alkynes (see equation 8).[24] Most importantly, the optical properties of these species have been found to be easily tuned by modifying the nature of the thiophene unit.



(8)

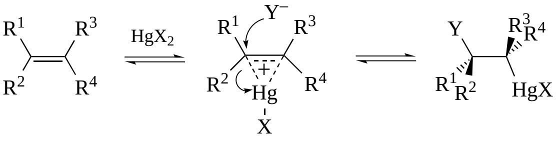
2.3 Mercuration of Alkenes

The reaction between mercury(II) salts and alkenes is the most important general method for the synthesis of organomercurials.[3] Although there are some examples where mercury reacts directly with olefins to produce vinyl mercurials, the most common reaction is the addition of mercury to the alkene's double bond with the participation of a nucleophile (equation 9).



(9)

The proposed mechanism for this reaction involves the electrophilic attack by mercury(II) on the double bond to generate a mercurinium intermediate, followed by attack of the nucleophile (see equation 10).



(10)

The solvomercuration of alkenes has an important synthetic value since it allows the asymmetric functionalization of olefins. Although a large number of organomercurials have been isolated from these reactions, more commonly, they are reduced with alkaline $NaBH_4$ to yield the corresponding metal-free organic species (see Section 4.1). In this way, olefins can be converted into a wide range of organic species such as alcohols, ethers, and amines.

2.3.1 Mercuration in the Presence of Oxygen-containing Nucleophiles

In the previous edition of EIC, Larock described in detail the hydro-, alkoxo-, peroxo-, and acyloxy-mercuration of olefins. These reactions generally proceed in a Markovnikov fashion yielding products of anti addition, although in some cases (e.g.

with strained olefins such as norbornene), the formation of syn products is observed. For the hydroxy-, alkoxy-, and acyloxy-mercuration reactions, $Hg(OAc)_2$ is the reagent of choice (although other mercury(II) salts such as $Hg(O_2CCF_3)_2$ and $Hg(BF_4)_2$ have been used to modify the rate or selectivity of the reaction). Peroxomercurations usually yield better results with $Hg(NO_3)_2$ or $Hg(O_2CCF_3)_2$.

Since the publication of the previous edition of the EIC, the scope of the mercuration of olefins in the presence of water, alcohols, peroxides, and carboxylic acids has considerably broadened. While studying the deprotection of monoallyloxyalcohols to yield sugar-containing systems, Jarosz optimized the reaction conditions yielding various organomercury compounds (see equation 11).[25] In this reaction, the resulting organomercurial is formed via preferential intramolecular attack of the hydroxy group of the monoprotected diol and not by the water present in the reaction medium. Paquette has reported a very detailed study on the intramolecular oxymercuration of a series of tetraspiro carbinols and trispiro cyclohexanones (equation 12).[26] An interesting conclusion from this work is that the approach of the mercury to the double bond (and consequently the stereochemistry of the final product) is largely governed by the interaction of the metal center with a proximal axially oriented ether oxygen. Similar interactions between the mercury ion and a proximal oxygen atom have been invoked to rationalize the stereochemistry observed in a series of intra- and intermolecular alkoxymercurations reported by Senda (equation 13).[27]

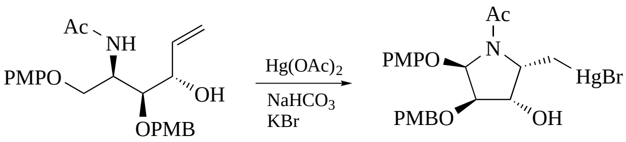
(13)

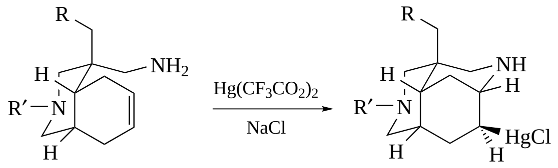
2.3.2 *Mercuration in the Presence of Nitrogen-containing Nucleophiles*

The mercuration of alkenes in the presence of nitrogen-containing species such as amines, amides, nitriles, azides, or nitro groups has also been studied, although not as systematically as that of the corresponding oxygen-containing species. The reaction can be performed with a variety of mercury salts, $Hg(OAc)_2$ and $HgCl_2$ being the most commonly used. When this reaction occurs in an intramolecular fashion, it provides a route to several heterocycles, such as pyrroles, piperidines, and a variety of polycyclic species. A selection of some recent examples is shown in equations (14–16). An intramolecular stereoselective amidomercuration reaction has been disclosed by Singh as an essential step for the synthesis of polyhydroxylated pirrolidines (equation 14).[28]

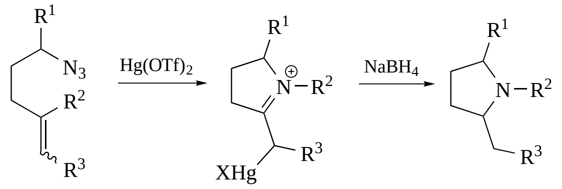


PMP = 4-(*p*-methoxy)phenoxy PMB = *p*-methoxybenzyl

(14)



(15)



(16)

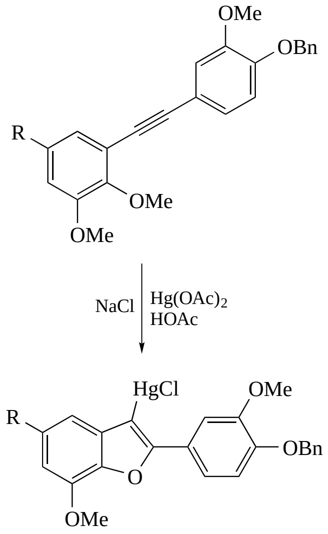
An example of intramolecular aminomercuration has been reported by Weinreb as part of the synthetic strategy to the tricyclic nucleus of madangamine A – an alkaloid that shows cytotoxicity toward a number of tumor cell lines (equation 15).[29] Pearson has recently reported the first example of an azidomercuration involving aliphatic azides (see equation 16) according to a protocol that exhibits wider applicability and is, therefore, more convenient than the analogous acid-promoted Schmidt reaction.[30]

2.3.3 *Miscellaneous Mercuration Reactions*

Halo-, carbo-, and nitro-mercurations of alkenes (and alkynes) have been previously described. However, these reactions are not as general and have not found as many applications in organic synthesis as the ones described in the previous two sections. Consequently, they will not be discussed any further in this review and the interested readers are directed to previous reviews and some recent references.[31–33]

2.4 Mercuration of Alkynes

Mercury(II) salts react with alkynes in two different ways. As discussed in Section 2.2, terminal alkynes react with mercury under basic conditions to yield species with general formula $Hg(C{\equiv}CR)_2$ or $Hg(X)(C{\equiv}CR)$. Alternatively, under neutral or acidic conditions, alkynes undergo solvomercuration reactions to yield anti addition products (for example, see equation 17).[34]

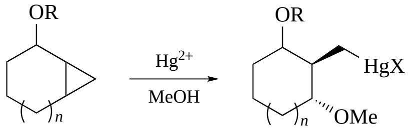


(17)

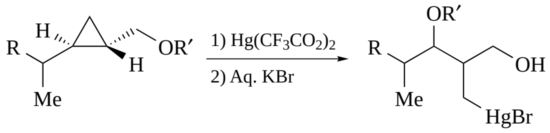
2.5 Mercuration of Cyclopropanes

The electrophilic ring opening of cyclopropanes is a well-established reaction. Detailed studies have shown that the nature of the electrophile is important in determining the mechanism of the reaction: for electrophiles with the capacity of back-donating (e.g. Pd^{2+} or Pt^{2+}), the reaction involves a stereoregiospecific 'edge attack', whereas a 'corner opening' mechanism is proposed for poor back-donors such as Hg^{2+} (see Scheme 1).[11] In both cases, the stereo- and regioselectivities are consistent with backside attack of the nucleophile on the carbon that can best stabilize a positive charge.

Although the initial interest in this type of reaction was mainly focused on the kinetics, stereochemistry, and mechanism, over the past 10 years, more emphasis has been given to its synthetic applications (see Section 4). As part of these studies, several stable organomercurials have been isolated and characterized (see e.g. equation 18).[35] However, Cossy has focused on reactions that lead to the formation of stereotriads via interaction of cyclopropylcarbinol derivatives with mercuric salts.[36] Some of the intermediate organomercurial species involved in this process have been isolated (see equation 19).

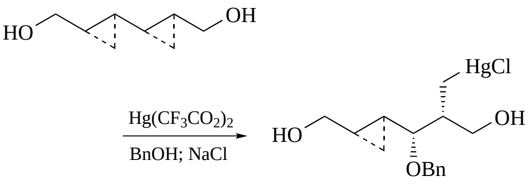


(18)

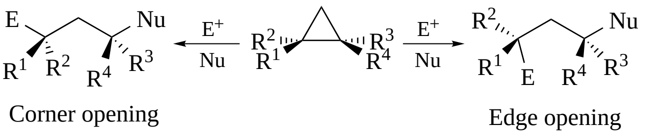


(19)

Barrett has reported a systematic study on the cleavage of multiple cyclopropanes (see e.g. equation 20).[37] Interestingly, it was found that while the mercury-mediated ring opening of monocyclopropanes usually proceeds via a concerted mechanism, in the case of multiple cyclopropanes, it occurs through a stabilized free carbocation. Furthermore, the presence of an adjacent cyclopropane increases the rate of the ring opening of the first cyclopropane.



(20)



Scheme 1

3 STRUCTURE

3.1 Structural Characterization

To date, the structures of more than four hundred organomercury compounds have been determined by X-ray diffraction methods. Detailed reviews by Wardell, Holloway, and Melkník,[9] and Casas,[6] have already been published covering the relevant literature up to the end of 1997. Consequently, only a representative set of recent examples will be discussed in this section.

A survey of the reported data reveals that, despite the known preference of mercury for linear di-coordination, the metal center generally displays sufficient residual acidity to engage in secondary intra- or intermolecular interactions. As a result, there are relatively few examples of organomercury complexes with coordination number two, while coordination numbers as high as seven can be reached when the groups (mainly oxygen-, nitrogen-, and sulfur-donors) involved in the secondary interactions are sufficiently small. The phenomenon is most pronounced not only for mono-organomercurials but also for the less acidic di-organomercury

compounds, particularly when their primary bonds involve perfluorinated ligands. Following Holloway's and Melkník's distinction,[9] monomeric organomercurials can be divided into three subgroups: (a) authentic digonal compounds; and digonal compounds displaying: (b) intramolecular; or (c) intermolecular interactions. The presence of secondary bonding causes a distortion in the L–Hg–L linearity and the L–Hg–L bond angle's mean value decreases from 176.5° to 174.5° to 171° on going from (a) to (b) to (c).

Although a number of intramolecular Hg–π-aryl interactions have been structurally identified, a rare example of unsupported π-aryl complex of Hg has been recently reported. In $[Hg(\eta^2\text{-}C_6H_5Me)_2(GaCl_4)_2]$, the two toluene molecules bind to mercury in an asymmetric η^2 fashion, with the Hg–C_{para} bond length of 2.349(9) Å being considerably shorter than the Hg–C_{meta} (2.71(1) Å).[38] Interestingly, coordination to the Hg/$GaCl_4$ system enhances the acidity of the aromatic molecule and catalytic hydrogen/deuterium exchange phenomena are observed in C_6D_6.

The molecular structure of $[Hg(CO)_2][Sb_2F_{11}]_2$, the first example of a thermally stable carbonyl derivative of a posttransition metal, has also recently been reported.[39] The $[Hg(CO)_2]^{2+}$ cation is nearly linear, with the Hg–C–O bond angle of 177.7(7)°. However, the coordination environment around the mercury atom is that of a distorted octahedron due to weak Hg···F interactions producing an extended two-dimensional structure where each anion links a pair of cations and each cation links four anions.

In addition to the 'conventional' secondary interactions described above, the presence of noncovalent mercuriophilic Hg···Hg attractions has been revealed in some organomercury compounds. Loose polymeric assemblies are formed through weak d^{10}-d^{10} Hg···Hg contacts (3.777−3.935 Å) in the solid-state structures of [R′HgC≡CRC≡CHgR′] (R = thiophene-2,5-diyl or [2,2′]bithiophene-5,5′-diyl, R′ = Me)[24] as well as of $[Hg(C{\equiv}CR)_2]$ (R = Ph, $SiMe_3$; Hg···Hg = 3.71−4.25 Å)[40] and [MeHgC≡CRC≡CHgMe] (R = 9,9′-dioctyl-2,7-diethynylfluorene; Hg···Hg = 3.738−4.183 Å).[41]

Clear examples of intermolecular mercuriophilic interactions have been described in $[MeHg(SC_4H_2N_2Me)]$ (Hg···Hg = 3.10 Å),[42] obtained from the reaction of methylmercury(II) hydroxide with 4-methylpyrimidine-2-thione hydrochloride, and in $[L_3Hg_3O][NO_3]$ (L = 1,3-dimethyluracil-5-yl) (Figure 1).[43] The cations $[L_3Hg_3O]^+$ dimerize, in the solid state, through weak Hg···Hg contacts to give hexanuclear compounds. The unit cell of $[L_3Hg_3O][NO_3]$ contains two different $[L_3Hg_3O]^+$ units. Cation **I** has the geometrical arrangement of a very flat pyramid, with intramolecular Hg···Hg distances in the range 3.4705(5)−3.5859(5) Å, while the two intermolecular contacts are of 3.5620(5) Å. In cation **II**, the Hg···Hg distances within the triangle range from 3.4552(6) to 3.5974(5) Å, while the intercationic separation is 3.6728(8) Å.

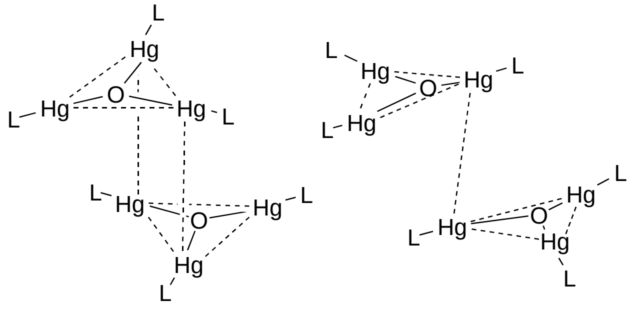


Figure 1 Hexanuclear compounds formed via mercuriophilic interactions in the solid-state structures of $[L_3Hg_3O][NO_3]$[43]

3.2 Organomercurials as Polydentate Lewis Acids

The search for receptors capable of interacting with neutral and anionic substrates has led to the design and development of polydentate Lewis acids. Polyfunctional organomercurials, due to their air and water stability, ease of preparation, and Lewis acidity at mercury, have grown into one of the most prominent classes of Lewis acidic hosts. Much work has focused on derivatives of 1,2-phenylenedimercury (**1**)[13] along with polymercuramacrocycles such as the tetranuclear mercuracarborands (**2**) developed by Hawthorne[7] and the trimeric perfluoro-*ortho*-phenylenemercury (**3**) used by Gabbaï[44] and Shur (Figure 2).[45]

These systems exhibit considerable affinity for halide anions. X-ray analysis ascertained the formation of an anionic 2:1 chloride adduct of (**1**) where the chloride is simultaneously bound by four mercury atoms.[13] In the crystal structures of (**2**) $\cdot Cl^-$ and (**2**) $\cdot I_2^-$, the anions are located within the macrocycle and complexed cooperatively by the four mercury(II) centers.[7] Several anionic complexes of (**3**), including bromide, iodide, and thiocyanide salts, have been isolated. The compounds adopt multidecker structures with the hexacoordinated anions effectively sandwiched between two successive molecules of (**3**). The Lewis acidity of perfluoro-*ortho*-phenylenemercury (**3**) has also been substantiated by its ability to form stable adducts with neutral substrates (HMPA, DMSO, ethyl acetate, and acetonitrile) and arenes. The (**3**) $\cdot C_6H_6$ adduct exists as extended stacks of nearly parallel, staggered molecules of (**3**), which sandwich benzene molecules. Similar structures have been reported for the corresponding adducts with biphenyl, naphthalene, pyrene, and triphenylene.

4 REACTIVITY

A summary of the most important reactions undergone by organomercurials is shown in Schemes 2 and 3. Most of

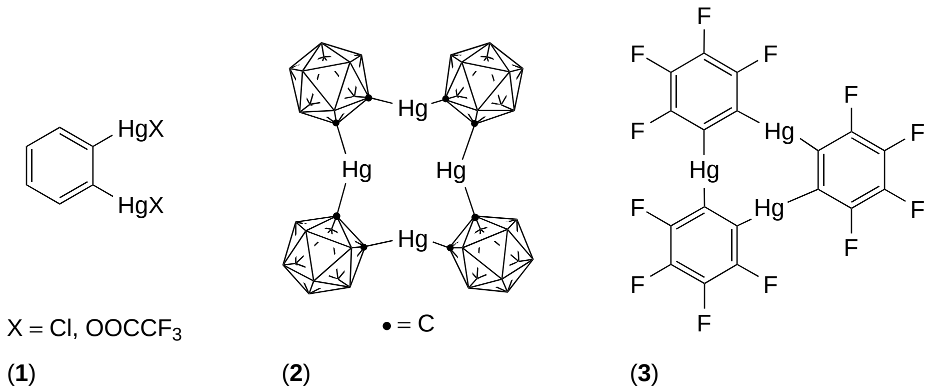

Figure 2 Examples of mercury-based polydentate Lewis acids[7,44,45]

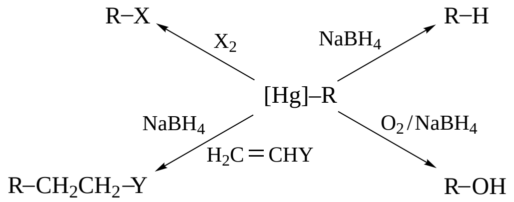
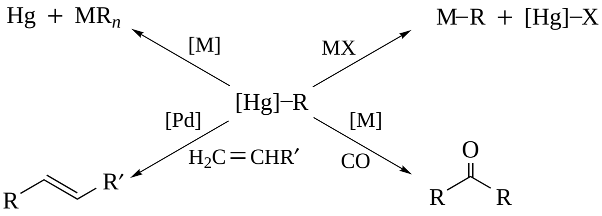


Scheme 2



Scheme 3

these reactions were described in detail by Larock in the previous edition of this encyclopedia. Consequently, herein, only a summary of their most relevant features, together with a selection of recent and novel examples, will be presented.

4.1 Substitution of Mercury to Yield Metal-free Products

Many of the organomercurials prepared using the methodologies described in Section 3, are used in situ to effect a transformation on the organic moiety of the complex. The substitution of mercury by hydrogen or halogens continues to be the most important reactions of organomercurials from the synthetic point of view. These two reactions provide general methodologies to yield the corresponding metal-free species. Similarly, the reactions of organomercurials with $NaBH_4$ in the presence of either O_2 or an alkene, have demonstrated to be relatively general procedures to yield alcohols and substituted alkanes, respectively. Selected examples of these different substitution reactions can be found in the references at the end of the review.[36,46–50]

4.2 Transmetallation

Organomercurials are useful reagents for the synthesis of other organometallic complexes. Direct transmetallation is the most common approach and a large number of main group and transition metal organometallic complexes have been prepared in this way from organomercurials.

Organomercurials can also react with other metals by oxidative addition. This has been previously employed for the synthesis of some organopalladium and -platinum compounds. More recently, this approach has been extended to the preparation of a series of novel organo-, organooxo-, and organoamido-lanthanoid complexes. Reaction of the appropriate diorganomercurial [generally $Hg(C_6F_5)_2$ or $Hg(C_6H_5)_2$] with metallic europium or ytterbium in THF leads to isolation of di- or trivalent organolanthanoid complexes (equations 21 and 22).[51,52]

$$Ln + HgR_2 \longrightarrow LnR_2 + Hg \qquad (21)$$

$$2Ln + 3Hg(C_6H_5)_2 \longrightarrow 2Ln(C_6H_5)_3 + Hg \qquad (22)$$

Protonolysis of the highly reactive Ln–C bond with protic reagents LH ($LH = C_5R_5H$, ArOH, R_2NH) generates cyclopentadienyl, aryloxo, and amido lanthanoids, respectively. The two steps, redox transmetallation and protonolysis, can be carried out separately when the intermediate organolanthanoid complexes are to be isolated, or combined in a convenient 'one-pot' synthesis involving Ln metal, HgR_2, and LH. Isolation of the half-sandwich complex $[Yb(C_5Me_5)(C_6F_5)(THF)_3]$ represents a recent extension of this synthetic protocol.[53]

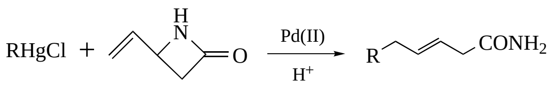
While reactions between lanthanide elements and $Hg(C_6F_5)_2$ proceed smoothly at room temperature, those

with $Hg(C_6H_5)_2$ are more difficult to induce and generally require activation of the metal and heating. However, redox transmetallation-ligand exchange reactions with $Hg(C_6H_5)_2$ have proven unique in providing a convenient way of preparing the first lanthanoid(II) pyrazolates.

4.3 Cross-coupling Reactions

The reaction of organomercurials with palladium salts in the presence of alkenes leads to cross-coupling of the two organic species. Over the past few years, several examples of this reaction have been reported. For instance, ferrocenylmercuric derivatives can undergo cross-coupling reactions to form ferrocene-containing conjugated species. Bis(ferrocenyl)mercury in the presence of palladium salts undergoes cross-coupling reactions with aryl, heteroaryl, and acid halides.[54]

A variation of the cross-coupling protocol involving the ring opening of 4-alkenyl-2-azetidinones to yield amides has been recently reported (equation 23). Differently substituted aryl- and vinylmercurials effect the transformation in good yields and stereoselectively.[55]



(23)

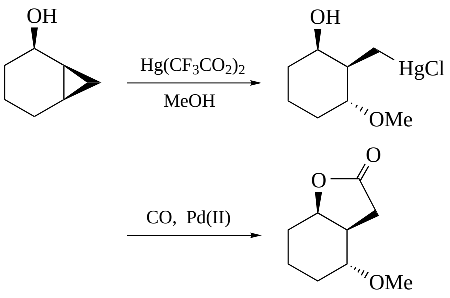
Cross-coupling of organomercurials has been employed in the generation of soluble, well-characterized poly(3-alkylthiophene) and poly(3-alkylthienyl ketone).[56] Facile mercuration of 3-alkylthiophenes with $HgCl_2$ produces 2,5-bis(chloromercurio)-3-alkylthiophenes. The mercurated intermediates subsequently undergo cross-coupling reactions in the presence of Cu and $PdCl_2$ to yield poly(3-alkylthiophene) and, under CO pressure, poly(3-alkylthienyl ketone) (Scheme 4).

4.4 Carbonylation of Organomercurials

Direct carbonylation of organomercurials is a low yielding process that requires high temperatures and pressures. However, it can be performed efficiently under milder conditions in the presence of transition metal catalysts, particularly, rhodium and palladium.[57,58] Two important applications of this protocol have recently been reported. The Rh^I-catalyzed formylation of organomercurials has been applied to the synthesis of a polyol-derived natural product.[59] The organomercury chloride substrate is synthesized by oxymercuration of the corresponding homoallylic alcohol with Hg(OAc)Cl (Scheme 5).

Subjection of this material to a formylation protocol involving a Rh^I catalyst, a bulky phosphite and DABCO (1,4-diazabicyclo[2.2.2]octane) in the presence of H_2/CO gas mixture, gives a high yield of the desired aldehyde. Iteration of these steps leads to the synthesis of *Tolypothrix* pentaether.

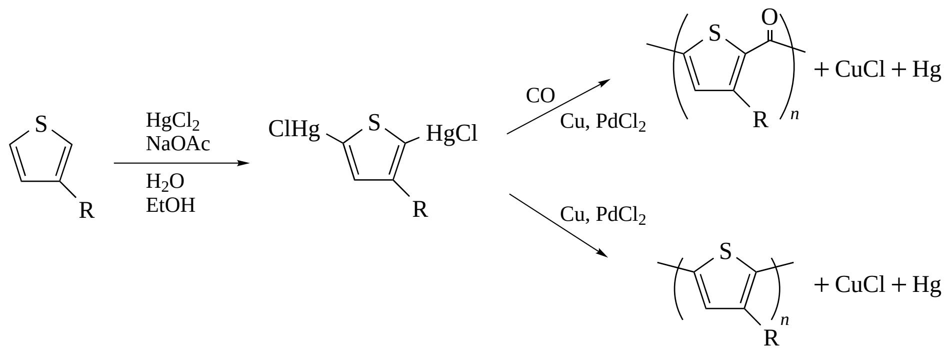
A Pd^{II}-catalyzed carbonylation procedure has been employed for the conversion of organomercurials into 5-membered cis- and trans-annulated lactones in which three consecutive chiral centers are introduced (equation 24).[60,61]



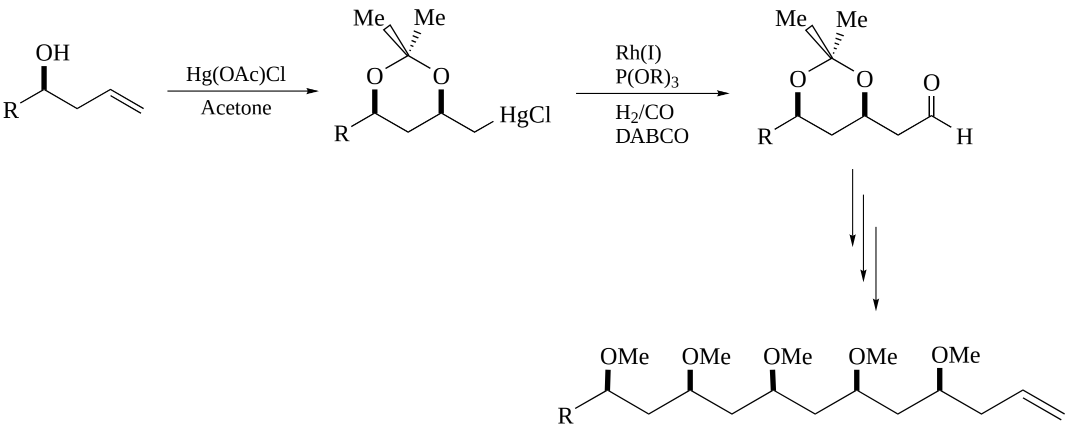
(24)

4.5 Mercury Photosensitized Reactions of Organic Compounds

A procedure for the dehydrodimerization of volatile organic compounds on a preparative scale by Hg photosensitized reactions has been reported by Crabtree and coworkers.[62,63]

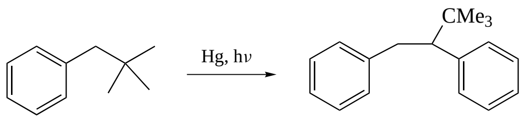


Scheme 4



Scheme 5

Detailed theoretical work has shown that alkane C–H activation by the $3P_1$ excited state Hg* proceeds by initial formation of a weak [Hg*(alkane)] exciplex, followed by C–H cleavage via a mechanism described as a mixture of oxidative addition and H atom abstraction. While alkanes react exclusively via C–H bond activation, sensitization of monosubstituted arenes $ArCH_2{-}X$ (Ar = aryl; X = H, alkyl, OR, NR_2) occurs with substantial C–X bond cleavage (equation 25).



(25)

On the basis of experimental photochemical studies and theoretical calculations, the proposed mechanism involves formation of a [Hg*(arene)] exciplex, energy transfer from Hg* yielding a vibrationally excited triplet arene that spontaneously undergoes C–X bond cleavage.[64] Calculations performed on the exciplex between Hg* and benzene point to a structure of the type $^3[Hg(\eta^2\text{-}C_6H_6)]$.

1 INTRODUCTION

This chapter does not focus primarily on *metal* toxicity, although metals may be toxic and damage lung tissue, especially in particulate form and in industrial settings. For comprehensive coverage of this topic see Reference 1. This chapter deals with *metal ion* toxicity because it is via their ions that metals are presented as toxic substances to most of us.

Figure 1 illustrates the biological response of a tissue to increasing concentrations of essential nutrients and toxic substances.[2] The solid curve for an essential nutrient is deliberately drawn with an immediate positive response above zero concentration as if the nutrient were saturating a site and no nutrient were consumed at the lowest levels by other interactions. The solid curve levels off at an optimal level, the width of which depends on the nutrient. Finally, at excess concentrations, deleterious effects settle in, the biological response becomes unfavorable, and the once nutritious substance becomes toxic.

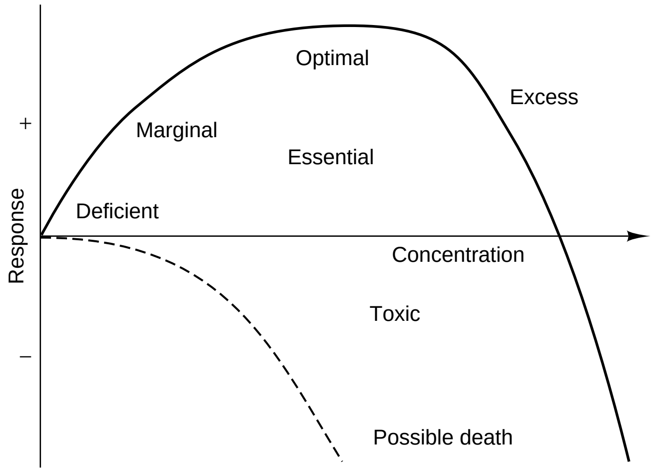

Figure 1 Biological response dependence on tissue concentration of an essential nutrient (solid curve) and of a deleterious substance (dashed curve). The relative position of the two curves on the concentration axis is arbitrary and one of convenience. (Reprinted from Ref. 2 by permission of Marcel Dekker, Inc)

The dashed curve in Figure 1 for a toxic substance shows a lag region under the assumption that an organism can cope with some amount of a substance before toxic effects become evident (threshold). For both essential nutrients and toxic substances, Figure 1 shows general characteristics; each substance has its own specific curve of biological response versus concentration.

Figure 1 emphasizes the point that an essential nutrient may become toxic at sufficiently high concentrations. Almost any substance in excess ultimately becomes harmful, even if the action is indirect, such as limiting absorption of other essential nutrients. The optimal region at the plateau in Figure 1 may be wide as for sodium or narrow as for fluoride and selenium. Animals maintain a concentration within the optimal range by a complex set of physiological reactions termed *homeostasis*. Concentrations of all essential metal ions are under homeostatic control. The detailed mechanism of homeostasis for individual substances remains an area of current research.[3]

Twenty-one elements are essential to humans. An essential nutrient is one for which a deficiency results in an impairment in function that is relieved only by administration of that substance. Vitamins by definition and some minerals are essential. The significance of essentiality may be illustrated by burlesquing an old adage.

> ‘For want of a nail the shoe is lost, for want of a shoe the horse is lost, for want of a horse the rider is lost.’

George Herbert, *Jacula Prudentum* (Outlandish Proverbs), 1640

> ‘For want of a nutrient the enzyme is lost, for want of an enzyme the function is lost, for want of a function the life is lost.’

Bruce Martin, *Summa Veritatis* (Lofty Truth), 1989

Four essential elements, H, O, C, and N, comprise more than 99 atom % and about 96 wt % of the human body. These 4 and 14 other essential elements occur among the first 30 elements (through zinc) of the periodic table. (Uncertainties surround the status of chromium (*see* ***Chromium: Biological Relevance***).[4]) Three heavier trace elements Se, Mo, and I are also essential in humans. For 17 tabulated essential elements, Table 1 shows the predominant elemental form at pH 7, typical adult concentrations in the blood plasma or serum, the approximate amount found in a 70-kg adult, and a recommended adult daily allowance. In addition to

Table 1 Essential elements for humans[a]

Element	pH 7 form	Serum conc.	Human amt.[b]	Daily allowance
Na	Na^+	140 mM	70 g	1–2 g
K	K^+	4 mM	130 g	2–5 g
Mg	Mg^{2+}	0.8 mM	22 g	0.3 g
Ca	Ca^{2+}	2.4 mM	1100 g	0.8 g
Mn	Mn^{2+}	10 nM	12 mg	3 mg
Fe	$Fe(OH)_3\downarrow$	17 μM	4 g	10–20 mg
Co	Co^{2+}	2 nM	1 mg	3 μg vitamin B_{12}
Cu	Cu^{2+}	17 μM	80 mg	3 mg
Zn	Zn^{2+}	14 μM	2.3 g	15 mg
Cr	$Cr(OH)_2{}^+$	3 nM	6 mg	0.1 mg
Mo	$MoO_4{}^{2-}$	6 nM	5 mg	0.2 mg
Cl	Cl^-	104 mM	80 g	2–4 g
P	$HPO_4{}^{2-}$	1.1 mM	600 g	1 g
S	$SO_4{}^{2-}$	24 mM	120 g	0.7 g Met[c]
Se	$HSeO_3{}^-$	1 μM	5 mg	0.1 mg
F	F^-	2 μM	2.5 g	2 mg
I	I^-	0.4 μM	30 mg	0.15 mg

the basic four elements, the essential elements include two alkali metal ions, two alkaline earth metal ions, six first-row transition metal ions (the most common, iron, contributes less than 0.01% of body weight), molybdenum, phosphorus, sulfur, selenium, and three halogens. Thus 11 metal ions are essential. Table 1 shows that most of the remaining 4% of body weight consists of two elements found in bone, Ca and P. Many of the elements do not exist predominantly in their pH-7 forms in the serum as they are combined with other components. For example, Fe^{3+} does not precipitate as the hydroxide but is retained by tightly chelating ligands. There is little free iodide; it occurs as part of the thyroid hormones. For sulfur, Table 1 lists the total serum concentration, most of which appears in proteins; there is only about 1 mM nonprotein sulfur. Sulfur is not important as an inorganic element but only as part of the amino acids cysteine and essential methionine. An additional four elements, B, Si, V, and Ni, not included in Table 1, are essential for other organisms.

2 INTERDEPENDENCIES

Metal ion toxicity does not relate to essentiality. Toxicity and essentiality do share, however, one feature: frequent interdependencies among metal ions, between metal ions and nonmetals, and between both, and organic molecules such as vitamins. For example, excess Zn^{2+} may reduce absorption of essential Cu^{2+}, while a deficiency of Zn^{2+} worsens Cd^{2+} toxicity. Such antagonisms and mutual dependencies produce variable toxicities for like concentrations of an element,

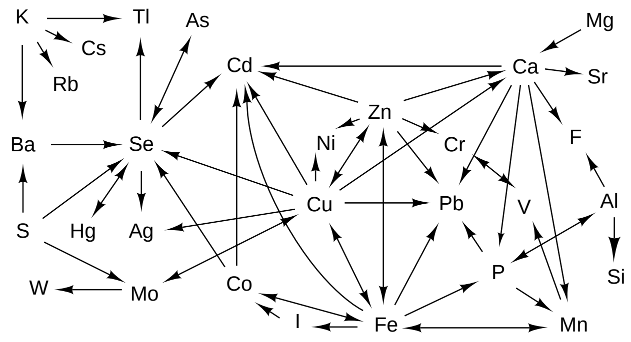

Figure 2 Interdependencies among 30 elements in mammals. An arrow from element A to B indicates that administration of element A may reduce toxicity of element B, low levels of element A may heighten toxicity of element B, or high levels of element B may inhibit salutary effects of element A. (Reprinted from Ref. 2 by permission of Marcel Dekker, Inc)

and hinder any attempt to formulate simple guidelines for essentiality or toxicity.

Interdependencies among 30 elements in mammals are diagrammed in Figure 2.[5] The figure does not exhaust all possibilities but serves to show both the commonality and complexity of the interactions among elements. Figure 2 points out that heavily supplementing a diet with one mineral may upset the balances with others.

Figure 2 shows that both Cd^{2+} and Pb^{2+} share interdependencies with several other elements, accounting for some of their toxicities. Cd^{2+} interferes with activities of essential Ca^{2+} and Zn^{2+}, and a low-Ca^{2+} diet enhances Cd^{2+} absorption. Pb^{2+} interacts with systems that use Ca^{2+}, iron, and Zn^{2+}. Ca^{2+}, Cd^{2+}, and Pb^{2+} possess similar ionic radii (Table 2), so that the pair of detrimental metal ions may substitute for Ca^{2+}.

3 IONIC RADII

Like size usually plays a greater role than identical charge in promoting metal ion substitutions in both mineralogy and biology. For example, the plagioclase feldspars display a continuous series of aluminum silicate mixtures in a common lattice from $NaAlSi_3O_8$ to $CaAl_2Si_2O_8$. Neither Mg^{2+} nor Sr^{2+} replace Ca^{2+} in this series. The charge compensation required in minerals is not critical when substitution occurs in a protein or in other biological ligands.

Table 2 presents effective ionic radii for many metal ions.[6] For any metal ion, the radius increases with coordination number since the greater number of bonds weakens the strength of any one bond. The radius of the most common coordination number is underlined in Table 2. The alkali and alkaline earth metal ions exhibit variable coordination numbers without strong directionality in bonding. Because they are of similar size, Ca^{2+} and Na^+ of differing charges

Table 2 Effective ionic radii in picometers[a,6]

	Coordination number					
Ion	4	5	6	7	8	9
Be^{2+}	$\underline{27}$		45

often interchange in biological systems. Ba^{2+} is poisonous because of its antagonism to K^{+} of similar radius and not to Ca^{2+} of identical charge but smaller radius. Ba^{2+} is a muscle poison for which one antidote is intravenous infusion of K^{+}. Table 2 shows that Co^{2+} and Zn^{2+} exhibit similar radii in all coordination numbers.

4 STABILITY SEQUENCES

From the many studies on stability constants, one finds the order of metal ion stabilities to be dependent on the ligand. Metal ion stabilities increase in the following orders:

$$\text{Glycine: Ca, Mg} \ll \text{Mn} < \text{Fe, Cd, Pb,} < \text{Co, Zn} < \text{Ni} \ll CH_3Hg^{+}, \text{Cu} \ll \text{Hg}$$

$$\text{1, 2-Diaminoethane(en)} : \text{Mg} \ll \text{Mn} \ll \text{Fe} < \text{Pb, Cd, Co, Zn} \ll \text{Ni} < CH_3Hg^{+} \ll \text{Cu} \lll \text{Hg}$$

The ion Ca^{2+} does not form stable amine complexes. Except for methyl mercury, CH_3Hg^{+}, all the metal ions carry two positive charges. Owing to the strongly chelating bidentate ligands, glycine (gly) and 1,2-diaminoethane (en), CH_3Hg^{+} with only a single, strong binding site is at a competitive disadvantage in the above series. CH_3Hg^{+} binds to a unidentate ligand more strongly than all of the above metal ions except Hg^{2+}.

In the above series, each inequality sign stands for an approximate 10-fold increase in the stability constant. The two series gly and en are similar, their major difference being a stability constant span from Mg^{2+} to Hg^{2+} of 10^9 for glycine and 10^{14} for en. Generally, the increment between metal ions increases on passing from O < N < S donor atoms. The presence of a sulfur donor promotes Cd^{2+} and Pb^{2+} to higher positions than in the above series. The order of increasing sulfur binding strengths is $Zn^{2+} < Cd^{2+} < Pb^{2+} < CH_3Hg^{+} < Hg^{2+}$. Sulfhydryl group interactions are the main mode of toxicity of the heavy metal ions. These general bonding features are expressed in the concept of the stability ruler.

5 STABILITY RULER

For a single ligand, the Irving–Williams stability sequence of dipositive metal ions is Mg < Mn < Fe < Co < Ni < Cu > Zn, irrespective of ligand. The uniformly progressive part of this sequence from Mg^{2+} to Cu^{2+} defines a *stability ruler* against which more variable metal ions may be compared.[2] The stability ruler appears across the top of Table 3. For several ligand donor sets, Table 3 shows the relative binding strengths of the variable dipositive metal ions Zn^{2+}, Cd^{2+}, Pb^{2+}, and Hg^{2+}. Their placement in Table 3 corresponds to their stability constants compared with those of the metal ions that define the ruler. The entries for glycine and en agree with the series in the previous section. With most of the metal ions in Table 3, histidine will be tridentate.[7,8] The increment between metal ions and hence the length of the stability ruler increases with the substitutions O < N < S. The ruler length for binding to each ligand appears in the next to last column of Table 3 in log K units. The longer the ruler, the more discriminating the ligand in selecting among metal ions. Thus, oxygen donor atoms are the least discriminating among metal ions, nitrogen donors intermediate, and sulfur donors the most discriminating.

From Table 2, we can see that not only do Co^{2+} and Zn^{2+} display nearly identical radii for the same coordination number but they also exhibit similar stabilities for all ligands in Table 3, except for those involving sulfur and hydroxide. The similarities allow the facile and useful substitution of Co^{2+} for Zn^{2+} in many enzymes. When a sulfhydryl group is present, as in 2-mercaptoethylamine, Zn^{2+} binding strengthens, equaling that for Ni^{2+}. Table 3 also shows the relative strengthening of Cd^{2+} and Pb^{2+} binding with the sulfhydryl donor in 2-mercaptoethylamine.

Table 3 Stability ruler[a]

Ligand	Donors	Mg	<	Mn	<	Fe	<	Co	<	Ni	<	Cu	Length[b]	Hg[c]
Hydroxide	OH^-				Cd						Zn	Pb	3.7	1.2
Acetate	O^-									Zn	Cd	Pb	1.3	1.2
Imidazole	=N							Zn	Cd				4.0	1.1
Ammonia	NH_3						Pb		Zn	Cd			4.0	1.1
Oxalate	O^-,O^-				Cd			Zn	Pb				2.1	
Glycine	N,O^-					Cd	Pb	Zn					6.1	0.4
Histidine	N,=N					Cd	Pb	Zn					8.2	0.2
$NH_2(CH)_2$ NH_2	N,N					Pb	Cd	Zn					10.1	0.4
$NH_2(CH)_2S^-$	N,S^-									Zn	Cd	Pb	12(est.)	0.2

[a]All dipositive cations. [b]Ruler length in difference between log stability constants of Cu^{2+} and Mg^{2+} complexes. [c]Relative magnitude that the Mg^{2+} to Cu^{2+} length must be extended to reach the Hg^{2+} value.

Cd^{2+} binds more strongly than Zn^{2+} to most unidentate ligands. Probably because of an unfavorable ring bite size for the relatively large Cd^{2+} (Table 2), Zn^{2+} chelates more strongly to ligands containing O and N donors in five-membered rings. Table 3 shows that upon introduction of an S donor atom into a chelate, Cd^{2+} becomes the stronger metal ion binder.

For all donor sets in Table 3, Hg^{2+} binds so strongly that it is off the end of the ruler scale. The number under Hg in the last column of Table 3 refers to the relative distance by which the length of the whole log stability constant scale from Mg^{2+} to Cu^{2+} must be extended to reach the value for Hg^{2+}. A telling contrast appears between the length of the extension for most bidentate ligands and that for unidentate ligands. The scale extension for Hg^{2+} amounts to 0.2 to 0.4 log units for bidentate ligands and to 1.1 to 1.2 log units for the three unidentate ligands at the end of Table 3. The difference arises because Hg^{2+} prefers linear, two coordination and binds the second donor atom in small chelate rings much more weakly than it does the first donor atom.

We may generalize the results and conclusions of the stability ruler by noting that alkali metal and alkaline earth metal ions, lanthanides, and Al^{3+} prefer oxygen donors; transition metal ions, oxygen and nitrogen donors; and the heavy metal ions, nitrogen and sulfur donors. For amplification of this topic, (*see* ***Hard & Soft Acids and Bases***).

6 METAL ION HYDROLYSIS

The higher the charge density or charge-to-radius ratio, the more likely a metal ion undergoes hydrolysis in aqueous solutions to give hydroxo complexes. Hydroxo complexes may abruptly form polynuclear complexes and precipitate even in solutions more acidic than the pK_a for the first hydroxo complex formation. The first five small metal ions in Table 2 hydrolyze even in acidic solutions and form precipitates. In six-coordination, the charge-to-radius ratio for the first five metal ions is greater than 0.044, while for all the other metal ions in Table 2, the ratio is less than 0.035. The first five metal ions cannot occur to an appreciable extent in the bloodstream (pH 7.4) as the free aqueous ion and must be complexed in some way. Covalency may also promote complex formation and hydrolysis in acidic solutions, as is the case for Hg^{2+}.

Hydroxo complex formation follows the same stability order as other ligands with the strongest binding at the right of the stability ruler in Table 3, where the hydroxide ion appears as the first entry. The stability ruler in Table 3 shows that both Zn^{2+} and Pb^{2+} exhibit a relatively strong tendency to form hydroxo complexes and precipitates.

7 HEAVY METAL ION COMPLEXES

The most serious side effects of many metal ions result from the inhalation of dusts, usually in an industrial setting. Especially bad are particles 0.1 to 1 μm in diameter, which are effectively absorbed in the lungs. The lungs are 10 times more effective in absorbing most metal ions into body fluids than are the intestines. Thus, the greater danger from radioactive plutonium-239, an emitter of damaging α particles with a half-life of 24 400 years, results not from its ingestion, but from adsorption of its powders onto lung tissue. Volatile metal compounds such as the carbonyls and alkyl compounds of mercury, tin, and lead are readily absorbed via the lungs and may give rise to acute toxicity. Obviously, inhalation of metal ions should be avoided. Since inhalation episodes are local events, we shall not mention them further; they are covered in the compendia.

Fortunately, many metal ions are less harmful than they might be because of their intrinsic chemical behavior, such as formation of insoluble compounds in the gut with subsequent elimination of the metal ion. Other fractions of metal ions travel in the blood to other tissues, where they are immobilized, like lead in bone, or to the liver or kidneys, where they are complexed in a less toxic or disposable form. Even a

relatively toxic metal ion (nonradioactive) requires almost a gram amount for lethality, much more than for potent organic toxins.

Sulfhydryl groups of proteins furnish the vehicle for both the toxicity and detoxification of most heavy metal ions. In the stability ruler (Table 3) discussion, we noted the special avidity of heavy metal ions for sulfhydryl groups. Both Cd^{2+} and Pb^{2+} exhibit enhanced binding to sulfhydryl groups compared with that to N or O donor ligands. Still stronger is the binding of both Hg^{2+} and CH_3Hg^+ to sulfhydryl groups.

In response to the presence of detrimental Cd^{2+}, Hg^{2+}, Pb^{2+}, and other heavy metal ions, the human liver and kidneys synthesize more *metallothionein,* an unusual small protein in which approximately one-third of the 61 amino acid residues are cysteine (*see* ***Metallothioneins***). The frequency and juxtaposition of sulfhydryl groups provide strong binding sites for several heavy metal ions. Though not as profusely as metallothionein, many proteins contain sulfhydryl groups that may become metalated by toxic heavy metal ions such as Cd^{2+}, Hg^{2+}, and Pb^{2+}, and it is widely believed that this complex formation explains the toxicity of these metal ions. The exact proteins where the most consequential damage occurs remain uncertain.

Toxic metal ions enter many tissues, and the greatest damage does not always occur where the metal ion is most plentiful. For example, more than 90% of Pb^{2+} may become immobilized in bone, but the toxic effects result from the remaining 10% distributed among other tissues, where it may react with sulfhydryl groups on any number of proteins. The immobilization of Pb^{2+} in bone may act as a detoxifying mechanism even though it is more likely the result of an incidental property of the metal ion rather than a deliberate intent of the organism.

Topics not included here or appearing in more length elsewhere include book-length discussions of concepts and summaries,[9–12] toxic metal ions in the environment[13] and nervous system,[14] and cisplatin as an anticancer agent (*see* ***Platinum-based Anticancer Drugs***).[15] An element by element discussion of toxicity appears in a convenient handbook.[1]

For the purpose of considering their toxicity, metal ions may be divided into three groups. In the first group are the alkali and alkaline earth metal ions and the Al^{3+} group. Of these, most are harmless in the amounts that they usually occur. Be^{2+} is a dangerous substance with latent toxicity and should be handled cautiously or not at all. Fortunately, it is quite rare, and it is not discussed further here. Of this first group, Al^{3+} is common and sometimes occurs in deleterious quantities, and is the only nonheavy metal ion that warrants discussion, in Section 8. The second group consists of the light first-row transition metal ions that are not especially harmful in available quantities and often are essential (Table 1). Finally, the third group consists of heavy second and third row transition metal ions that include toxic Cd^{2+}, Hg^{2+}, Tl^+, and Pb^{2+}, which are discussed below. The emphasis is on toxicity in humans. For many metal ions, *acute* toxicity arising from a sudden exposure to a large dose leads to different effects and symptoms than *chronic* toxicity, which may be due to low-dose exposures over a long time period. The symptomatic descriptions of acute and chronic toxicity rely on two comprehensive compendia.[1,10]

7.1 Cadmium[2]

Relatively rare, Cd^{2+} occurs in minerals and soils in association with zinc to about 0.1%. Like Zn^{2+}, the metal occurs only as a 2+ ion, Cd^{2+}. Cd^{2+} is larger than Zn^{2+} and more nearly the size of Ca^{2+} (Table 2), leading to its use as a Ca^{2+} probe in protein systems. However, in its binding strength to ligands, Cd^{2+} is much more like Zn^{2+} (stability ruler, Table 3), and it is in competition with Zn^{2+} that the greater number of its toxic effects arise (Figure 2). In contrast to Ca^{2+}, both metal ions bind strongly to nitrogen and sulfur donor ligands. Excess Cd^{2+} disturbs mineral metabolism, interferes with Zn^{2+} and other enzymes, and may redistribute Zn^{2+} in the body.

In strong contrast to CH_3Hg^+, Cd^{2+} does not easily cross the placental barrier, and newborns are virtually Cd^{2+} free. For most individuals, Cd^{2+} is slowly accumulated from foods. The body only slowly releases absorbed Cd^{2+}, which has a half-life of 30 years in the kidneys. As a consequence, the Cd^{2+} content of the kidneys increases throughout life from zero at birth to about 20 mg in a middle-aged nonsmoker and more than twice as much in an adult smoker. Much of the Cd^{2+} is bound by metallothionein, a small protein with sulfhydryl binding sites, whose production is stimulated by Cd^{2+}.

Acute Cd^{2+} poisoning, signaled by vomiting, abdominal cramps, and headache, may arise from drinking water or other, especially acidic, liquids that have contacted cadmium-containing solders in water pipes and vending machines with cadmium-glazed pottery. Ingested Cd^{2+} is transported to other organs by the blood, where it is bound by glutathione and hemoglobin in the red cells. The blood of smokers contains about seven times as much Cd^{2+} as that of nonsmokers. Cd^{2+} stimulates metallothionein synthesis in the liver. The metal–protein complex passes through the blood to the kidney. Chronic Cd^{2+} poisoning damages the liver and kidneys, leading to severe kidney malfunction. There is no specific therapy for Cd^{2+} poisoning; chelating agents may harmfully redistribute Cd^{2+} to the kidney. Consuming plentiful quantities of Zn^{2+}, Ca^{2+}, phosphate, vitamin D, and protein may lessen the impact of Cd^{2+} toxicity.

An especially serious form of Cd^{2+} poisoning has been described in Japan as itai-itai (Japanese for ouch-ouch) disease. The name derives from pain in the back and legs due to osteomalacia or bone decalcification (usually in older women) leading to easy fracturing (72 fractures in one victim). There is also severe kidney damage with proteinuria (protein in the urine) persisting even after exposure ceases. This disease leads to early death. In Japan, it was caused by the consumption of Cd^{2+}-laden water, either directly through drinking or through the eating of crops, especially rice, irrigated by

the water over a period of many years. Though there was earlier, visible damage to the rice crop, it took 17 years from the first medical studies on humans to the final fixing of legal responsibility on to the zinc-mining company that had discarded the unwanted cadmium by-product into a river used for drinking and irrigation.[16]

7.2 Mercury[2]

Mercury is detrimental to mammals in all of its forms. The global release of mercury by degassing from the earth's crust and oceans exceeds that produced by humans by a factor of at least 5, but industrial discharges are more local and concentrated. The average person carries 13 mg of mercury in the body; this does not serve any useful purpose, although various mercuric salts have been used as therapeutic agents, for example, mercuric benzoate to treat syphilis and gonorrhea. Use of mercury reagents as insecticides and fungicides has led to many small-scale and several disastrous large-scale poisonings involving thousands of people. Mercury poisoning is a worldwide problem.

Mercury occurs in three common forms and in one uncommon form as mercurous ion that disproportionates to two of the common forms, elemental mercury and the mercuric ion:

$$Hg_2{}^{2+} \rightleftharpoons Hg^0 + Hg^{2+} \qquad K = \frac{Hg^{2+}}{Hg_2{}^{2+}} = \frac{1}{170}$$

The value of the equilibrium constant for the reaction indicates that the favored direction of the reaction is actually from right to left. It is driven to the right by the strong complexation of Hg^{2+} with any of a large number of ligands. The third common form of mercury is as organic mercurials such as methyl mercury, CH_3Hg^+.

Mercury is one of the few elements that remains liquid at room temperature. Though its boiling point is 357 °C, it is more volatile and hence more dangerous than generally appreciated. At saturation at 25 °C, a cubic meter of air holds 20 mg of Hg. Spilled mercury is a health hazard in rooms with poor ventilation. Elemental mercury is almost insoluble in water, dissolving to the extent of 0.29 µM at 25 °C, 58 µg liter^{-1}, or 58 ppb.

Both the mercuric ion, Hg^{2+}, and methyl mercury, CH_3Hg^+, prefer linear two-coordination. They form stronger complexes with a single donor atom, especially N and S, than most metal ions. Rare among metal ions, Hg^{2+} in basic solutions substitutes for a hydrogen on amines (in contrast with ammonium ions) as in mercuric amidochloride, $ClHgNH_2$. At high pH values, excess CH_3Hg^+ substitutes for a hydrogen on the $-NH_2$ groups at C4 in cytidine and C6 in adenosine.[17] Hg^{2+} may add third and fourth donor atoms to give a distorted tetrahedron. The last two ligands are bound much more weakly than the first two and exhibit longer Hg^{2+}–donor atom bond lengths. The ability of linear, two-coordinated Hg^{2+} and CH_3Hg^+ to associate weakly with additional donor atoms accounts for the rapid metal ion exchange among donor atoms, as is discussed below.

Because they prefer linear, two-coordination, there is not much chelate effect with Hg^{2+} and CH_3Hg^+. In contrast to most metal ions, the stability constant logarithm for Hg^{2+} and CH_3Hg^+ binding to 1,2-diaminoethane is less than the sum of the values for binding to two ammonia molecules, that to glycine is less than the sum for ammonia and acetate, and that to histidine is less than the sum for ammonia and imidazole. However, owing to the great strength of binding to a single nitrogen donor atom, the stability constants for the weakly chelated Hg^{2+} and CH_3Hg^+ with diaminoethane, glycine, and histidine still exceed those for most metal ions.

In pure water, HgO precipitates at pH > 2 and CH_3HgOH forms at pH > 5. The chloride ion binds with high stability. The first two Cl^- that give linear $HgCl_2$ are bound 10 times more strongly than the last two Cl^- that give tetrahedral $HgCl_4{}^{2-}$.[18] In seawater, with its high 0.56 M Cl^- background, the predominant species are $HgCl_4{}^{2-}$ and CH_3HgCl.

In almost any biological system, an excess of sulfhydryl donors is expected to bind all Hg^{2+} and CH_3Hg^+. The name mercaptan ('mercury capture') derives from the strong Hg^{2+} binding to thiols. In red blood cells, Hg^{2+} links glutathione and hemoglobin sulfhydryl groups in a mixed complex. Only a fraction of body Hg^{2+} remains in the blood. Though the molecular basis of Hg^{2+} toxicity by interaction at sulfhydryl groups is generally understood, the specific proteins undergoing consequential damage remain uncertain. Many proteins contain reactive sulfhydryl groups. Hg^{2+} also forms inert bonds at C5 in pyrimidines. The long retention times of mercury in tissues may result from formation of inert aromatic carbon–mercury bonds involving nucleic bases or amino acid side chains.

In spite of being very strongly bound, ligands show rapid exchange in and out of coordination to Hg^{2+} and CH_3Hg^+. Substitution of inner-sphere water in Hg^{2+} occurs with a half-life of less than 10^{-9} s, as fast as any metal ion. For CH_3Hg^+ binding to the sulfhydryl group of glutathione, the stability constant log K = 15.9. For such strong binding, the half-life for exchange by a dissociation mechanism is about 10 days, yet the average lifetime for the CH_3HgSR complex in the presence of excess glutathione is less than 0.01 s. This comparison shows that the exchange does not occur by a dissociation mechanism. The clue to the exchange mechanism in Hg^{2+} and CH_3Hg^+ compounds is the weak coordination of third and fourth ligands (mentioned near the beginning of this section). Excess ligand participates in a nucleophilic attack at an uncoordinated site on the metal ion, with rearrangement in the coordination geometry and release of a formerly bound ligand. This addition–elimination mechanism accounts for the very rapid exchange in Hg^{2+} and CH_3Hg^+ complexes.

The rapid exchange of Hg^{2+} and CH_3Hg^+ among excess donor ligands such as sulfhydryl groups plays a key role in toxicology. It accounts for the fast partitioning of the

mercury among sulfhydryl groups in tissues. In the blood, CH_3Hg^+ partitions in the same proportion as the populations of sulfhydryl groups, about 10% in the plasma and 90% in the erythrocytes, which contain both hemoglobin and glutathione sulfhydryl groups. To be avoided as an antidote for mercury poisoning, British anti-Lewisite or BAL (2,3-dimercaptopropanol) promotes the distribution of mercury throughout the body.

Inhaled mercury vapor is efficiently absorbed and accumulates in the brain, kidneys, and testicles. It also crosses the placental barrier. Acute poisoning causes lung damage. In tissues, elemental mercury is converted to the mercuric ion, which combines with sulfhydryl-containing molecules, including proteins. Chronic poisoning gives rise to permanent nervous system damage, resulting in fatigue, and at higher levels, to a characteristic mercurial tremor in which a fine trembling is interrupted every few minutes by coarse shaking.

Ingestion of even 1 g of a mercuric salt is lethal. Mercuric salts accumulate in the kidneys; in contrast with elemental mercury, they do not readily cross the blood–brain or placental barriers. Acute poisoning by ingestion results in precipitation of proteins from the mucous membranes of the gastrointestinal tract, causing pain, vomiting, and diarrhea. If the patient survives this damage, the kidney becomes the critical organ. There is some red cell hemolysis. Chronic poisoning gives rise to central nervous system damage. The Mad Hatter in *Alice in Wonderland* by Lewis Carroll represents an occupational disease caused by poisoning by $Hg(NO_3)_2$, used in the treatment of furs.

Organic mercurials such as methyl mercury chloride, CH_3HgCl, are highly toxic owing to their high volatility. Microorganisms in polluted waters freely convert various forms of inorganic mercury to methyl mercury, CH_3Hg^+. Most of the mercury in fish occurs as CH_3Hg^+, which is retained for years or until the fish is eaten. High levels of CH_3Hg^+ do not appear as toxic to fish as to humans. In humans, inhaled or ingested CH_3Hg^+ is efficiently absorbed; appears in the red blood cells, liver, and kidneys; and accumulates in the brain, including the fetal brain, where it causes serious, cumulative, irreversible damage to the central nervous system. In the human body, the retention half-life ranges from months to years. The effects are insidious, the appearance of symptoms often delayed for many years.

Two of the most well-known examples of mercury poisoning were both due primarily to CH_3Hg^+. In 1956, ‘Minamata disease’ was discovered near Minamata Bay in southern Japan. In 1959, it was shown that the disease was caused by eating fish contaminated by mercury from CH_3HgCl discharged by a chemical manufacturer into the bay. The mercury load was so great that some fish died, fish-eating birds dropped into the sea, and cats would stagger, ‘whirl violently, then dash away on a zigzag course or collapse’.[19] Even as early as 1954, this ‘dancing disease’ had markedly reduced the local cat population. No records of mercury contamination levels in the area were taken before 1959. Owing to the Japanese custom of saving dried umbilical cords of infants, it was possible to demonstrate human mercury contamination as far back as 1947. Not until 1968 was the dumping brought to a halt.

In humans, the onset of Minamata disease due to CH_3Hg^+ begins with numbness in the limbs and face, sensory disturbance, and difficulty with hand movements such as writing. Later there is a lack of coordination, weakness, tremor, uncoordinated walking, mental disturbance, slurred speech, impaired hearing, and constriction of the visual field. Finally, there is general paralysis, limb deformity especially in the fingers, difficulty in swallowing, convulsions, and death. Tragically also, children born of mildly diseased mothers, who may or may not have exhibited symptoms themselves, suffered from cerebral palsy and idiocy. (Normally, cerebral palsy is not associated with significant mental retardation.) Evidently, the mother discharges CH_3Hg^+ through the placental barrier into the highly susceptible fetus.[19] Women with more serious disease levels are unable to give birth to live children.

In Iraq, in the winter of 1971 to 1972, ingestion for 2 to 3 months of bread made from seed wheat treated with a CH_3Hg^+ fungicide resulted in over 6000 hospital admissions and 500 deaths. Symptoms were similar to those listed above for Minamata disease. In the United States, registration of CH_3Hg^+ as a seed fungicide was suspended in 1970, but a manufacturer obtained an injunction against the suspension, allowing sales to continue. A suspension by the Environmental Protection Agency was finally made to stick in 1972.[20]

7.3 Thallium

This dispersed element occurs with lead in galena, PbS, where Tl^+ and Bi^{3+} (or Sb^{3+}) replace two Pb^{2+}. Tl^+ replaces the similarly sized K^+ and Rb^+ (Table 2) occurring in some feldspars and micas. Thallium usually appears in the 1+ oxidation state, but appears as 3+ in the rare mineral Avicennite, Tl_2O_3, found in Central Asia. If Tl(III) were to appear in the ocean, it would be present as $Tl(OH)_3(aq)$.[18] Contrary to the usual principle of hard and soft acids and bases (*see* ***Hard & Soft Acids and Bases***), Tl(III) is softer than Tl(I).[21]

Once used as medicinal agents and rodenticides, thallium salts are no longer available in most countries for these purposes owing to their high toxicity. Other uses for thallium salts continue, especially in communication systems where there is an increasing demand for them as an ingredient of fiberglass. The sulfides in coal carry thallium, and coal burning is the major source of thallium release into the environment. A typical coal consists of 1 ppm thallium, but some coals contain more. Except in the vicinity of coal burning plants, thallium release is probably not a hazard to humans. Worldwide, thallotoxicosis from ingestion of thallium-based rodenticides

remains one of the most common acute toxic diseases caused by metals.[22]

Both Tl(I) and Tl(III) salts are readily absorbed by the gastrointestinal tract and the skin. Excretion is slow with a half-life of nearly one month. Thallium concentrates in the brain and testes. The lethal dose is less than 1 g of a thallium compound in a single ingestion. Thallotoxicosis involves the nervous system, skin, hair loss, and the cardiovascular system. Tl^+ can substitute for the similarly sized K^+ (Table 2 and Figure 2) and interfere in K^+-dependent processes (Figure 2). Recovery from thallotoxicosis takes months and may be incomplete as nervous system damage may be irreversible.[22] Thallium may be the most toxic nonradioactive metal.

As this summary indicates, thallium compounds are dangerously and cumulatively toxic even at low levels. They should be handled with great care and respect, never being allowed to touch the skin or be ingested.

7.4 Lead[23]

Owing to its easy reduction from its ores upon heating, metallic lead has been known for 6000 years. Wealthy Romans suffered from lead toxicity because their food was cooked, their wine and acidic fruits stored, and their water piped in leaden vessels. What part such lead exposure played in the demise of Roman culture and empire has been debated.[24,25] Under stomach conditions, metallic lead is oxidized to Pb^{2+}, the only important oxidation state under biological conditions. Painters, such as Goya, suffered from inhalation and accidental ingestion of Pb^{2+} from paints. Benjamin Franklin diagnosed himself a 'lead colic' because of his long exposure to lead type used in printing.

Today food and water are the main sources of lead in the body, and children are more likely to absorb and retain lead. With the elimination of lead additives in gasoline, their airborne combustion products contribute much less to pollution than in the past. The body burden of lead increases with age, beginning with the fetus as lead crosses the placental barrier. Today, the average adult body contains about 120 mg of lead, 10 times the amount found in Egyptian mummies. More than 95% of the body burden of Pb^{2+} accumulates in bones.

Acute lead toxicity produces appetite loss and vomiting. Chronic toxicity leads to renal malfunction, anemia, gout, and nervous system disorders, including brain damage in children. (Lead inhibits development in fetal and child brains.) The effects are more serious for a patient deficient in calcium, zinc, or iron (see Figure 2). Available Pb^{2+} affects the structure and function of the bone marrow, where it inhibits several enzymes involved in heme synthesis. It also affects mitochondrial functions in diverse ways. It has proven difficult, however, to specify critical interactions in lead toxicity. Pb^{2+} is not particularly carcinogenic but quite toxic. Acute toxicity is dealt with by infusion of Ca^{2+}-EDTA, with the intent of exchanging metal ions on the EDTA, (ethylenedinitrilotetraacetate).

Interactions of Pb^{2+} severely restrict the free Pb^{2+} concentration in body fluids. More than 95% of the Pb^{2+} in blood occurs in the red cells, where glutathione promises to be the strongest small molecule binder. From the limited solubility of insoluble $HOPO_3Pb$, a detailed calculation reveals that the allowed free Pb^{2+} concentration is only about 25 nM for extracellular fluids and 10 nM for intracellular fluids.[23] These very low concentrations indicate that in body fluids any significant quantities of total Pb^{2+} must be complexed in some way.

Pb^{2+} exhibits irregular coordination geometries (often with bridging) and variable coordination numbers, 6 to 10 being common. In a crystal structure of $Pb(H_2PO_4)_2$, bridged Pb^{2+} is surrounded by seven oxygen atoms from seven different $H_2PO_4^-$ groups, five at short distances and two farther away.[26] The variable and adaptive coordination about Pb^{2+} presumably accounts for its ability to interact in biological systems at sites normally harboring smaller metal ions such as Ca^{2+} and Zn^{2+}.[2,5]

Contrary to some expectations, Pb^{2+} is not an extraordinarily strong ligand binder, and (in contrast to the hard and soft precept) favors oxygen as well as sulfur donors over nitrogen (see stability ruler, Table 3). In the calmodulin family of proteins, Pb^{2+} binds more strongly than the native Ca^{2+} to the calcium sites, composed solely of O donors. In oncomodulin and chick vitamin D–induced intestinal calcium-binding protein, Pb^{2+} binding occurs exclusively at the Ca^{2+} sites, despite the presence of a free sulfhydryl group on the proteins.[27] Calmodulin in which Pb^{2+} has replaced Ca^{2+} yields a protein that retains many of its native activities. Such Pb^{2+}-induced activities may be responsible for some of its toxicity. Interactions of Pb^{2+} with a variety of nucleotides have received review.[23] Leadzymes, ribozymes of Pb^{2+}, are RNA molecules that catalyze a number of transformations utilizing Pb^{2+}.[28]

The rate of exchange of ligands into and out of the coordination sphere of Pb^{2+} is among the fastest of any metal ion; there should be a rapidly attained equilibrium distribution of Pb^{2+} among ligand sites not separated by barriers.[2,5]

Aqueous Pb^{2+} undergoes loss of protons from bound water molecules with successive pK_a values of 7.8, 9.4, and 10.7 (at 0.16 ionic strength and 25 °C).[18] Thus, at low total lead concentrations, both intracellular (pH 6.6) and extracellular (pH 7.4) body fluids contain mostly aquated Pb^{2+} with some aquated $Pb(OH)^+$. Assuming that a similar pK_a7.8 value prevails in Pb^{2+} complexes, an hydroxo complex may serve as a general base catalyst, a role that has been proposed several times. (Hydroxo complexes of metal ions may also serve as an effective hydroxide nucleophile.[23]) At the total concentrations of lead prevailing in many experiments, soluble polynuclear complexes form. First to appear at about 0.010 mM total lead is $Pb_3(OH)_4^{2+}$, from pH 8 to 10. Greater total lead concentrations yield polynuclear species over the entire pH scale.[18]

8 ALUMINUM[29,30]

Comprising 8% of the earth's crust, aluminum is locked in minerals as oxides and complex aluminosilicates that conceal its status as the most abundant metal and the third most abundant element, after oxygen and silicon. For the first time in the history of the earth, this metal ion is being released by acid rain into water supplies. Until recently, most natural waters contained insignificant amounts of aluminum. With the advent of acid rain, metal ions such as aluminum, mercury, and lead escape from mineral deposits and dissolve in fresh waters. Acid rain serves as the key that springs the lock for metal ion release. The Al^{3+} concentration increases sharply in clear water lakes at $pH < 6$ where micromolar amounts may occur. Al^{3+} is more damaging to fish than is increased acidity; even 5 μM Al^{3+} kills fish. Humans have set in motion an epic experiment to test the ability of living organisms to cope with higher levels of Al^{3+} activity.

Worldwide, given adequate nutrients, the presence of Al^{3+} is the main limiting factor in plant productivity in acidic soils. Plants such as tea that accumulate Al^{3+} are rare and do so in acidic soils and evidently detoxify the Al^{3+} by storing a chelated version in cell vacuoles of older leaves separate from the more metabolically active parts of the plant.[31] Tea plants have been found with as much as 3% Al^{3+} in older leaves and only 0.01% in younger ones, a 300-fold difference. Typical tea infusions contain about 50 times as much Al^{3+} as do infusions from coffee. Adding milk to tea should immobilize Al^{3+} as an insoluble phosphate, while lemon will strongly complex the Al^{3+} in deleterious soluble citrate complexes described below.

Coupled with the increasing availability of Al^{3+} is the role it plays in several human disorders. Aluminum in antacids and in waters used for dialysis is known to cause dementias, bone deterioration, and even death. Al^{3+} is the likely primary cause of three conditions arising from long-term hemodialysis: vitamin D–resistant osteomalacia, iron-adequate microcytic anemia, and dialysis dementia.[32] Because of the large amounts of dialysis fluid used, even small quantities of Al^{3+} may become deleterious over time. Dialysis centers now test for the Al^{3+} content. A study of 10^4 long-term hemodialysis patients found that a serum Al^{3+} concentration of greater than 1.5 mM increased the mortality risk and that 40% of the patients exceeded this level.[33] In normal individuals, the serum Al^{3+} level is less than 0.4 mM. Similar conditions occur in children suffering from renal failure after prescribed high intakes of Al^{3+} to combine with excess phosphate of hyperphosphatemia. Upon acute ingestion, even normal adults may accumulate Al^{3+} in bones. It is debated whether the presence of Al^{3+} is a coincidence, consequence, or cause of Alzheimer's disease.[34]

There are four categories of exposure of healthy adults to aluminum. For an individual, wide variations in intakes occur in each category, and some typical values appear in Table 4. Natural sources contribute only about 5 mg day^{-1} and probably even less for nontea drinkers. High aluminum levels occur naturally in only a few foods. Food additives add 5 to 100 mg day^{-1} with the high amounts being due to alum baking powder products and Al^{3+}-containing emulsifiers added to processed cheese. Except in instances of long stewing of acidic or highly salted foods, aluminum cookware, especially if not new, furnishes little aluminum to the diet. As indicated by the last category in Table 4, the greatest potential sources of intake are Al^{3+}-containing antacids and buffered aspirins. Most ingested aluminum is poorly absorbed by the intestine and is eliminated by the body. The last entry in Table 4, vaccines, provides an example of a solution that bypasses the intestinal barrier. Solutions given intravenously to patients may result in significant quantities of aluminum being injected into the blood and may be especially critical in infants.[35]

Table 4 Aluminum intakes by healthy adults

- Natural sources, about 2–5 mg day^{-1}
  - Tea, typical 0.1% with up to 1% in dry tea, but poorly extracted in steeping, ≈1 mg/cup
  - Drinking water, avg. is 0.02 mg Al liter^{-1}
  - Herbs, many high in Al but little consumed
  - Spinach
- Food additives, about 20 mg day^{-1}
  - Alum baking powder products, corn bread
  - Emulsifier in American cheeses
  - In cream substitutes
  - Aluminum silicates as anticaking agents
  - $Al_2(SO_4)_3$ as anticoagulant for turbid drinking water
- Al containers (new) in stewing of acidic fruits, spaghetti sauce, sauerkraut (<0.1 mg day^{-1})
- Pharmaceuticals, if used, to 4000 mg day^{-1}
  - Antacids, 4000 mg day^{-1} for heavy users
  - Buffered aspirin, 500 mg day^{-1} for arthritics
  - Antiperspirants
  - Vaccines (intramuscular injection bypasses intestinal barrier)

Appreciation of the basic chemistry of aluminum leads to understanding and prediction of its potential roles in more complex systems.[36] The chemistry of aluminum is relatively simple. It reacts 10^7 times faster than Cr^{3+}, its hydroxide is much more soluble than that of Fe^{3+}, and it exhibits only one oxidation state in biological systems, Al^{3+}. There is no oxidation–reduction chemistry to Al^{3+} in biology. Al^{3+} interactions are primarily ionic, and as can be seen from Table 2, its ionic radius is the second smallest listed (after Be^{2+}) and is smaller but comparable to Fe^{3+} and Mg^{2+}, both of which compete with it in biological systems. Both Al^{3+} and Mg^{2+} favor oxygen donor ligands, especially phosphate groups. Al^{3+} is 10^7 times more effective than Mg^{2+} in promoting polymerization of tubulin to microtubules.[37] Ca^{2+} is much larger with a volume nine times greater than Al^{3+}. Wherever there is a process involving Mg^{2+} (*see* ***Cation-activated Enzymes***), seek there an opportunity for interference by Al^{3+}.[29]

In solutions with pH < 5, aluminum occurs as the octahedral hexahydrate, $Al(H_2O)_6{}^{3+}$, usually abbreviated as Al^{3+}. As a solution becomes less acidic, $Al(H_2O)_6{}^{3+}$ undergoes successive deprotonations to yield $Al(OH)^{2+}$, $Al(OH)_2{}^{+}$, and soluble $Al(OH)_3$, with a decreasing and variable number of water molecules. Neutral solutions give an $Al(OH)_3$ precipitate that redissolves, owing to formation of tetrahedral aluminate, $Al(OH)_4{}^{-}$, the primary soluble Al^{3+} species at pH > 6.2. The four successive deprotonations squeeze into a narrow range 5.5 < pH < 6.2; the deprotonations from octahedral hexahydrate to tetrahedral aluminate occur cooperatively.[38,39]

The most likely Al^{3+} binding sites are oxygen atoms, especially if they are negatively charged.[29,40,41] Carboxylate, catecholate, and basic phosphate groups[41–43] are the strongest Al^{3+} binders. In contrast with their reaction with the heavy metal ions discussed above, even when part of a potential chelate ring, sulfhydryl groups do not bind Al^{3+}.[44] Amines do not bind Al^{3+} strongly except as part of multidentate ligand systems such as nitrilotriacetate (NTA) and EDTA. Amino acids are weak binders barely competing with metal ion hydrolysis.[40,45] Neither the nitrogenous bases[36,46] nor the phosphates (nonbasic)[29,40,41] of DNA and RNA bind Al^{3+} strongly. Within a cell, Al^{3+} binds mainly to ATP with a stability constant 4000 times greater than Mg^{2+}, making Al^{3+} at only 0.1 μM competitive with intracellular Mg^{2+} at 1 mM.[29,42]

Fluoride binds Al^{3+} strongly, and at the 1 ppm level where it is added to acidic drinking water, most aluminum appears as $AlF_2{}^{+}$ and as neutral AlF_3.[29,47] In mixed complexes of Al^{3+}, ADP, and F^{-}, the ternary complex appears with the frequency expected statistically on the basis of binary complex stabilities.[48] Contrary to a common misconception, when bound to proteins (such as G-proteins), fluoride complexes of Al^{3+} do not contain a tetrahedral, four-coordinate metal ion but hexacoordinate Al^{3+} with six donor atoms.[29,49]

It is as the citrate complex that Al^{3+} passes the intestinal barrier into the blood. Al^{3+} levels were elevated in both the brain and bones of rats fed a diet containing aluminum citrate or even just citrate. Evidently, citrate alone chelates trace Al^{3+} in the diet. Increased levels of serum Al^{3+} were found in patients with chronic renal failure taking an Al^{3+}-containing phosphate binder with citrate or $Al(OH)_3$ with citrate. A rapidly fatal encephalopathy in human patients with chronic renal failure has been attributed to concomitant ingestion of $Al(OH)_3$ and citrate. Moreover, healthy adults taking $Al(OH)_3$-based antacids along with citric acid, citrate salts, or citrus fruits showed substantial increases in Al^{3+} levels of blood and urine. ‘Only those who cared for children in the late 1970s during the liberal use of aluminum-containing antacids and citrate can appreciate the horror of helplessly watching previously normal children die of severe encephalopathy over months to years.’[50] On the basis of information from equilibrium constants, it was strongly urged in 1986 that people not take Al^{3+} and citrate together.[46]

Citrate exists mainly in the form of the tricarboxylate anion at pH > 6, and at 0.1 mM in the blood plasma, it is the leading small molecule Al^{3+} binder.[29,51] In neutral solutions, the main species is $HOAlLH_{-1}{}^{2-}$ followed by $AlLH_{-1}{}^{-}$ with $pK_a \approx 6.5$ for the loss of a proton from metal ion–bound water.[29,52] Citrate solubilizes Al^{3+} from both insoluble $Al(OH)_3$ and $AlPO_4$, making it more available to an organism.[40,41,51] Proton nuclear magnetic resonance spectroscopy provides direct evidence that Al^{3+} binds to citrate in human blood plasma.[53] From detailed calculations for several biological fluids, estimates of the free Al^{3+} concentration ranges from $10^{-14.2}$ to $10^{-12.6}$ M.[54]

Transferrin binds to Al^{3+} and is the main protein carrier of Al^{3+} in the plasma.[55,56] Displacement of the 10^9 times stronger binding Fe^{3+} is unnecessary because plasma transferrin is about 50 μM in unoccupied sites. On the basis of values of requisite stability constants, it was suggested that in blood plasma about 89% of Al^{3+} is bound to transferrin and 11% to citrate.[51] This distribution is supported by direct measurements by a variety of methods.[56]

1 INTRODUCTION

1.1 Bulk Metals versus Atoms

The chemistry of transition metals with a variety of substrates is now well established. It has been learned that the reactivity and reaction speed of one specific element and an appropriate ligand depends in part on the metal particle size. Freshly prepared metal powders often react differently from aged and passivated metal powders, metal wire, pellets, or ingots. Therefore, the highest reactivity might be expected from single metal atoms. The first steps in the direction of producing metal vapor atoms were taken in the 1920s and 1930s. Those studies began with chemical reactions of high-temperature gas phase Na and K with organohalides. Also, small carbon species ($C_1, C_2, C_3, \ldots$) were prepared in the early 1960s to function as macroscale (>50 mg) synthons. In order to demonstrate the use of single metal atoms in synthetic applications, efforts were made in the early 1970s[1,2] to develop techniques to vaporize metals in macroscale amounts. In a short time, these efforts led to a new important field of research.

This article is organized primarily according to the periodic table and secondarily with regard to the importance of substrates found to react with metal vapor atoms. Tables, lists, and figures will display many of the known compounds prepared via the metal vapor-substrate cocondensation method and give further information about physical properties, chemical behavior, spectroscopic data, and structural details.

1.2 Energetics of Vaporization

Table 1 shows relevant information for the metallic elements.

1.3 Vapor Compositions

There exist more than 100 elements in the periodic table from which high-temperature particles can be formed. In order to generate highly reactive free atoms, a great deal of energy is required. For instance, at least 400 kJ mol^{-1} are necessary in order to break nickel–nickel bonds and allow the escape of nickel atoms. Thus nickel must be under vacuum and heated to about 1400 °C to accomplish this. We must also consider small particles, such as Mn_2, V_3, or Co_2. These clusters might react differently from single metal atoms. As the number of atoms in a metal cluster increases, its chemical behavior resembles active metal powders more and more. The chemistry of small clusters is a rather young field, in that experimental advances in vacuum technology, high-temperature ceramics, and cryochemical techniques have been absolutely necessary. However, cluster chemistry, a major new research field, contributes less to synthetic applications than metal atom chemistry, and therefore will not be emphasized here. Similar considerations preclude much discussion of microscale, low-temperature matrix isolation studies.

1.4 Techniques of Vaporization

The most widely used method of metal vaporization in the laboratory is resistive heating of crucibles consisting of Mo or W coils and an Al_2O_3 coating. Typical transition metals, like Cr, Fe, or Ni, can be vaporized in gram amounts per hour. A freshly prepared single metal atom carries some kinetic energy and has orbitals poised for reaction without steric restrictions. To control the reaction parameters, moderate the vapor pressures for incoming reactants, and minimize gas phase interactions, very low substrate temperatures are desired: in the range −50 to −200 °C. Drawbacks to this method are competition between complex formation and metal aggregation, the frequent low yields, and the large amount of cooling agent required. Figure 1 shows a macroscale stationary cocondensation vessel for macroscale reactions. Only the resistive heating method offers the advantage of low concentrations of metal atom dimers, trimers, oligomers, and metal particles that may react with substrates differently. Other widely used vaporization methods, like electron beams and lasers, are more technologically complex and problematic. Resistively heated Al_2O_3 sources are quite satisfactory for most of the transition metals. Elements with a very high heat of vaporization (W, Re) require more advanced and powerful methods of vaporization, and an electron beam is usually employed.

The electron beam method was developed in the late 1960s and uses a focused electron beam to vaporize the central portion of a metal sample. Despite the necessity of

an extremely good vacuum (10^{-5} mbar) to avoid arcing and stray electron and X-ray damage of organometallic products, this technique does allow large-scale vaporization (kilograms per hour), and even high-boiling transition metals like W (bp 5660 °C) can be vaporized. Figure 2 illustrates an electron beam apparatus schematically. Only volatile substrates can be conveniently employed in both types of reactors.

A solution metal atom reactor (after Timms), as shown in Figure 3, offers the opportunity to evaporate metal atoms continuously into a substrate dissolved in an inert solvent at low temperature and can be equipped with a crucible or an electron beam heating source. Another, less efficient, evaporation method can be carried out by means of a laser. Figure 4 shows an IR laser beam passing through a window and rapidly heating up a small area on the metal sample. Lasers bring high energy flux densities focused on one point, and stray radiation is less damaging to products than stray electrons and X-rays from electron beam setups. One great disadvantage of the laser method is that molten metals reflect the laser beam like a mirror. Another problem is the need for a window that does not become coated during the metal evaporation and shuts out the light. The latter problem can be partly solved by a slight gas stream near the window keeping

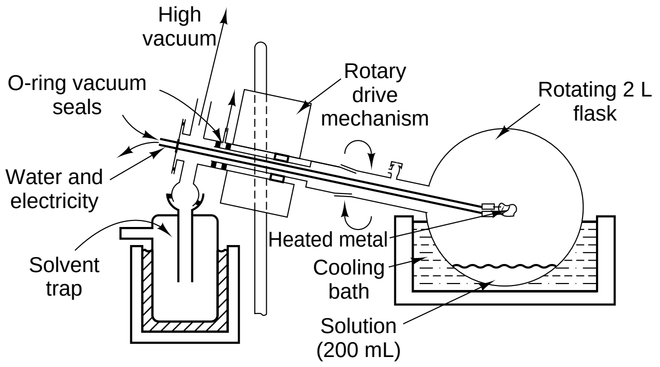

Figure 3 Schematic diagram of a solution metal atom (vapor) reactor

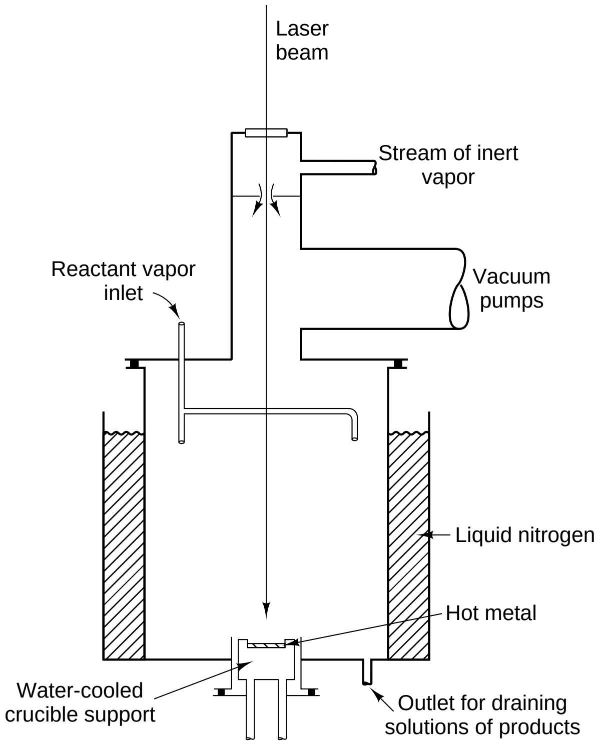

Figure 4 Schematic diagram for laser vaporization and cocondensation of vapor with chemical substrates

it clear of metal deposits. The gas must be continually pumped away, rapidly, and this causes the necessity for faster pumping speed (thus larger pumps).

Other less sophisticated evaporation techniques are, for instance, the wrapping of W coils with Pt wire. Only small amounts of Pt can be vaporized, because alloying with the hot W occurs. The problem is also found with electrodeposited Rh on W coils. Other metal powders like Ru can be glued on W wires with epoxy cement. Slow annealing drives off the carbonaceous residue leaving Ru coated on W. The Ru can then be vaporized with more vigorous resistive heating.

Arc metal vaporization has proven less efficient. Many metals can be vaporized in this way, but metal vapor often condenses on the copper electrode and forms nonvolatile compounds, finally decreasing vaporization rates.

2 EARLY TRANSITION METALS (Sc–Mn GROUPS)

2.1 Chromium–Arene Chemistry

2.1.1 Bis(benzene)chromium

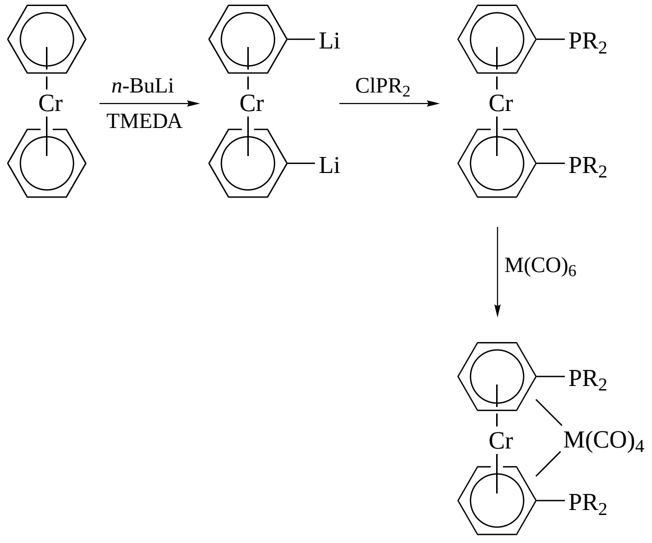
The most important ligand for early transition metal atoms is the arene ligand. Bis(benzene)chromium has been known since 1955 (E. O. Fischer) and was prepared first via wet chemical methods. Not all desired substituents on the arene are stable to the extreme conditions employed in the *Fischer–Hafner Synthesis*. The cocondensation technique offers a new synthetic pathway to bis (η^6-arene)metal complexes simply by codepositing Cr atoms together with the appropriate ligand, normally at the temperature of liquid nitrogen ($-196\,°C$). Chromium is quite easy to vaporize, it sublimes before melting, and can be evaporated in gram amounts by resistive heating.

The diamagnetic, air-sensitive, black $(C_6H_6)_2Cr$ is a thermally stable 18-electron complex (mp 284 °C), with D_{6h} symmetry according to electron diffraction and low-temperature X-ray studies. The structure reveals a ring–ring distance of 322 pm, equal to the van der Waals separation of two π-systems, compared to free benzene. The average C–C bond distance of 142 pm is enlarged, compared to the bond parameters in free benzene. The π-bonding alters the reactivity of the arene rings in $(arene)_2Cr$ complexes in several ways. Unlike ferrocene, bis(benzene)chromium undergoes no electrophilic aromatic substitution reactions. Electrophilic attack oxidizes Cr^0 to Cr^I, yielding the paramagnetic cation $[(C_6H_6)_2Cr]^+$, which does not react further. The coordinated benzene is metallated more readily than free benzene by means of n-butyllithium/TMEDA, because of the increased kinetic acidity of benzene upon complexation to chromium. The lithiated product serves as a valuable precursor for substituted $(arene)_2Cr$ compounds (Scheme 1).

2.1.2 Substituted Arenes and Six-Membered Rings

Other stable $(arene)_2Cr$ complexes[3] prepared by the metal atom technique are listed in Table 2.

The variously substituted bis(arene)chromium(0) compounds are generally easy to purify by crystallization or sublimation. Bis(arene)chromium complexes with substituents like Cl, F, OMe, or NMe_2 are not preparable by classical means



Scheme 1

and show different chemical behavior compared to $(C_6H_6)_2Cr$. While all hydrocarbon-substituted (arene)$_2$Cr complexes are air sensitive, $(\eta^6\text{-}C_6H_5Cl)_2Cr$ is air stable because of the presence of electron-withdrawing groups. Elschenbroich and his coworkers have prepared a wide series of new Cr sandwich complexes, including arene complexes containing strained-ring substituents, as well as bis(naphthalene)Cr, which serves as an example of a kinetically labile complex (*see Hapticity*). Unlike $(C_6H_6)_2Cr$, $(C_{10}H_8)_2Cr$ undergoes ring exchange under moderate conditions:

$$(C_{10}H_8)_2Cr + 3\text{bipy} \longrightarrow (\text{bipy})_3Cr + 2C_{10}H_8 \qquad (1)$$

For higher polycyclic arenes, like phenanthrene, triphenylene, or coronene, the chromium coordinates preferentially to the ring with the highest index of local aromaticity (usually the terminal ring). The codeposition of a large excess of Cr with biphenyl gives, among other side-products, the interesting bis[μ-(η^6:η^6-biphenyl)]dichromium, whose paramagnetic dication acts as an organometallic triplet species.

The heterobenzene $(\eta^6\text{-}C_5H_5P)_2Cr$ can be directly prepared by the metal–ligand vapor cocondensation technique. This heterocycle is aromatic and prefers η^6-coordination to η^1-coordination. For pyridine, σ-coordination via a lone pair is highly preferred over bonding that utilizes the π-electron system. Therefore the direct synthesis of η^6-pyridine metal complexes requires the N-atom to be blocked by means of substitution in the 2,6-positions:

$$2\,2{,}6\text{-}Me_2C_5H_3N(g) + Cr(g) \longrightarrow (2,6\text{-}Me_2C_5H_3N)_2Cr \qquad (2)$$

The labile parent complex bis(η^6-pyridine)chromium can be prepared by occupying the 2,6-positions with protecting

Table 2 Bis(arene)chromium(0) compounds prepared by cocondensation of chromium atoms and ligand vapor

Complex	Yield (%)	Product characteristics
Bis(benzene)chromium	13	Black solid, oxidized by air to cation, volatile (60 °C, 10^{-3} mbar), mp 284 °C
Bis(1,2-dimethylbenzene)chromium	25	Black solid, oxidized by air to cation, volatile (80 °C, 10^{-3} mbar), mp 127–128 °C
Bis(*t*-butylbenzene)chromium	27	Black solid, oxidized by air to cation, volatile (80 °C, 10^{-3} mbar), mp 76–88 °C
Bis(indane)chromium	17	Olive-green solid, oxidized by air to cation, volatile (80 °C, 10^{-3} mbar), mp 107–109 °C
Bis(2,6-dimethylpyridine)chromium	17	Deep-red solid
(η^{12}-[2.2]Paracyclophane)chromium[4]	5	Lemon-yellow solid, volatile (120 °C, 10^{-3} mbar), yield based on unrecoverable ligand
Bis(cyclobuta-η^6-benzene)chromium[5]	12	Reddish-brown solid, volatile (80 °C, 10^{-4} mbar), mp 122 °C
Bis[μ-(η^6:η^6-biphenyl)]dichromium[6]	0.4	Dark brown solid, volatile (180 °C, 10^{-4} mbar)
Bis(naphthalene)chromium	18	Dark brown solid, volatile (80 °C, 10^{-4} mbar), mp 160 °C (dec.), pyrophoric when finely divided
Bis(*p*-methylmethoxybenzene)chromium	12	Brown–black solid, oxidized by air to cation, volatile (130 °C, 10^{-3} mbar), mp 130–133 °C
Bis(*m*-chlorotoluene)chromium	5	Black solid, oxidized by air to cation, volatile (80 °C, 10^{-3} mbar), mp 56–57 °C
Bis(*p*-fluorobenzotrifluoride)chromium[7]	7	Dark green solid, air stable for several days, volatile (56 °C, 10^{-3} mbar), mp 60.5–61 °C
Bis(*p*-difluorobenzene)chromium	12	Dark violet, air stable, volatile (50 °C, 10^{-3} mbar), mp 172–174 °C (dec.)
Bis(phenylether)chromium	3	Olive-green solid, oxidized by air to cation, volatile (130 °C, 10^{-3}, mbar), mp 130–133 °C
Bis(*N*,*N*,-dimethylaniline)chromium	6	Red solid, oxidized by air to chromium oxide, volatile (80 °C, 10^{-3} mbar), mp 87.5–88.5 °C
Bis(trimethylsilylbenzene)chromium	5	Brown solid, oxidized by air to cation, reduced by K to anion, volatile (70 °C, 10^{-3} mbar)
Bis(methyl benzoate)chromium	4	Red solid, moderately air stable, volatile (100 °C, 10^{-3} mbar), mp 111 °C
Bis(arsabenzene)chromium[8]	15	Reddish-black, air-sensitive solid, sublimable, mp 253 °C (dec.)

groups, which can be removed after complex formation:

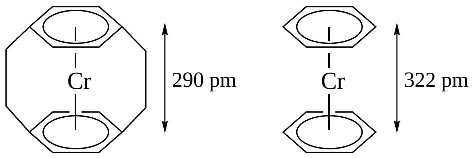
$$2\,2,6\text{-}(SiMe_3)_2C_5H_3N(g) + Cr(g) \longrightarrow$$

$$[2,6\text{-}(SiMe_3)_2C_5H_3N]_2Cr \xrightarrow[Na_2S_2O_4]{O_2/5\,min} (C_5H_5N)_2Cr \qquad (3)$$

The cocondensation of paracyclophane with Cr atoms gives, besides bis(paracyclophane)chromium, (η^{12}-[2.2]paracyclophane)chromium in low yield, which represents a compressed sandwich complex. The average ring–ring distance of 290 pm falls considerably short of the corresponding distance in $(C_6H_6)_2Cr$ (322 pm) (Scheme 2).

2.1.3 *Mixed Arenes*

A series of new mixed bis(arene)Cr complexes have been made by simultaneously codepositing two different arenes. These reactions yield three complexes, $(arene)_2Cr$, $(arene')_2Cr$, and (arene)(arene′)Cr, that can be separated by chromatography or sublimation (Table 3). Efforts to prepare bis(arene) complexes from hexafluorobenzene or $C_6(CF_3)_6$ have been unsuccessful because of highly electron-demanding groups like F and CF_3. Neither of those ligands forms thermally stable sandwich complexes with chromium. The mixed (arene)(arene′)Cr complex $(C_6H_6)(C_6F_6)Cr$ is surprisingly stable to air and heat. Electrochemical studies show remarkably large variations in $E_{1/2}[(Ar)_2Cr^0 \rightarrow (Ar)_2Cr^+]$, ranging from −0.2 V for the electron-rich $(C_6H_5OMe)_2Cr$ to +1.2 V for $[(CF_3)_2C_6H_4]_2Cr$. Electron-withdrawing and donating groups greatly affect the σ-framework of the arene ring as well as the π-framework in the M–ring bond. NMR studies by Lagowski on a series of bis(arene)Cr complexes showed that substituent effects are not transmitted through the Cr atom and are confined to the corresponding arene ring.



Scheme 2

2.1.4 *Arene/Phosphine/Phosphite Combinations*

Phosphines, particularly PF_3, have been employed for trapping organometallic species generated in low-temperature atom matrices. PR_3 groups are valuable moieties in stabilizing sandwich compounds with potentially labile ligands. Therefore, phosphine ligands act as a stabilizing ancillary ligands in unstable $(Ar)_2Cr$ species. Representative examples for arene–ligand combinations, attached to Cr, are listed in Table 4.

2.2 Other Transition Metals with Arenes

The most important synthetic chemistry of the early transition metal atoms continues to be the preparation of bis(arene)M^0 sandwich complexes, as shown in Table 5:

$$M(g) + 2Ph(X) \longrightarrow [Ph(X)]_2M \qquad (4)$$

The metal vapor–ligand codeposition method has extended the array of such sandwich complexes. A wide range of substituents can be tolerated on the arene ring; unusual arene–M complexes have been prepared. Elschenbroich made the interesting compound bis(η^6-phosphabenzene)vanadium, which is less air sensitive than the ligand itself. It turned out that the phosphorus heteroatom has a much stronger influence on the electron affinity of the free arene than of the bound arene.

Table 3 Mixed bis(arene)chromium compounds prepared by metal vapor–ligand codeposition

Complex	Yield (%)	Product characteristics
$(C_6H_6)(C_6F_6)Cr$	9	Yellow solid, air stable for several weeks, mp 139 °C
$(C_6H_6)(C_6F_5H)Cr$[9]	22	Orange solid, air stable, volatile (35 °C, 0.2 mbar), mp 117 °C
$(C_6H_6)(C_5H_5N)Cr$	2	Red–brown solid, oxidized by air to cation, volatile (50 °C, 10^{-3} mbar)

Table 4 Mixed arene/ligand complexes of Cr prepared via metal vapor–ligand codeposition method

Complex	Yield (%)	Product characteristics
$(C_6H_5Me)Cr[P(OMe_3)_3]_3$[10]		Yellow–orange solid
$(C_6H_6)Cr(PF_3)_3$		Pale yellow solid, air-sensitive, mp 220 °C (dec.)
$(C_6F_6)Cr(PF_3)_3$	1–2	dec. >250 °C
$(C_5H_5N)Cr(PF_3)_3$[11]		
$(C_6H_3Me_3)(PF_3)_3Cr$	10	Cream-colored solid, air-sensitive, mp 130 °C (dec.)

Table 5 Bis(arene)M^0 complexes and properties

Complex	Number of valence electrons	Complex properties
$(C_6H_6)_2Ti$	16	Air sensitive, autocatalytic decomposition in aromatic solvents
$(C_6H_6)_2V$	17	Black solid, very air sensitive, paramagnetic, reducible to $[(C_6H_6)_2V]^-$, mp 227 °C
$(C_6H_5F)_2V$	17	Red solid, air sensitive
$(C_5H_5P)_2V$[12]	17	Reddish-brown solid, mp 210 °C
$(C_6H_6)_2Nb$	17	Purple solid, very air sensitive, paramagnetic, decomposes at ca. 90 °C
$(C_6H_6)_2Mo$	18	Green solid, very air-sensitive, mp 115 °C
$(C_6H_5OMe)_2Mo$	18	Sublimable (50–80 °C, $<10^{-3}$ Torr)
$(C_6H_5CO_2Me)_2Mo$	18	Sublimable (50–80 °C, $<10^{-3}$ Torr)
$(C_6H_5F)_2Mo$	18	Sublimable (50–80 °C, $<10^{-3}$ Torr)
$(C_6H_6)_2$ W	18	Yellow–green solid, less air sensitive than $(C_6H_6)_2Mo$, mp 160 °C
$(C_6H_5F)_2$ W	18	Sublimable (50–80 °C, $<10^{-3}$ Torr)

Table 6 Mono- and bis(arene)/phosphino derivatives of early transition metals prepared by metal vapor synthesis

Metal	Arene	σ-Donor ligand	Product
Zr	Toluene	PMe_3	$(\eta^6\text{-}C_6H_5Me)_2ZrPMe_3$
Hf	Benzene	PMe_3	$(\eta^6\text{-}C_6H_6)_2HfPMe_3$
Mn	Benzene	PMe_3	$(\eta^6\text{-}C_6H_6)Mn(PMe_3)_2H$
Re	Benzene	PMe_3	$[(\eta^6\text{-}C_6H_6)Re(PMe_3)_2]_2$
Mn	Toluene	I_2	$(\eta^6\text{-}C_6H_5Me)_2Mn^+I^-$

The cocondensation of Nb atoms with toluene has yielded bis(η^6-toluene)niobium, which serves as a useful intermediate for the preparation of a wide series of mono- and bis-arene derivatives.[13] While Ti, V, Nb, Cr, Mo, and W form $(Ar)_2M^0$ sandwich complexes, Mn, Tc, and Re appear less promising, because Mn–arene complexes have already been shown to be unstable,[14] Tc is radioactive, and Re remains to be investigated. As already mentioned, Ti forms fairly labile bis(arene)Ti complexes. The unstable 16-electron sandwich complexes from elements of group 4 can be stabilized with phosphine ancillary ligands, yielding bis-arene derivatives as in Table 6.

2.3 Dienes, Trienes, and Tetraenes

Novel organometallics have been prepared via metal atom synthesis since the 1970s. Especially interesting have been diene reactions with early transition metal atoms. Cyclopentadiene on cocondensation with metal atoms reacts with Cr through a bis(cyclopentadienyl)chromiumdihydride intermediate to yield chromocene. For Mo and W, the intermediate species can be isolated. Labeling studies with Cp*H and Cp*D indicate that oxidative addition of the C–H bond to M occurs stepwise ($\rightarrow Cp^*MH \rightarrow Cp^*_2MH_2$) (*see Oxidative Addition*).

$$Cr(g) + 2CpH \longrightarrow [Cp_2CrH_2] \longrightarrow Cp_2Cr + H_2 \quad (5)$$

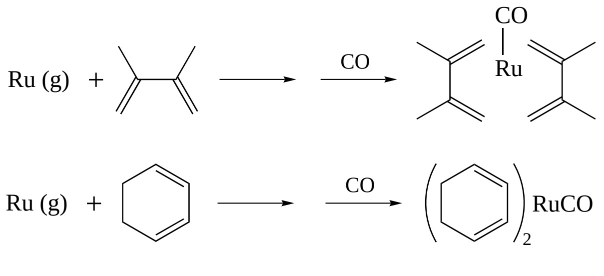
$$Mo(g) + 2CpH \longrightarrow Cp_2MoH_2 \quad (6)$$

$$W(g) + 2CpH \longrightarrow Cp_2WH_2 \quad (7)$$

Ru atom codeposition with dienes at 77 K, followed by warming in the presence of CO, has yielded gram quantities of $Ru(CO)(diene)_2$ complexes (Scheme 3) (*see **Hydride Complexes of the Transition Metals***).

The 18-electron complex $(C_6H_6)MnCp$ can be prepared in low yield from the reaction of Mn atoms and a mixture of benzene and cyclopentadiene. 1,3-Butadiene–Mo or –W macroscale depositions yielded unique, stable $(diene)_3Mo/W$ complexes.[15] Those molecules are, according to X-ray crystallography, wrapped cisoid about the Mo and W, so that all 12 carbons are equidistant from the metal.[16] Cyclic dienes like cod are excellent ligands in organometallic chemistry. Pure $(1,5\text{-cod})_nCr$ complexes are unstable, but addition of trapping ligands at low temperature yields stable $(1,5\text{-cod})CrL_4$ complexes. Representative examples are listed in Table 7.

Cyclic triene (nonaromatic) and tetraene reactions form a series of new complexes. While some cyclotrienes yield mostly unstable species, heating or ligand trapping can generally lead to stable, isolable compounds. Hydrogen transfer also plays an important role in the synthesis of η^7–η^5 sandwich complexes. With cot and Cr atoms a Cr≡Cr bonded $Cr_2(C_8H_8)_3$ complex is formed,[17] while in the case of Ti–cot, a novel *Triple Decker Sandwich* is obtained.[18]



Scheme 3

Table 7 Transition metal complexes of cyclic dienes/trienes/polyenes/σ-donor ligands prepared via the metal vapor–ligand codeposition method

Metal	π-Ligand	σ-Donor ligand	Product
Zr	Cycloheptatriene	–	$(\eta^7\text{-}C_7H_7)Zr(\eta^4\text{-}1,3\text{-}C_7H_{10})$
Hf	Cycloheptatriene	–	$(\eta^7\text{-}C_7H_7)Hf(\eta^4\text{-}1,3\text{-}C_7H_{10})$
Mn	Cycloheptatriene	CO	$(\eta^6\text{-}C_7H_8)_2Mn(CO) + (\eta^5\text{-}C_7H_9)Mn(CO)_3$
Mn	Cycloheptadiene	CO	$(\eta^5\text{-}C_7H_9)Mn(CO)_3 + (\eta^3\text{-}C_7H_{11})Mn(CO)_4$
Mn	Cyclopentadiene	CO	$(\eta^5\text{-}C_5H_5)Mn(CO)_3$
Mn	Cyclohexadiene	CO	$(\eta^4\text{-}C_6H_8)_2Mn(CO)$
Cr	1,5-Cyclooctadiene	PF_3	$(\eta^4\text{-}C_8H_{11})Cr(PF_3)_3H$
Cr	1,3-Cyclohexadiene	PF_3	$(\eta^4\text{-}C_6H_8)_2Cr(PF_3)_2$
Ti	Cycloheptatriene	–	$(\eta^7\text{-}C_7H_7)Ti(\eta^5\text{-}C_7H_9)$
Ti	Cyclooctatetraene	–	$(\eta^8\text{-}C_8H_8)_2Ti_2(\eta^6\text{-}C_8H_8)_3$
Cr	Cyclooctatetraene	–	$Cr_2(C_8H_8)_3$

2.4 Phosphines, Amines, and σ-Donor Combinations

Pure phosphine–metal atom studies with the early transition metals have been lacking. The only complex prepared this way prior to 1978 was $Cr(PF_3)_6$. King and Chang, with the unique aminophosphine systems Me_2NPF_2 and $MeN(PF_2)_2$, have generated a variety of new homoleptic $M{-}(L)_n$ systems (*see Homoleptic Compound*). The codeposition of Cr vapor with these ligands yields the complexes shown:

$$Cr(g) + 6MeN(PF_2)_2 \longrightarrow [MeN(PF_2)_2]_6Cr \qquad (8)$$

$$Cr(g) + 6Me_2NPF_2 \longrightarrow (Me_2NPF_2)_6Cr \qquad (9)$$

$$Cr(g) + 4Me_2NPF_2 + MeN(PF_2)_2 \longrightarrow Cr(PF_2NMe_2)_4[(PF_2)_2NMe] \qquad (10)$$

The chelating ligand $Me_2PCH_2CH_2PMe_2$ (dmpe) is a useful σ-donor ligand and forms complexes with metal vapors of Cr, Mo, W, V, and Nb, to give the corresponding $(dmpe)_3M$ derivatives.[19] Similarly, the codeposition of Cr, Mo, and W vapors with trialkoxyphosphites, $P(OR)_3$, leads to the synthesis of a series of novel zerovalent complexes, such as $Cr[P(OR)_3]_6$. The substituent R = Et yields sterically hindered complexes that are thermally unstable. When R = Me, the zerovalent complex can be isolated.

2.5 Miscellaneous

Codeposition experiments have shown that vapors of the early transition metals Ti, V, and Cr deoxygenate[20] or desulfurate organic compounds. Epoxides yield alkenes with these metal atoms. The early transition metals are generally more efficient for these types of reactions. Aminoxides and DMSO undergo deoxygenation, while nitro compounds and nitroarenes yield coupled azo and azoxy products:

$$(\text{pyridine } N\text{-oxide})_x + Cr(g) \longrightarrow (\text{pyridine})_x + CrO_x \qquad (11)$$

Mo is the element of choice for clean and direct sulfur abstractions.[21] A comparison with appropriate C atom reactions, where the ratio cyclopropane/propene was 10:1, indicates an *Insertion* mechanism, in which Mo atoms attack the C–H bond to form an allyl intermediate (*see* ***Mechanisms of Reaction of Organometallic Complexes***).[22]

Mo and W atoms play an important role in oxidative addition to C–H bonds. W activates linear and cyclic saturated hydrocarbons in the presence of PMe_3,[23] while Mo reacts with bidentate phosphine to give a Mo (hydride)phosphine complex:[24]

$$W(g) + C_5H_6 + PMe_3 \longrightarrow C_5H_5WH_5PMe_3 \qquad (12)$$

$$Mo(g) + i\text{-}Pr_2PCH_2CH_2P\text{-}i\text{-}Pr_2 \longrightarrow MoH_4(i\text{-}Pr_2PCH_2CH_2P\text{-}i\text{-}Pr_2) \qquad (13)$$

Re inserts in pure hydrocarbons and in C–H bonds near an aromatic or triene group. The intermediate metal hydride species react further in order to fill their coordination shell:[25,26]

$$Re(g) + C_6H_{12} + 2C_6H_6 \longrightarrow (\eta^6\text{-}C_6H_6)_2Re_2H_2C_6H_{10} \qquad (14)$$

$$Re(g) + C_6H_6 + 2C_6H_5Me \longrightarrow (\eta^6\text{-}C_6H_5Me)_2Re_2H_3C_6H_5 \qquad (15)$$

Little is known about the oxidative addition of organohalides to early transition metal atoms. Nevertheless, macroscale amounts of solvated transition metal halides in lower valency states have been obtained. Re yields interesting clusters in reactions with 1,2-dibromoethane and oxalyl chloride:[27]

$$Re(g) + BrCH_2CH_2Br \longrightarrow Re_3Br_9(THF)_3 \qquad (16)$$

$$Re(g) + ClOCCOCl \longrightarrow [Re(CO)_4Cl]_2 \qquad (17)$$

Pure alkyl transition metal complexes are rare, owing to the *β-Elimination* decay mechanism. An effective strategy to prepare such compounds must therefore aim at blocking possible decomposition pathways. Neopentyl is void of hydrogen in the β-position, and neopentyl

bromide with Cr yields the known thermally stable tetrakis(neopentyl)chromium complex:[28]

$$2Cr(g) + 4Me_3CCH_2Br \longrightarrow (Me_3CCH_2)_4Cr + CrBr_4 \qquad (18)$$

3 LATE TRANSITION ELEMENTS (Fe–Zn GROUPS)

3.1 Organic and Inorganic Halides

The high-boiling points of the late transition metals, especially the second- and third-row elements, require resistive heating or electron beam vaporization methods.

Organic halides, codeposited with a late transition metal, form the oxidative addition product RMX. Some intermediate products decompose during the macroscale codeposition or, more often, on matrix warm up. The unique ligand bromopentafluorobenzene yields thermally more stable RMX species upon codeposition with Ni, Pd, and Pt. In fact, for Pd the formally coordinatively unsaturated species C_6F_5PdBr, CF_3PdI, C_2F_5PdI, and $CF_3CF_2CF_2PdI$ are isolable as reactive, sensitive, red polymeric solids, which are trimers or tetramers in solution.[29] The first step in the reaction mechanism is believed to be formation of a weakly bonded aryl/alkyl halide–Pd complex that gives RPdX. Trapping leads to $RPdXL_2$, while warm up without stabilizing ligands often leads to organic coupling products, PdX_2, and Pd. Suitable trapping ligands are PEt_3, Me_2S, Me_2NH, C_5H_5N, Me_2CO, and others. The corresponding Ni analog, C_6F_5NiBr, is an intriguing system. It is, unlike the Pd complex, not isolable. It decomposes at about −80 °C to form $C_6F_5C_6F_5$, $NiBr_2$, and Ni. It resembles the Pd homolog (dec. 100 °C), but is far less stable. Both intermediates can be trapped at −80 °C or lower with PEt_3. However, in the presence of toluene or other arene systems, C_6F_5NiBr disproportionates and binds an arene molecule, thus forming $(\eta^6\text{-}C_6H_5Me)Ni(C_6F_5)_2$.[30] Similar results are obtained in the analogous Co–C_6F_5Br system. These are unique π-systems in that they are the first examples of such complexes for Co^{II} and Ni^{II}. The arene ligand is extremely labile and can be displaced by stronger ligands, such as cot, norbornadiene, butadiene, PEt_3, or even THF. The weakly bonded arene ring is responsible for the catalytic activity of the Ni complex and catalyzes the polymerization of norbornadiene, the trimerization of butadiene, and the *Hydrogenation* of toluene. The formation and the fascinating chemistry of C_6F_5NiBr are shown in Scheme 4.

In related studies, Fe and Ni atoms were found to oxidatively insert Si–H bonds.[31,32] In the presence of arenes, η^{6-} complexes are formed that are formally Fe(IV) and Ni(II) complexes:

$$Fe + HSiCl_3 + toluene \longrightarrow (\eta^6\text{-}C_6H_5CH_3)\text{–}Fe(H)_2(SiCl_3)_2 \qquad (19)$$

$$Ni + HSiF_3 + toluene \longrightarrow (\eta^6\text{-}C_6H_5CH_3)\text{–}Ni(SiF_3)_2 + H_2 \qquad (20)$$

Several halogenated silanes behaved similarly, including H_2SiCl_2, $HSiF_3$, $HSiCl_3$, and $HSiCl_2CH_3$. In the case of $(toluene)Ni(SiCl_3)_2$, a crystal structure indicated a $p_{\bar{1}}$ space group with two molecules per unit cell. The nickel-silane distances are relatively short, 2.174(4) and 2.182(4) Å, owing to strong Π-backbonding from the Ni to the $SiCl_3$ groups. The toluene possesses a small ‘boat type’ distortion amounting to a rotation of the two end carbons of 5° away from the nickel.

The late transition metals of Groups 11 and 12 can be conveniently vaporized by resistive heating in $W\text{–}Al_2O_3$ crucibles, although many other vaporization techniques have been employed. The d orbitals are filled for these metals, and they have a strong tendency to undergo abstraction and oxidative additions owing to the ease of ionization and loss of electrons from 4s, 5s, or 6s levels. The earliest report of a synthetic application of the macroscale cocondensation was made by Timms in 1968. Copper atoms abstracted halogen very efficiently from BCl_3, forming B_2Cl_4 in high yield:

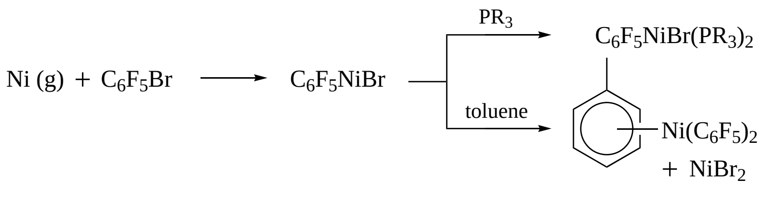
$$2BCl_3 + 2Cu(g) \longrightarrow 2CuCl + B_2Cl_4 \qquad (21)$$

With PCl_3, Cu atoms yielded smaller amounts of product. Copper also proved useful in dehalogenation reactions with alkyl halides:

$$MeCH_2C^*HClMe + Cu\ (g)\ or\ Ag\ (g) \longrightarrow MeCH_2CH(Me)CH(Me)CH_2Me \quad (S,S)(70\%\ optical\ purity) \qquad (22)$$

$$MeCH_2C^*HClMe + Na(g) \longrightarrow MeCH_2CH(Me)CH(Me)CH_2Me \quad \text{Same product, but optically inactive} \qquad (23)$$

Unlike Na, Cu atoms do not generate radical intermediates. Cu or Ag/RX always seem to be associated with R$^\bullet$, which is possibly complexed as RM at low temperatures.



Scheme 4

The first perfluoro R_fAg and Ar_fAg compounds have been prepared:

$$R_fI + Ag(g) \longrightarrow R_f\text{–}I\cdots Ag \longrightarrow R_f\bullet + IAg \longrightarrow R_fI + R_fAg \quad (24)$$

New, sensitive R_fAg complexes, such as $CF_3CF_2CF_2Ag$ and CF_3Ag, are only isolable if complexed to a donor solvent (MeCN). Gold atoms also abstract halide from RX. The resulting complex consists of polymeric $(C_6F_5Au)_n$ units. No abstraction reactions occurred with ground state Zn, Cd, or Hg. However, Zn, codeposited with R_fI ($R_f = CF_3$, CF_3CF_2, $CF_3CF_2CF_2$, and $(CF_3)_2CF$) yielded R_fZnI at low temperatures in a nonsolvated state, which decomposed to ZnIF and [:CF_2]. The very reactive carbene [:CF_2] can be trapped by an alkene, to give a cyclopropene:

$$CF_3ZnI \longrightarrow \text{‘[ZnFI]’} + [:CF_2] \xrightarrow{\text{2-butene}}$$  (25)

3.2 Phosphines, Phosphites, and Combinations with Other σ-Donor/π-Ligands

The macroscale codeposition of PF_3 has yielded a series of M–PF_3 complexes. Some of these M–PF_3 complexes can only be prepared by the metal vapor–ligand cocondensation technique. Very electron-rich M–phosphine and M–phosphite derivatives have been prepared by M–PMe_3 and M–$P(OMe)_3$ depositions, as shown in Table 8. A series of new homoleptic compounds have been prepared. Cocondensation of Fe and Ni with some arene systems gives stable $(Ar)_2$Fe/Ni species, if maintained at low temperatures. Addition of σ-donor ligands leads to a variety of new ML_n or mixed $ArML_n$ complexes.

Nitric oxide, a three-electron ligand, is too volatile to be cocondensed at −196 °C for macroscale preparations. The BF_3 adduct of NO, which is less volatile, has been used. Deposition of BF_3–NO and appropriate metal/ligand systems yields the corresponding complexes. The codeposition of a wide series of isocyanides gives macroscale amounts of NiL_4 and FeL_5.

3.3 Dienes, Trienes, and Tetraenes

Cyclopentadiene reacts with metal atoms in a combination of oxidative addition and simple orbital mixing processes. The very reactive M–H species form tetrahapto and trihapto complexes under loss of hydrogen. Important representative complexes are listed in Table 9.

The thermally sensitive $(cod)_2Ni$ has shown unusual reactivity and resembles ‘naked nickel’ in its chemistry. The chemistry of Ni atoms and $(cod)_2Ni$ is often very similar. The following examples demonstrate the high reactivity of $(cod)_2Ni$:

$$(cod)_2Ni + 3C_2H_4 \longrightarrow (C_2H_4)_3Ni + 2cod \quad (26)$$

$$(cod)_2Ni + 4PR_3 \longrightarrow (PR_3)_4Ni + 2cod \quad (27)$$

The corresponding paramagnetic complex $(cod)_2Fe$ decomposes at temperatures above −30 °C. Nevertheless, this weakly bonded Fe complex is an excellent precursor for ligand-exchange reactions. Treatment at low temperatures with a variety of π- and σ-binding ligands leads to partial or complete displacement of the cod units:

$$[(cod)_2Fe] + 3PF_3 \longrightarrow (cod)Fe(PF_3)_3 \quad (28)$$

Table 8 M–L_n and $ArML_n$ complexes from the late transition metals prepared by macroscale metal atom methods

Metal	π-Ligand	σ-Donor ligand	Product
Fe	–	PF_3	$Fe(PF_3)_5 + (PF_3)_3Fe(PF_2)_2Fe(PF_3)_3$
Fe	–	PMe_3	$Fe(PMe_3)_5 + [Me_3Fe(H)CH_2(PMe)_2]$
Fe	–	NO, PF_3	$(NO)_2Fe(PF_3)_2$
Fe	C_6H_6	PF_3	$(\eta^6\text{-}C_6H_6)Fe(PF_3)_2$
Co	–	PF_3	$Co_2(PF_3)_8$, $HCo(PF_3)_4$
Co	C_6H_6	NO	$(\eta^6\text{-}C_6H_6)Co(NO)$
Co	–	$MeN(PF_2)_2$,Me_2NPF_2	$Co_2(PF_2NMe_2)[(PF_2)_2NMe]_2$
Co	C_5H_6	PF_3	$C_5H_5Co(PF_3)_2$
Ni	–	PF_3	$Ni(PF_3)_4$
Ni	–	PPh_3	$Ni(PPh_3)_4$
Ni	–	$MeN(PF_2)_2$	$Ni[(PF_2)_2NMe]_n$
Ni	–	C_6F_5Cl, PEt_3	$C_6F_5NiCl\ (PEt_3)_2$
Ni	–	CF_3COCl, PEt_3	$CF_3NiCl(PEt_3)_2$
Pd	–	PF_3	$Pd(PF_3)_4$
Pd	–	CF_3I, PEt_3	$CF_3PdI(PEt_3)_2$
Pd	–	C_6F_5Cl, PEt_3	$C_6F_5PdCl(PEt_3)_2$
Pd	$CF_3CF{=}CFCF_3$	PEt_3	$(CF_3CF{=}CFCF_3)\ Pd(PEt_3)_2$

Table 9 Late transition metal complexes from diene, triene, and tetraene ligands, prepared by the metal atom/ligand cocondensation method

Metal	π-Ligand	σ-Ligand	Complex
Fe	Cyclopentadiene	–	Ferrocene
Co	Cyclopentadiene	–	$(\eta^5\text{-}C_5H_5)Co(\eta^4\text{-}C_5H_6)$
Ni	Cyclopentadiene	–	$(\eta^5\text{-}C_5H_5)Ni(\eta^3\text{-}C_5H_7)$
Ni	1,5-Cyclooctadiene	–	$(\eta^4\text{-}C_8H_8)_2Ni$
Fe	Cycloheptatriene	–	$(\eta^7\text{-}C_7H_7)Fe(\eta^3\text{-}C_7H_{11})$
Co	Cycloheptatriene	PF_3	$(\eta^3\text{-}C_7H_{11})Co(PF_3)_3 + HCo(PF_3)_4$
Ru	Cyclohexadiene	CO	$(\eta^4\text{-}C_6H_8)_2Ru(CO)$

$$[(cod)_2Fe] + 2cot \longrightarrow (cot)_2Fe \quad (29)$$

$$[(cod)_2Fe] + 2diphos + N_2, CO \longrightarrow (diphos)_2Fe(N_2, CO) \quad (30)$$

$$[(cod)_2Fe] + 5CO \longrightarrow Fe(CO)_5 \quad (31)$$

4 MISCELLANEOUS

Very little successful synthetic work with alkynes and metal atoms has been published. Generally, alkynes are efficiently trimerized by group 8 metal atoms, but a few stable metal complexes have been found:

$$M(g) + 6RC{\equiv}CR \longrightarrow (\eta^6\text{-}C_6R_6)_2M \quad (32)$$

Only a few alkenes form stable homoleptic metal complexes. Norborene allows the formation of relatively stable tris(bicyclo[2.2.1]heptene)palladium. The slight strain energy in the C=C bond results in a stronger π–M interaction.[33] In the past 10 years, examples of synthesis of transition metal compounds have become much less frequent. One reason for this is that other 'wet' methods have been developed to gain access to the desired compounds. Another reason is that the metal vapor method has been adapted for synthesis of metal clusters and nanoscale particles. These are topics of material science rather than organometallic chemistry. However, in some cases, the nanoparticles produced are so monodisperse that they are indeed discrete molecules, although very large ones. For example, gold vapor (atoms) codeposited with acetone (or butanene or 2-pentanone) at 77K leads to colloidal gold with a variety of particle sizes. Treatment with a long chained thiol in refluxing toluene causes a remarkable particle size narrowing so that each gold nanoparticle is 4.6 nm ± 0.1 nm (about 5000 atoms/particle

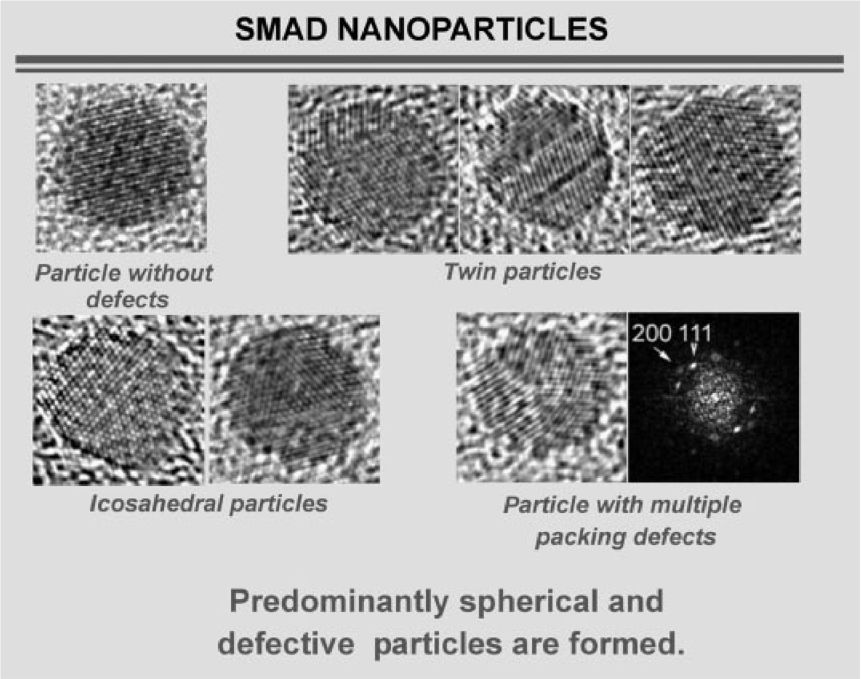


Figure 5 High-resolution electron microscope images of SMAD gold nanoparticles. Note the rows of gold atoms and the exact monodispersity of the samples. Some of the particles are single crystals, while others are multi-domain

and 300 $C_{12}H_{25}SH$ ligands/particle). This particle narrowing is caused by the transfer of gold atoms/clusters from particle to particle until a thermodynamic equilibrium is achieved between the formation of more gold-sulfur bonds and the size of the particles.[34,35,36]

$$\text{Au vapor} + \text{acetone} \xrightarrow{77\,\text{K}} \text{(Au) (acetone) solvate} \quad (33)$$

$$\text{Au (acetone)} + C_{12}H_{25}SH \longrightarrow (\text{Au})_x(HSC_{12}H_{25})_y \quad (34)$$

$$(\text{Au})_x(HSC_{12}H_{25})_y \xrightarrow[\text{reflux (digestive ripening)}]{\text{toluene}} (\text{Au})_{5000}(HSC_{12}H_{25})_{300} \quad (35)$$

Figure 5 shows high-resolution electron microscope images of several gold nanoparticles formed by this metal vapor synthesis method, often called Solvated Metal Atom Dispersion (SMAD).

Glossary

Atomic layer deposition (also termed atomic layer epitaxy): a process in which alternate pulses of two volatile precursors are passed over the substrate to promote layer-by-layer film growth
Chemical beam epitaxy: a process in which one or more beams of volatile metal-organic precursors is directed to the substrate surface to effect film growth
Chemical vapor deposition (CVD; also termed vapor-phase epitaxy): the deposition of a thin film of an element or compound using some form of excitation for the decomposition of a volatile precursor
Laser-assisted chemical vapor deposition: a CVD in which the excitation is delivered from photons delivered from a laser
Metal-organic chemical vapor deposition (MOCVD): the same as CVD, except that the precursor is a volatile organometallic or coordination compound with carbon-containing ligands
Metal-organic vapor-phase epitaxy: the same as MOCVD, but implying specific induced crystalline orientation of the deposited film
Molecular beam epitaxy: a process in which one or more beams of elemental precursors is directed to the substrate surface to effect film growth
Organometallic chemical vapor deposition: the same as MOCVD
Plasma-enhanced chemical vapor deposition (also known as plasma-assisted chemical vapor deposition): a CVD in which the excitation of the material to be deposited is accomplished by thermal means at reduced pressure in the presence of an electric field. This method may also be used for the decomposition of a volatile precursor introduced in a gas stream at low pressure

1 INTRODUCTION

1.1 Scope of This Article

Thin films of metal-containing materials are widely employed in many technological applications ranging from coatings on architectural glass to microelectronics devices.[1–6] While many methods can be used to create thin films, considerable emphasis in recent years has been placed on film growth techniques that use chemical compounds as precursors. These collected techniques are known generally as CVD (chemical vapor deposition), and many different variations of the CVD technique are known.[1–6] However, all CVD methodologies are similar in that they involve the delivery of volatile chemical compounds in the gas phase to the growing film. This article focuses on the chemical compounds that

have been used for the growth of metal-containing materials by CVD methods. Specifically, this review describes metal-organic precursors, which contain hydrocarbon groups on the ligands used to satisfy the metal valency and to saturate the coordination sphere. The precursors that are discussed in this article are collected in tables in the subsections. Specific features of the precursors are discussed in the subsections. Wherever possible, volatility data on the precursors are presented, although information on vapor pressures is often limited or not reported. Each entry is accompanied by a leading reference to allow rapid access to the appropriate literature. Recent reviews of metal-organic precursors are cited where appropriate. The major emphasis herein is on precursors that have been reported since 1994, when the last review on metal-organic precursors appeared in this encyclopedia.[7]

1.2 Advantages of Metal-organic Precursors

Metal-organic precursors have several advantages for film growth, compared to the elemental sources that are used in physical vapor deposition processes. Most importantly, metal-organic precursors tend to be much more volatile than most metals in their elemental form, which allows high film growth rates to be achieved and allows the use of simple precursor delivery systems. Since film growth occurs by a series of chemical reactions, it is possible to design the precursor chemistry to favor the desired inorganic phase, minimize undesirable element incorporation into the final material, control and lower the deposition temperature, and avoid corrosive byproducts that might damage the reactor or the substrate on which the film is grown. Metal-organic precursors can also be obtained in very high chemical purity, which is important for many applications.

1.3 Types of Ligands

Many different types of ligands have been employed to create volatile metal-organic precursors for film growth. In general, the ligands are anionic with carbon, oxygen, or nitrogen donor atoms. In some cases neutral donor ligands are present. The ligand backbone usually consists of a hydrocarbon fragment. Several distinct strategies are used to remove the undesired organic groups during the film growth process. Many CVD processes entail the reaction between a metal-organic precursor with basic ligands and a coreactant that contains acidic element-hydrogen bonds. Mixing of these reactants in the gas phase results in protonation reactions that eliminate the basic ligand in its protonated form and results in the formation of a new metal-element bond (Figure 1).[8] The coreactant with acidic element-hydrogen bonds is generally chosen so that the element corresponds to one of the atoms required for the final thin-film material. Examples of this type of reactant include water and ammonia for the deposition of oxides and nitrides, respectively. A

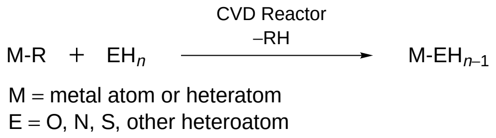

Figure 1 Protonolysis reaction in a CVD precursor

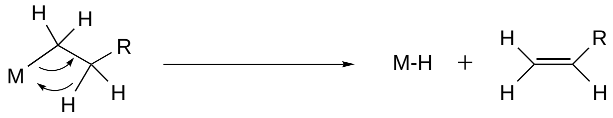

Figure 2 β-Hydrogen elimination

second type of strategy that is used to eliminate excess hydrocarbon groups from the metal-organic precursor is β-hydrogen elimination (Figure 2).[9] Hydrocarbon groups such as ethyl, propyl, isopropyl, *n*-butyl, and isobutyl, when bonded to a metal atom or a heteroatom, can eliminate an alkene through a low-energy decomposition pathway. This β-hydrogen elimination (*see β-Hydride Elimination*) often provides an efficient pathway through which carbon groups are removed from precursors. If a precursor is properly designed, the carbon incorporation in the thin-film material can be minimized. Precursors with hydrocarbon fragments that lack β-hydrogen atoms, such as a methyl or *tert*-amyl groups, are likely to lead to higher carbon incorporation in the thin film.

There are two distinct approaches to metal-organic precursor design. Most commonly, precursors are designed to react with separate gas stream of a reactive element hydride such as ammonia or water, to remove the hydrocarbon ligands and to provide the desired oxide, nitride, or other element needed for the desired thin-film material. The individual precursors are delivered to the reactor chamber as separate gas streams, and are then mixed over the substrate to achieve film growth. Advantages of this approach include being able to maximize the volatility of precursors, greatest flexibility of the deposition variables to achieve the desired outcome, as well as the ability to build desired reactivity paths into the metal-organic precursors. Disadvantages can include poor control over stoichiometry in multicomponent materials and inability to grow desired phases of materials that are not favored thermodynamically. Another approach involves the design of a volatile precursor that contains all of the elements necessary for the desired film material, and which has a low-energy decomposition pathway that affords the desired material. Such compounds are termed single-source precursors.[9] Advantages of single-source precursors can include excellent control over stoichiometry in the thin-film material, reduced incorporation of undesired elements, as well as the ability to deposit kinetic phases that are inaccessible by conventional multi-precursor film growth procedures. Disadvantages of the single-source precursor approach include the low volatility of high molecular

weight precursors, attendant low film growth rates, and the expense associated with the synthesis of structurally complex precursors.

1.4 Methods of Deposition

Many different embodiments of the CVD technique are available for the growth of thin films, and the readers is referred to excellent recent monographs for more detail.[1–6] The last review on metal-organic precursors that appeared in this encyclopedia contained a detailed overview of thermal CVD processes, schematics of several reactors, as well as a listing of common variants of thermal CVD processes.[7] In addition to these well-known techniques, several new CVD techniques have gained importance in recent years.

ALD (atomic layer deposition) is a method for the controlled growth of thin films,[10,11] and recent interest in this technique has been driven by the semiconductor industry through its need to decrease feature sizes in integrated circuit manufacturing while increasing aspect ratio and complexity. ALD film growth proceeds by exposing the substrate surface alternatively to the different precursors. It differs from CVD film growth by keeping the precursors strictly separate from each other in the gas phase. There are four distinct steps in an ALD growth cycle: (1) exposure of the substrate surface to a gas stream of the first precursor and formation of a monolayer of this precursor on the substrate, (2) an inert gas purge to remove any excess of the first precursor, (3) introduction of a second precursor to the substrate surface and surface reaction to produce the desired thin-film material, and (4) another inert gas purge to remove the gaseous byproducts. In principle, each growth cycle should produce one monolayer of the desired material. However, the steric bulk of the precursors often reduces the surface density of the adsorbed species, and each growth cycle usually leads to a fraction of a monolayer. Metal-organic precursor design for ALD film growth processes differs from CVD precursor design. In ALD, it is essential that the metal-organic precursor be thermally stable on the surface of the substrate at the deposition temperature to avoid uncontrolled CVD growth. In addition, the metal-organic precursor should be extremely reactive toward the second growth reagent, so that the desired thin-film material forms efficiently and potential film contaminants are removed from the growth ambient. There is an ‘‘ALD window’’, where ALD film growth is surface controlled (Figure 3). Outside of this window, the film growth is limited by insufficient precursor reactivity, formation of greater than one monolayer of precursor through condensation, precursor decomposition, or precursor desorption. Many recently reported metal-organic precursors do not have a distinct ALD window, but still can be useful in film growth by ALD.

Another emerging film growth technique that employs metal-organic film growth precursors is termed CBE (chemical beam epitaxy).[5] CBE is a variant of the widely used MBE (molecular beam epitaxy) technique, except that metal-organic

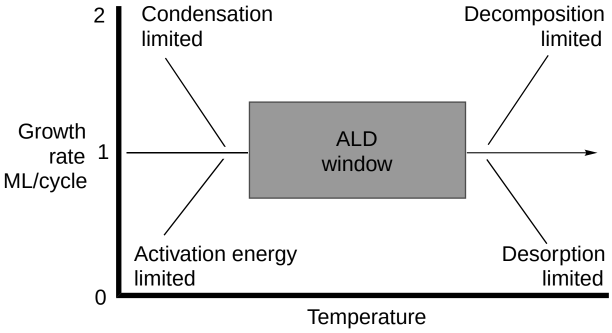

Figure 3 Concept of ALD window, or temperature region for surface-controlled growth

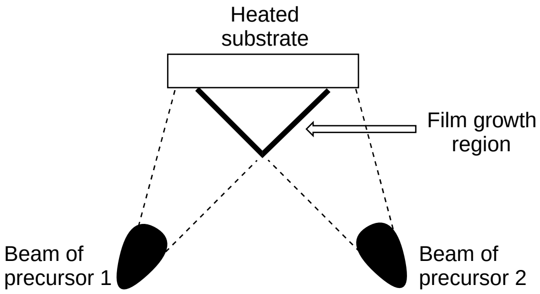

Figure 4 Schematic depiction of CBE film growth

precursors are used instead of the element sources that are used in MBE. Figure 4 shows a schematic of the basic reactor configuration used in CBE. The film growth process involves decomposition of the precursor beams on the surface of the heated substrate. Since the process occurs at low pressures and the chemical beams are pointed directly at the substrate surface, there is little gas-phase reactivity and the film growth is surface controlled. CBE allows excellent control of film thickness and monolayer abruptness, like the MBE technique. The use of metal-organic precursors with high vapor pressures allows better scale up and reproducibility of precursor delivery, compared to MBE.

2 PRECURSORS FOR MAIN GROUP METALS AND LANTHANIDES

Some main group metal MOCVD (Metal-organic chemical vapor deposition) precursors are listed in Table 1.

2.1 Lithium and Sodium

Film growth precursors for lithium are limited owing to the tendency of lithium compounds to form high nuclearity species

Table 1 MOCVD precursors of main group elements

Compound (mp or bp)	Vapor pressure
Li(tmhd)[12]	bp 295 °C, 760 torr
$[LiOtBu]_6$[13]	0.0016 torr at 70 °C
$Na(OCR(CF_3)_2)$[14]	subl 75–90 °C at 0.01 torr
$Be(C_2H_5)_2$[15]	3 torr at 63 °C
$Be(C_5H_5)_2$[16]	not reported
$Be(C_5H_4CH_3)_2$[17]	1 torr at 60 °C
$Mg(C_5H_5)_2$[18,19]	subl 60 °C, 0.01 torr
$Mg(C_5H_4CH_3)_2$[20,21]	subl 60 °C, 0.01 torr
$Mg(C_5H_4CH_2CH_3)_2$[22]	0.006 torr at 10 °C
$MgAl_2(CH_3)_8$[23]	not reported
$[Mg(CH_3)(OtBu)]_4$[24]	subl 140 °C, 1×10^{-6} torr
$Mg(dmto)_2$[25]	subl 126 °C, 5×10^{-5} torr
$Mg(tmhd)_2(tmeda)$[26]	subl 120 °C, 5 torr
$Mg(tmhd)_2$[27]	subl ∼200 °C, 5 torr
$Mg(acac)_2$[28]	subl 185–240 °C, 10^{-5} torr
$Sr(1,2,4\text{-}C_5iPr_3H_2)_2$[29,30]	subl 100 °C, 10^{-3} torr
$Ba(C_5(CH_3)_5)_2$[30]	subl 160 °C, 10^{-3} torr
$Sr(tmhd)_2$[31]	subl 200–225 °C, 10^{-3} torr
$Ba(tmhd)_2$[32]	prepared in situ at 350 °C from $Ba(OH)_2$ and tmhdH
$Ba(hfac)_2(PEB)$[33]	subl 110 °C, 4 torr
$Ba(dpmCAP\text{-}4)_2$[34]	subl ∼140 °C, 6 torr
$Sr(methd)_2$ and $Ba(methd)_2$[35]	liquid injection as solutions in *n*-butyl acetate
$Sr[Ta(OEt)_5(OCH_2CH_2OCH_3)]_2$[36]	liquid injection as a solution in tetrahydrofuran
$AlMe_3$[37]	bp 20 °C, 11 torr; 126 °C, 760 torr
$AlEt_3$[38]	bp 36 °C, 0.1 torr
$AlHMe_2$[39]	bp 25 °C, 2 torr
$AlH_3(NMe_2Et)$[40]	bp 24 °C, 1.5 torr
$GaMe_3$[41]	bp 56 °C, 760 torr
$InMe_3$[42]	34 torr, 50 °C
$AlMe_3(OEt_2)$[43]	1 torr, 20 °C
$Al(acac)_3$[44]	subl 120 °C, low pressure
$Al(OEt)_3$[45]	subl 137 °C, low pressure
$Mg[(\mu\text{-}OiPr)_2AlMe_2]_2$[46]	subl 60 °C, 10^{-6} torr
$Ga(N_3)_2(CH_2CH_2CH_2NMe_2)$[47]	2×10^{-3} torr, 25 °C
$In(N_3)(CH_2CH_2CH_2NMe_2)_2$[48]	subl 70 °C, 0.5×10^{-4} torr
$GaH_2(N_3)$[49]	bp 40 °C, 0.2 torr
$Ga_2(NMe_2)_6$[50]	subl 70–80 °C, 10^{-2} torr
$In(C_5Me_5)$[51]	1.8 torr, 40 °C
$[InMe_2(OC(CF_3)_2CH_2NHMe)]_2$[52]	subl 120 °C, 0.42 torr
$InMe_2(acac)$[53]	subl 150 °C, low pressure
$[iPr_2InOH\cdot iPr_2InNH_2]$[54]	bp 86–88 °C, 10^{-2} torr
$[In(OCMe_2Et)_3]_2$[55]	subl 95 °C, 10^{-2} torr
$In(OCMe(CF_3)_2)_3(H_2NtBu)$[56]	subl 45–50 °C, 4 torr
$Ga(OCH(CF_3)_2)_3(HNMe_2)$[57]	subl 100 °C, 0.5 torr
$[Ga(OtBu)_3]_2$[58]	subl 60 °C, 2.5 torr
$In(SOCNEt_2)_3$[59]	subl 150 °C, 10^{-2} torr
$Ga(SOCNEt_2)_3$[60]	liquid delivery as tetrahydrofuran solution
$InMe_2(S_2CNEt_2)$[61]	subl 110 °C, 10^{-2} torr
$In(S_2CNMeBu)_3$[62]	subl 250 °C, 10^{-2} torr
$Ga(tBu)_2(S_2CNMe_2)$[63]	subl 60 °C, 760 torr
$Ga(SOCMe)_2Me(dmpy)$[64]	liquid delivery
$[dmpyH]^+ [In(SOCMe)_4]^-$[65]	liquid delivery as tetrahydrofuran solution
$[(Me_2EtC)In(\mu_3\text{-}Se)]_4$[66]	subl 160 °C, 10^{-3} torr
$[(tBu)Ga(\mu_3\text{-}Se)]_4$[67]	subl 149 °C, 0.2 torr
$[(tBu)Ga(\mu_3\text{-}Te)]_4$[67]	subl 172 °C, 0.2 torr
$SnMe_4$[68]	108 torr, 25 °C
$SnMe_2Cl_2$[68]	0.35 torr, 25 °C
$Sn(OtBu)_4$[69]	subl 50–55 °C, 10 torr

with low vapor pressures. Important lithium-containing thin-film materials that have been prepared by CVD methods include $LiNbO_3$, $LiTaO_3$, $LiNb_xTa_{1-x}O_3$, and lithium-doped diamond. Deposition methods to these materials have included CBE, MOCVD, thermal plasma spray CVD, and PECVD (plasma-enhanced chemical vapor deposition). Precursors that have been employed are primarily Li(tmhd)[12] and $[Li(O\textit{t}Bu)]_6$.[13,95] Li(tmhd) decomposes under vacuum, and was suggested as a less useful precursor than $[Li(O\textit{t}Bu)]_6$.[12] Precursors used for thermal plasma spray CVD film growth consisted of commercial 3 wt% solutions of $LiNb(OR)_6$ or $LiTa(OR)_6$ in 3-methylbutyl acetate (R was not identified, but is presumably ethyl).[96]

A series of sodium alkoxide complexes of the formula $Na(OCR(CF_3)_2)$ (R = H, CH_3, CF_3) was examined as precursors for the MOCVD growth of sodium fluoride films.[14] Sodium fluoride films were deposited between 255 and 400 °C, and the lowest deposition temperature was obtained where R = H.

2.2 Beryllium

Beryllium has few applications in thin-film materials, owing to toxicity issues and the generally high air sensitivity of its compounds. Beryllium is a desirable ablator material in fusion research, and beryllium ion is an excellent p-type dopant in compound semiconductors such as InP and (In,Ga)As. There are limited precursors available for the CVD growth of beryllium-containing materials. $BeEt_2$ has been used to make heavily beryllium-doped (In,Ga)As.[15] $Be(C_5H_5)_2$ was used as a precursor for the growth of beryllium metal thin films.[16] Problems with this precursor included extreme air sensitivity and carbon and oxygen incorporation. $Be(C_5H_4Me)_2$ has been suggested as the best CVD precursor for beryllium.[17] It was used for the growth of beryllium-doped InP films.

2.3 Magnesium

Magnesium has emerged in the past ten years as an important component of certain thin-film materials grown by CVD methods. In particular, magnesium-doped group 13 nitride films grown by MOVPE form the basis of blue and green light emitting diodes and laser diodes.[97] Precursors that have been used to dope GaN and other group 13–15 semiconductors with magnesium ion include $Mg(C_5H_5)_2$,[18,19] $Mg(C_5H_4Me)_2$,[20,21] $Mg(C_5H_4Et)_2$,[22] and $MgAl_2(CH_3)_8$.[23] $Mg(C_5H_5)_2$ is the most widely used metal-organic dopant precursor for the growth of magnesium-doped group 13–15 nitride semiconductors.

MgO has emerged recently as a useful substrate on which to grow perovskite superconductor and ferroelectric materials, because it has a good lattice match with these phases. MgO has also been used as a protective layer in plasma displays. A range of metal-organic precursors has been described, including $Mg(C_5H_5)_2$ in the presence of O_2,[98] $[Mg(CH_3)(O\textit{t}Bu)]_4$,[24] $Mg(dmto)_2$,[25] $Mg(tmhd)_2(tmeda)$,[26]

$[Mg(tmhd)_2]_2$,[27] and $Mg(acac)_2$.[28,99] Use of $Mg(C_5H_5)_2$ and O_2 allowed the growth of epitaxial MgO films by MOCVD. $[Mg(CH_3)(O\mathit{t}Bu)]_4$ has a tetrameric solid-state structure, but is sufficiently volatile to serve as an MOCVD precursor. The precursor $Mg(dmto)_2$ contains a pendant amine donor ligand that is attached to the β-ketiminato ligand core by an alkyl chain. These pendant amine donors lead to octahedral geometry at the magnesium center, which is sterically saturated and prevents formation of an oligomeric, low volatility species. MgO films were grown from this precursor at 450 °C, and there was no need to add additional O_2 to form the oxide. $Mg(tmhd)_2(tmeda)$ is a relatively volatile source compound that was suggested to be superior to $[Mg(tmhd)_2]_2$ owing to its monomeric structure and good thermal stability. By contrast, $[Mg(tmhd)_2]_2$ is dimeric and has a lower vapor pressure than other magnesium precursors owing to its higher molecular weight. $Mg(acac)_2$ is trimeric in the solid state[100] and thus has a very low vapor pressure. It has been used to grow MgO films using MOCVD[28] and PECVD[99] growth techniques.

2.4 Calcium, Strontium, and Barium

The growth of thin films containing calcium, strontium, and barium has been an active area of research in recent years owing to the importance of materials including $SrTiO_3$, $BaTiO_3$, $Ba_xSr_{1-x}TiO_3$, $SrBi_2Ta_2O_9$, $Ba_xPb_{1-x}TiO_3$, $YBa_2Cu_3O_{7-x}$, $Tl_2Ba_2CaCu_2O_{7-x}$, BaB_2O_4, $La_{0.66}Ba_{0.33}MnO_3$, BaS, and other phases. Owing to the high molecular weights, the high coordination numbers, and the low formation constants of complexes containing these elements, it is difficult to identify structures that combine sufficient volatility and thermal stability to serve as film growth precursors. Significant advances have been made in this area, and are overviewed in this section. Several recent reviews have described progress in this area.[101–105]

Metallocenes (*see Metallocene Complexes*) of calcium, strontium, and barium have been the subject of intense basic research scrutiny in recent years, and it is well known that substituted metallocenes are volatile and have vapor pressures that are high enough to be useful in film growth.[101] However, the first reports of film growth using substituted metallocenes have only appeared recently. $Sr(1,2,4\text{-}C_5\mathit{i}Pr_3H_2)_2$ was used as the strontium precursor in the ALD growth of $SrTiO_3$ with titanium tetraisopropoxide and water at temperatures between 250 and 325 °C.[29,30] There was evidence for thermal decomposition of $Sr(1,2,4\text{-}C_5\mathit{i}Pr_3H_2)_2$ during the depositions. $Ba(C_5(CH_3)_5)_2$ was used as a precursor for the ALD growth of $BaTiO_3$ films, along with titanium tetraisopropoxide and water at temperatures at or below 275 °C.[30] Higher deposition temperatures resulted in significant decomposition of $Ba(C_5(CH_3)_5)_2$, and reproducibility of composition and properties were problems even at a growth temperature of 275 °C. It has been reported that thermal decomposition and carbon incorporation are problems associated with the use of strontium and barium metallocene precursors in MOCVD film growth.[106]

Diketonate complexes of calcium, strontium, and barium have been extensively explored as precursors for the growth of oxide materials.[101–105] Two bidentate diketonate ligands are not sufficient to saturate the coordination spheres of the large metal ions, and oligomerization occurs in the absence of neutral donor ligands to provide compounds with very low vapor pressures. Such oligomers have low utility as precursors for film growth, since extensive decomposition can occur at the high temperatures required to achieve volatility. Thermal decomposition is a particularly severe problem with barium precursors. A recent review has summarized the properties and film deposition characteristics of bis(diketonato) precursors of calcium, strontium, and barium.[103] To address the volatility and decomposition problems, a trend in recent years has been to identify neutral donor ligands that can coordination to the bis(diketonato)metal(II) fragment, and thus provide monomeric species with higher vapor pressures. The general features of these adducts will be discussed herein, along with a summary of recent advances in precursor design.

The diketonate ligands that have been employed to create volatile complexes are substituted with alkyl or fluoroalkyl groups to afford steric bulk about the coordination sphere and to minimize intermolecular interactions that reduce volatility. Fluoroalkyl groups, in particular, lead to increased volatility, but can cause problems in film depositions through fluorine incorporation into the film material. The most widely used diketonato ligand is tmhd, which has *tert*-butyl groups attached to the diketonato ligand core. However, the reduced Lewis acidity of the metal center in an alkyl-substituted diketonato ligand means that neutral donor ligands bond less strongly to the metal ion. Thus, such precursors can have reduced thermal stability compared to a precursor containing fluoroalkyl-substituted diketonato ligand. Neutral ligands are generally polyethers or polyamines that can wrap around the metal center to provide complexes with higher formation constants than is possible with monodentate donor ligands.

$Sr(tmhd)_2$ has been used as a precursor for the ALD growth of $SrTiO_3$, along with titanium tetraisopropoxide and ozone at 250–470 °C.[31] The as-deposited films contained some carbon apparently present as $SrCO_3$, but thermal annealing reduced the carbon content and led to good quality $SrTiO_3$. To avoid problems with thermal decomposition, $Ba(tmhd)_2$ was prepared in situ by passage of tmhdH vapor over $Ba(OH)_2$ held at 350 °C.[32] The resultant $Ba(tmhd)_2$ was used to for the ALD growth of BaS at 300–350 °C using hydrogen sulfide as the sulfur source. The precursor $Ba(hfac)_2(PEB)$ contains an unsymmetrical polyether, has a low-melting point of 71 °C, and sublimes at rate useful for CVD film growth at 110–120 °C/4 torr.[33] This precursor was used for the epitaxial growth of $BaTiO_3$ films at substrate temperatures of 700–800 °C by MOCVD using titanium tetraisopropoxide and water as coreactants. The use of water

was necessary to avoid the formation of BaF_2 as impurity in the film material. Ba(dpmCAP-4)$_2$ is a monomeric β-ketiminato complex that contains a polyether ligand tethered to the nitrogen atom by a carbon chain.[34] The polyether fragments provide intramolecular neutral Lewis bases that saturate the coordination sphere of the barium ion. The β-ketiminato ligand backbone is substituted with two *tert*-butyl groups, and thus Ba(dpmCAP-4)$_2$ represents a fluorine-free volatile film growth precursor. This class of precursors was used to grow epitaxial films of $BaTiO_3$. The complexes Sr(methd)$_2$ and Ba(methd)$_2$ contain a tmhd ligand that has been modified at one methyl group to include a pendant ether donor ligand that caps the coordination sphere of the metal ions, thus affording volatile complexes.[35] These precursors were used for the MOCVD growth of $Ba_xSr_{1-x}TiO_3$ at substrate temperatures of 400–500 °C.

An example of a single-source precursor for the growth of $SrBi_2Ta_2O_9$ films is Sr[Ta(OEt)$_5$(OCH$_2$CH$_2$OCH$_3$)]$_2$.[36] The fixed Sr/Ta ratio of 1:2 in the precursor is needed for the thin-film material, and presumably a single-source precursor would control this ratio. The growth of $SrBi_2Ta_2O_9$ films was examined using a tetrahydrofuran solution of Sr[Ta(OEt)$_5$(OCH$_2$CH$_2$OCH$_3$)]$_2$ and $BiPh_3$ with substrate temperatures between 540–580 °C. Use of the single-source precursor afforded excellent control over the Sr/Ta ratio in the thin-film material and provided good quality $SrBi_2Ta_2O_9$ films.

2.5 Aluminum, Gallium, and Indium

There is considerable interest in the CVD growth of thin films containing the group 13 elements aluminum, gallium, and indium. Phases of major interest include oxides, nitrides, sulfides, and the metals. Most film growth procedures for group 13 materials employ group 13 alkyls and hydrides, such as trimethylaluminum,[37] triethylaluminum,[38] dimethylaluminum hydride,[39] alane dimethylethylamine,[40] trimethylgallium,[41] trimethylindium,[42] and related hydrocarbon analogs. These compounds are liquids at ambient temperature or are solids with high vapor pressures and are listed in Table 1. Precursors for the growth of aluminum metal films have been reviewed in a recent monograph.[107] Other precursors that have been employed for CVD film growth are summarized in the following sections.

Many new metal-organic precursors for aluminum-containing materials have been reported recently. The precursors AlMeCl$_2$(OEt$_2$), AlMe$_3$(OEt$_2$), AlEtCl$_2$(OEt$_2$), and Al(NMe$_2$)Et$_2$ were used to grow (Ti,Al)(O,N) coatings using titanium tetrachloride and hydrogen in a PECVD process.[43] The aluminum precursors have vapor pressures between 0.1–1 torr at 20 °C. Al(acac)$_3$ and Al(tmhd)$_3$ have been used for the growth of Al_2O_3 films by MOCVD.[44,108] AlMe$_2$(O*i*Pr) has been used for the growth of Cu-Al-O films by MOCVD.[109] Al(OEt)$_3$ and Al(O*i*Pr)$_3$ were used to grow Al_2O_3 films by ALD.[45] Water, dioxygen, and various alcohols were used as added oxygen sources. The single-source precursor Mg[(μ-O*i*Pr)$_2$AlMe$_2$]$_2$ was used for the MOCVD growth of $MgAl_2O_4$ films.[46]

The growth of gallium and indium nitride, oxide, sulfide, and selenide phases from metal-organic precursors has been intensively studied. An exhaustive listing of precursors is beyond the scope of the present article, but readers are directed toward several recent reviews that summarize progress.[97,110–113]

Growth of epitaxial GaN or InN layers by CVD techniques mostly relies on $GaMe_3$, $InMe_3$, or related alkyl precursors in combination with ammonia.[97,110,111] Several more complex metal-organic precursors have been reported. The azido-based single-source precursor Ga(N$_3$)$_2$(CH$_2$CH$_2$CH$_2$NMe$_2$) was used for the epitaxial growth of GaN layers on sapphire substrates at 850 °C using MOCVD.[47] The related single-source precursor In(N$_3$)(CH$_2$CH$_2$CH$_2$NMe$_2$)$_2$ was used for the MOCVD growth of InN films at 300–500 °C.[48] The precursor GaH$_2$(N$_3$) has a high vapor pressure, and allows MOCVD growth of GaN films on silicon substrates at temperatures as low as 200 °C.[49] GaN films were grown by MOCVD using Ga$_2$(NMe$_2$)$_6$ and ammonia at substrate temperatures of >200 °C.[50] AlN films were grown from the related aluminum dimethylamido precursor. InP films were grown by MOCVD using In(C$_5$Me$_5$) and P_4 at temperatures between 150 and 250 °C.[51] It was noted that these alternate precursors avoided the use of pyrophoric $InMe_3$ and toxic PH_3, which are commonly used precursors for the growth of InP films.

Several metal-organic precursors for the CVD growth of Ga_2O_3 and In_2O_3 films have appeared recently. These oxides are of interest for high-temperature gas sensors and as transparent conducting coatings. The precursor [InMe$_2$(OC(CF$_3$)$_2$CH$_2$NHMe)]$_2$ was used for the MOCVD growth of In_2O_3 films at 400–500 °C.[52] Molecular oxygen was added as a second precursor to induce oxide film growth and to suppress carbon contamination in the film. The precursors InMe$_2$(acac),[53] [*i*Pr$_2$InOH·*i*Pr$_2$InNH$_2$],[54] and [In(OCMe$_2$Et)$_3$]$_2$[55] have been evaluated as MOCVD precursor to In_2O_3 films. MOCVD film growth using In(OCMe(CF$_3$)$_2$)$_3$(H$_2$N*t*Bu) and molecular oxygen at substrate temperatures of 400–550 °C afforded fluorine-doped In_2O_3 films with 2–3 atom % fluorine.[56] The precursors Ga(OCH(CF$_3$)$_2$)$_3$(HNMe$_2$)[57] and [Ga(O*t*Bu)$_3$]$_2$[58] were used for the MOCVD growth of Ga_2O_3 films.

There has been considerable development of precursors for the CVD growth of group 13 sulfide and selenide semiconductors.[113] Sulfur precursors that have been reported to date are based upon monothiocarbamato, dithiocarbamato, thiocarboxylato, thiolato, and dialkylselenophosphoryl-amido ligands. In certain cases, selenium analogs of these ligands have been employed to create precursors for the respective selenide phases. In addition, sulfur and selenium tetramers of the formula [RME]$_4$ have been used as precursors to metal sulfide and selenide phases, and have shown phase selectivity that appears to correlate with the cubic cores of the

precursors. Monothiocarbamato precursors are exemplified by $In(SOCNEt_2)_3$, which was used for the MOCVD growth of β-In_2S_3 films at substrate temperatures of 350–500 °C.[59] The gallium analog, $Ga(SOCNEt_2)_3$, provided the cubic GaS phase under aerosol-assisted CVD growth conditions.[60] Dithiocarbamato precursors have included $InMe_2(S_2CNEt_2)$, which was used for the MOCVD growth of β-In_2S_3 at 325 °C.[61] The In-S phase that was deposited was found to be sensitive to the substrate temperature as well as the nature of the alkyl group attached to indium. The precursor $In(S_2CNMeBu)_3$ was used in the MOCVD growth of α-In_2S_3 films, and afforded this phase under all growth conditions.[62] $Ga(t\mathrm{Bu})_2(S_2CNMe_2)$ was used for the atmospheric pressure MOCVD growth of GaS films.[63] Dithiocarbamato and diselenocarbamato precursors have been used for the growth of $CuInS_2$ and $CuInSe_2$ films by aerosol-assisted CVD.[114] Thiocarboxylato precursors are exemplied by $Ga(SOCMe)_2Me(dmpy)$[64] and $[dmpyH]^+$ $[In(SOCMe)_4]^-$.[65] Use of $Ga(SOCMe)_2Me(dmpy)$ in aerosol-assisted CVD afforded crystalline Ga_2S_3 films at substrate temperatures of 275–310 °C. The aerosol-assisted CVD of $[dmpyH]^+$ $[In(SOCMe)_4]^-$ gave β-In_2S_3 at temperatures as low as 210 °C. Metal sulfide and selenide films have been grown from a variety of precursors containing cubic M_4E_4 cores. The precursor $[(Me_2EtC)In(\mu_3\text{-}Se)]_4$ in low pressure MOCVD film growth afforded stoichiometric InS at temperatures between 260 and 350 °C.[66] Use of $[(t\mathrm{Bu})Ga(\mu_3\text{-}Se)]_4$ and $[(t\mathrm{Bu})Ga(\mu_3\text{-}Te)]_4$ in MOCVD film growth led to hexagonal GaSe and GaTe films.[67] It was proposed that the cubic cores in these precursors fragment during film growth to afford Ga_3E_3 building blocks that lead to the hexagonal phases. The precursors $Ga_2(S(i\mathrm{Pr}))_6$[115] and $In[SeC(SiMe_3)_3]_3$[116] were used as single-source precursors in the MOCVD growth of Ga_2S_3 and In_2Se_3 films, respectively. The complex $[InMe_2(SeMe)]_2$ was used as an MOCVD precursor to InSe in the temperature range of 270–370 °C.[117] The dialkylselenophosphorylamide complexes $GaMe_2((SeP\,i\mathrm{Pr}_2)_2N)$ and $InMe_2((SeP\,i\mathrm{Pr}_2)_2N)$ were used as precursors to Ga_2Se_3 and In_2Se_3 films with both aerosol-assisted CVD and low pressure MOCVD.[118] Precursors containing dialkylselenophosphorylamide ligands were used to grow $CuInSe_2$ films by aerosol-assisted CVD.[119]

2.6 Tin and Lead

The main technological application of tin-containing thin-film materials is as transparent conducting oxides for use in computer displays, televisions, and low-emissivity coatings for glass.[120,121] Tin(IV) compounds containing alkyl groups have been widely employed as CVD precursors to SnO_2 and other oxides.[68] $SnMe_4$ was used a dopant source for the atmospheric pressure MOCVD growth of tin-doped CdO films.[122] $SnMe_2Cl_2$ has been evaluated as a source compound for the large area CVD of tin oxide coatings for high volume low-emissivity coatings on commercial glass.[123] Low resistivity tantalum-doped SnO_2 films were grown by MOCVD using $Sn(Ot\mathrm{Bu})_4$ and $Ta(OEt)_5$ as the precursors.[69] Low resistivity fluorine-doped SnO_2 films were grown by low pressure CVD at substrate temperatures of 200–450 °C using $Sn(OCH(CF_3)_2)_4(HNMe_2)$ as the tin and fluorine precursor.[70] $Sn(NO_3)_4$ was used as a source compound for the MOCVD growth of compositional spreads of Ti-Sn-Hf oxides.[71] $Hf(NO_3)_4$ and $Ti(NO_3)_4$ were also used as precursors.

Thin films of tin sulfides are of interest as semiconductors and photovoltaic materials. The precursor $Sn(SCH_2CH_2S)_2$ was used for the aerosol-assisted CVD growth of tin sulfide phases in the presence of hydrogen sulfide.[72] SnS_2, Sn_2S_3, or SnS films were obtained, depending upon the substrate temperature. Tin sulfide films were grown by atmospheric pressure CVD using $Sn(SCH_2CF_3)_4$ and hydrogen sulfide with substrate temperatures of 300–600 °C.[73] The phase of tin sulfide obtained (SnS_2, Sn_2S_3, or SnS) depended upon the growth temperature. SnS films were grown by an atmospheric CVD process using $Sn(n\mathrm{Bu})_3(O_2CCF_3)$ and hydrogen sulfide at 350–600 °C.[124]

Several other precursors to tin phases have been reported. $Sn(NMe_2)_4$ and ammonia were used for the MOCVD growth of Sn_3N_4 films at <200 °C.[74] The single-source precursor $Me_3SnCo(CO)_4$ was used for the growth of CoSn thin films by MOCVD at 250–300 °C.[75] The major phase present in the film was CoSn, suggesting that the precursor controls the final film stoichiometry. Ni-Sn intermetallic particles were made by a CVD process that involved CVD of $SnMe_4$ onto Ni/SiO_2.[125]

Interest in the CVD growth of lead-containing thin films has been driven by the importance of several complex oxides, including $PbTiO_3$, $Pb(Zr,Ti)O_3$, $(Pb,La)(Zr,Ti)O_3$, $Pb(Mg_{0.33}Nb_{0.67})O_3$, and $Pb(Sc_{0.5}Ta_{0.5})O_3$. Lead diketonates have been evaluated for their volatility,[76] and $Pb(tmhd)_2$ is the most widely used of these precursors. $Pb(tmhd)_2$ has been used for the MOCVD growth of $Pb(Sc_{0.5}Ta_{0.5})O_3$ using direct liquid injection of a solution containing Sc and Ta precursors along with $Pb(tmhd)_2$.[126] Many other oxides have been grown with $Pb(tmhd)_2$. $Pb(tmhd)_2$ was used as a source compound for the growth of PbO films by laser-assisted CVD.[127] $PbEt_4$ is another precursor that is widely used for the CVD growth of lead-containing thin-film materials.[77] It is a volatile, air-stable liquid (bp 78 °C, 10 torr), and is commercially available. PbS films have been grown by MOCVD and PECVD from $Pb(S_2CNEt_2)_2$.[128]

2.7 Antimony and Bismuth

A major motivation for the development of antimony metal-organic precursors is the growth of antimony-based semiconductor materials. Advances and problems in this area have been summarized in recent reviews.[129,130] The simplest volatile precursor, SbH_3, is thermally unstable even at −65 °C and rapidly reverts to elemental antimony and hydrogen.[78] However, SbD_3 is more stable thermally, owing to the lowering of the zero point energy (*see Zero*

Point Energy) compared to SbH_3.[78] In fact, SbD_3 shows no signs of decomposition over one week when stored in a glass vessel at 10 torr. Up to 30 wt% of SbD_3 can be stored on solid absorbents, and there was no evidence of decomposition after 2 weeks at 23 °C. SbD_3 was used for the growth of antimony films at temperatures as low as 200 °C.[78] Other antimony hydrides that have been reported as film growth precursors include $SbH_2CH_2CMe_3$,[79] $SbH(CH_2CMe_3)_2$,[79] SbH_2iBu,[131] and SbHiBu$_2$.[131] MOCVD growth with $SbH_2CH_2CMe_3$ and $InMe_3$ afforded InSb films at substrate temperatures as low as 350 °C.[79] Trialkyl-based metal-organic precursors for antimony include $SbEt_3$[80] and $SbMe_2(t$Bu).[132] $SbEt_3$ is a widely used precursor, and was employed for the MOCVD growth of InAsSb/InPSb strained layer superlattices.[80] Antimony alkoxides $Sb(OR)_3$ (R = Et, nBu) have been used for the atmospheric pressure CVD growth of antimony oxide films.[81] $Sb(O_2CNMe_2)_3$ was used as a precursor for the low pressure CVD growth of Sb_2O_3 films.[82] The single-source precursor $[AlEt_2(Sb(SiMe_3)_2)]_2$ was employed for the growth of AlSb films by MOCVD.[83]

Development of metal-organic bismuth film growth precursors has been driven by the importance of bismuth-containing ferroelectric and superconducting oxides.[133] $BiMe_3$ is a highly volatile liquid, and has been used recently for the MOCVD growth of $SrBi_2Ta_2O_9$,[84] Bi_2Te_3,[134] and Bi_2Se_3 films.[135] Apparently $BiMe_3$ can explode, so it needs to be handled carefully. $BiPh_3$ is a volatile solid, and is widely used as a metal-organic precursor. Materials that have grown using $BiPh_3$ include $SrBi_2Ta_2O_9$,[85] MoO_3-Bi_2O_3,[136] Bi-doped ZrO_2,[137] and $Bi_4Ti_3O_{12}$.[138] $Bi(OCMe_2CH_2OMe)_3$ has been used for the MOCVD growth of Bi_2O_3[86] and $Bi_4Ti_3O_{12}$.[139] $Bi(tmhd)_3$ was used for the MOCVD growth of $SrBi_2Ta_2O_9$.[87] Bi_2E_3 films (E = S or Se) have been grown from $Bi(S_2CNEt_2)_3$,[140] $Bi(Se_2CNEt_2)_3$,[141] and $Bi[(i Pr_2PSe)_2N]_3$.[142]

2.8 Zinc and Cadmium

ZnO and CdO are wide bandgap semiconductors, and these materials may serve as transparent conducting oxides for photovoltaics and flat panel displays. ZnO may also have applications in blue and ultraviolet light emitting devices and laser diodes. Thin films of zinc and cadmium chalcogenides also have many potential applications. The technological goals of these materials have been summarized in several recent reviews.[143,144]

Several different classes of precursors have been used for the growth of ZnO films. The most commonly used metal-organic precursor is $ZnEt_2$, in combination with molecular oxygen or water. Many types of deposition processes have been used, and include both thermal and plasma activation of the precursors. For example, ZnO films have been grown from $ZnEt_2$ using MOCVD,[88] PECVD,[145] and ALD[146] methods. $ZnMe_2$ and tBuOH were used as precursors for the MOCVD growth of ZnO films.[89] The amine adducts $ZnMe_2(NR_3)$ are less pyrophoric than $ZnMe_2$, inhibit prereaction with the oxygen source, and facilitate purification. The vapor pressures of some $ZnMe_2(NR_3)$ precursors have been reported.[90] Other zinc alkyl precursors include $ZnEt(NEt_2)$[147] and ZnMe(OR) (R = iPr, tBu).[148] Oxygen-based metal-organic precursors to ZnO films include $Zn(acac)_2$,[91] $Zn(hfac)_2(H_2O)_2$·diglyme,[92] $Zn(OAc)_2$,[149] and $Zn_4O(O_2CNEt_2)_6$.[150] Atmospheric pressure CVD of $Zn(dmp)_2$ with dry molecular oxygen afforded ZnO films.[151] Atmospheric pressure CVD using $Zn(N(SiMe_3)_2)_2$ with molecular oxygen afforded Zn_2SiO_4 films owing to the presence of silicon in the metal-organic precursor.[152]

The first CVD growth of CdO films was reported only recently by several groups. Low pressure CVD of $CdMe_2$ with molecular oxygen afforded CdO films at substrate temperatures between 150 and 450 °C.[93] Precursors containing hfac ligands include $Cd(hfac)_2(tmeda)$,[94] $Cd(hfac)_2(H_2O)_2$,[153] and $Cd(hfac)_2(dme)$.[154]

Zinc and cadmium chalcogenide (*see* ***Chalcogenides: Solid-state Chemistry***) films have been grown from several different precursors. $CdMe_2$ has been used along with various chalcogenide precursors to deposit CdS films,[155] CdSe/CdTe films,[156,157] and CdSe/ZnSSe quantum islands.[158] CdSe and ZnSe films have been grown by MOCVD using the single-source precursors $M(Se_2CNMe(n\text{-hexyl}))_2$.[159] CdS films were grown from the related precursor $Cd(S_2CNMe(n\text{-Bu}))_2$.[160] ZnS and CdS films were grown by low pressure MOCVD from $M(S_2Pi Bu_2)_2$.[161] ZnS, CdS, ZnSe, and CdSe films could be grown by low pressure MOCVD using $M(EPi Pr_2)_2N_2$ as single-source precursors.[162] CdSe films were also grown from the single-source precursor $Cd(SeR_F)_2$, where R_F = 2,4,6-$(CF_3)_3C_6H_2$.[163]

2.9 Lanthanides

Some lanthanide MOCVD precursors are listed in Table 2.

Interest in the development of metal-organic precursors for the lanthanide elements is due to the many important applications of lanthanide-containing materials. These include erbium-doped semiconductors for use as optical fiber communications, lanthanide-doped GaN for full color displays, high-temperature superconductors, and lanthanide-doped ferroelectric (*see Ferroelectricity*) phases. Despite the importance of these materials, lanthanide film growth precursors

Table 2 MOCVD precursors of lanthanide metals

Compound (mp or bp)	Vapor pressure
$Er(C_5H_5)_3$[164]	~0.1 torr, 200 °C
$Er(C_5H_4i Pr)_2(C_5H_5)$[164]	0.1 torr, 150 °C
$Er(C_5H_4t Bu)_3$[164]	subl 150 °C, 10^{-4} torr
$Er(tmhd)_3$[165]	subl 150 °C, low pressure
$Eu(tmhd)_3$[166]	subl 135 °C, 0.05 torr
$Er(N(SiMe_3)_2)_3$[167]	subl 160 °C, 75 torr
$Er(t Bu_2pz)_3(4\text{-}t Bupy)_2$[168]	subl 150 °C, 0.1 torr
$Er(t BuNC(CH_3)Nt Bu)_3$[169]	subl 140 °C, 760 torr

have not been the subject of intense development. This area was reviewed in 1994,[170] and the following section summarizes the state of metal-organic precursor development. Owing to the common +3 oxidation state of lanthanide metal-organic precursors and the similar sizes of the lanthanide(III) ions, complexes with identical ligands tend to have similar vapor pressures. Thus, in the following sections, film growth precursors are illustrated only for representative lanthanide elements.

Precursors containing cyclopentadienyl (*see Cyclopentadienyl*) and substituted cyclopentadienyl ligands have been the most commonly used for the MOCVD growth of lanthanide-doped semiconductors. Much of the available information is available for erbium, owing to the importance of erbium-doped semiconductors in optical fiber technology. Various cyclopentadienylerbium complexes have been compared with regards to their precursor properties.[164] $Er(C_5H_5)_3$ is polymeric in the solid state through bridging cyclopentadienyl ligands, and as a result, requires heating to 200 °C or higher to achieve vapor transport for film growth.[164] Alkyl substitution on the cyclopentadienyl ligands leads to monomeric complexes that have higher vapor pressures. $Er(C_5H_4\textit{i}Pr)_2(C_5H_5)$ and $Er(C_5H_4\textit{t}Bu)_3$ were found to be more volatile than $Er(C_5H_5)_3$, and were used as erbium dopant precursors in the MOVPE growth of erbium-doped GaAs epitaxial films.[164] $Er(C_5H_4\textit{i}Pr)_2(C_5H_5)$ provided erbium levels that were about one order of magnitude higher than was possible with $Er(C_5H_4\textit{t}Bu)_3$, demonstrating that the growth chemistry is subtly affected by the structure of the erbium precursor. $Er(tmhd)_3$ has been used as a precursor for the growth of erbium-doped GaN films, but it was noted that high transport temperatures limited the doping efficiency.[165] $Eu(thmd)_3$ was used as a precursor for the MOCVD growth of europium-doped GaN.[166] $Er(N(SiMe_3)_2)_3$ was used as a dopant precursor for the MOCVD growth of erbium-doped silicon[171] and GaAs.[167] Use of this precursor led to lower carbon and oxygen levels in the GaAs film, but also led to silicon incorporation (an n-type dopant for GaAs).[167] The pyrazolato-based (*see Tris(pyrazolyl)borates*) precursor $Er(\textit{t}Bu_2pz)_3(4\text{-}\textit{t}Bupy)_2$ was used in the growth of erbium-doped GaAs films.[168,172] This precursor gave a better defined erbium emitting center than was obtained with cyclopentadienyl-based precursors. $Er(\textit{t}BuNC(CH_3)N\textit{t}Bu)_3$ and $Er(tmhd)_3$ were employed as precursors for the growth of erbium-doped silicon nanocrystals using a CVD process with disilane as the silicon source.[169] $Er(\textit{t}BuNC(CH_3)N\textit{t}Bu)_3$ gave higher erbium concentrations in the nanoparticles and led to larger nanoparticles, compared to $Er(tmhd)_3$ under identical growth conditions.

3 PRECURSORS FOR TRANSITION METAL GROUPS 4 AND 5

Some MOCVD precursors containing these elements are listed in Table 3.

Table 3 MOCVD precursors of the group 4 and 5 metals

Compound (mp or bp)	Vapor pressure
$Ti(O\textit{i}Pr)_4$[173–176]	bp 58 °C, 1 torr
$Ti(O\textit{t}Bu)_4$[177]	bp 70 °C, 0.2 torr
$Ti(NO_3)_4$[178]	subl 50 °C, 0.5 torr
$Zr(O\textit{t}Bu)_4$[179]	bp 90 °C, 5 torr
$Hf(O\textit{t}Bu)_4$[180]	bp 90 °C, 5 torr
$Zr(tmhd)_4$[181]	subl 180 °C, 0.1 torr
$Zr(NO_3)_4$[182]	subl 85 °C, 1.1 torr
$Zr(C_5H_5)_2Me_2$[183]	subl 85 °C, 0.6 torr
$Ti(NMe_2)_4$[184]	bp 50 °C, 0.5 torr
$Ti(NMeEt)_4$[185]	bp 85 °C, 0.05 torr
$Ti(NEt_2)_4$[186]	bp 133 °C, 1.2 torr
$Zr(NEt_2)_4$[187]	bp 112 °C, 0.1 torr
$Hf(NMe_2)_4$[188]	bp 85 °C, 0.1 torr
$TiCl_4(HSC_6H_{11})_2$[189]	2 torr, 23 °C
$TiCl_4(SeEt_2)_2$[190]	2 torr, 23 °C
$TiCl_4(H_2PC_6H_{11})_2$[191]	subl 100 °C, 0.1 torr
$VO(acac)_2$[192]	subl 150–175 °C, 15 torr
$Nb(OEt)_5$[13]	bp 142 °C, 0.1 torr
$Ta(OEt)_5$[193]	bp 145 °C, 0.1 torr
$V(NMe_2)_4$[194]	subl 50 °C, 760 torr
$Nb(NEt_2)_4$[194]	subl 130 °C, 760 torr
$Ta(NMe_2)_5$[194]	subl 100 °C, 0.1 torr

3.1 Titanium, Zirconium, and Hafnium

Titanium is an important component of many oxide materials, including titanium dioxide and various more complex titanates. Several reviews have summarized recent developments in thin-film growth and precursor selection.[195,196] $Ti(O\textit{i}Pr)_4$ is the most widely employed metal-organic precursor, and is a liquid at ambient temperature with a boiling point of 58 °C at 1 torr. It has been used for the growth of a range of titanium oxide-containing materials with a variety of CVD deposition techniques. Illustrative examples of film growth with $Ti(O\textit{i}Pr)_4$ include MOCVD of TiO_2,[197] LACVD (laser-assisted chemical vapour deposition) of TiO_2,[173] PACVD of $BaTiO_3$,[174] ALD of $SrTiO_3$,[175] and ALD of TiO_2.[176] Related alkoxide precursors that have been used in film growth procedures include $Ti(O\textit{t}Bu)_4$,[177] $Ti(OCH_2\textit{t}Bu)_4$,[198] $Ti(OEt)_4$,[199] $[Ti(OCH_2CH_2O)(OCH_2CH_2NMe_2)_2]_2$,[200] $Ti(O\textit{i}Pr)_2(OCH_2CH_2NMe_2)_2$,[201] $Ti(OCH_2CH_2NMe_2)_4$,[202] and $Ti(HB(pz)_3)(O\textit{i}Pr)_3$.[203] A drawback of $Ti(O\textit{i}Pr)_4$ and related alkoxo-based precursors is their extreme moisture sensitivity. Thus, one avenue of precursor development has been to explore β-diketonato complexes, which tend to be less reactive toward water. Examples of such precursors include $Ti(tmhd)_2(O\textit{i}Pr)_2$,[204] $Ti(tmhd)_2(O\textit{t}Bu)_2$,[205] $Ti(tmhd)_2(OMe)_2$,[206] $Ti(acac)_2(O\textit{i}Pr)_2$,[207] $Ti(tbaoac)_2(O\textit{i}Pr)_2$,[208] and $Ti(tmhd)_3$.[209] β-Ketoiminato complexes of titanium containing pendant alkoxy groups on the nitrogen atoms have been synthesized and were suggested to be good CVD precursors.[210] The nitrato complex $Ti(NO_3)_4$ has a high volatility, and has been demonstrated as a precursor to TiO_2

films.[178] A detailed comparison of TiO_2 MOCVD growth from $Ti(NO_3)_4$ and $Ti(O\mathit{i}Pr)_4$ was reported.[211]

Precursors for the growth of zirconium and hafnium oxide materials have been of considerable recent interest, owing to the importance of dielectric and ferroelectric materials that contain these elements. Several reviews have appeared recently that summarize technological progress.[212–214] In the following examples, most of the precursor development has occurred for zirconium. However, zirconium(IV) and hafnium(IV) are very similar chemically, and the properties of many hafnium complexes are usually very close to those of their zirconium analog. Hafnium precursors are mentioned where information is available. The most commonly used precursors for oxide film growth are $Zr(O\mathit{t}Bu)_4$[179] and $Hf(O\mathit{t}Bu)_4$,[180] since they are liquids at ambient temperature and have convenient volatilities. Other tetraalkoxide precursors that have been reported include $Zr(OCH_2\mathit{t}Bu)_4$,[215] $Zr(O\mathit{i}Bu)_4$,[216] $Zr(OCH_2CH_2NMe_2)_4$,[217] $Zr(O\mathit{t}Bu)_2(OCMe_2CH_2OMe)_2$,[218] $Zr(OCH(CF_3)_2)_4$,[14] and various other $Zr(OR)_4$.[219] Like the titanium alkoxides, the zirconium and hafnium alkoxides are extremely water sensitive, and there has been interest in finding precursors that can be handled more easily. $Zr(tmhd)_4$[181] and $Zr(acac)_4$[220] have been used as film growth precursors. While they possess increased hydrolytic stability, their vapor pressures are very low and they have not seen wide application as a result. A compromise between good vapor pressure and increased hydrolytic stability has been found in mixed diketonato-alkoxo complexes. Precursors of this general class include $Zr_2(tmhd)_2(O\mathit{i}Pr)_6$,[221] $Zr(tmhd)_2(OR)_2$ ($R = \mathit{i}Pr$, $\mathit{t}Bu$),[222] $Zr(acac)_2(OCH(CF_3)_2)_2$,[223] and $Zr(tbaoac)(O\mathit{i}Pr)_3$.[224] $Zr(NO_3)_4$[182] and $Hf(NO_3)_4$[225] have been used as precursors to the respective dioxide phases. Dimethylzirconocene ($Zr(C_5H_5)_2Me_2$) has been used for the MOCVD[183] and ALD[226,227] growth of zirconium oxide phases, in combination with molecular oxygen, water, or ozone. $Zr(NMe_2)_4$[228] and $Hf(NEt_2)_4$[229] were used for the growth of oxide films using molecular oxygen as a coreactant. The single-source precursor $Zr(acac)_2(OSiMe_3)_2$ was used for the growth of $Zr_xSi_{1-x}O_2$ films for high dielectric constant gate materials in microelectronics devices.[230]

The growth of group 4 nitride phases have been the subject of intense scrutiny, owing to the importance of TiN as a barrier layer between copper and silicon dioxide in microelectronics devices. Work on metal-organic precursors has been reviewed.[8,231] Amido-based precursors have been examined by many workers. Available precursors include $Ti(NMe_2)_4$,[184] $Ti(NMeEt)_4$,[185] and $Ti(NEt_2)_4$.[186] MOCVD of these precursors in the presence of ammonia or another nitrogen source affords high quality TiN films. The step coverage is greatest with $Ti(NEt_2)_4$,[186] due to its slower reaction with ammonia and resultant higher selectivity. MOCVD film growth using $Ti(NMe_2)_4$, ammonia, and silane affords Ti-Si-N films, which is a promising barrier materials for microelectronics devices.[232] Use of $Ti(NMe_2)_4$ as a single-source precursor yields Ti(C,N) films, which are also of potential use as a barrier material in microelectronics devices.[233] Growth of TiN films from single-source precursors has been reported by several authors,[234–237] but these precursors have not been subject to broad investigation. Available metal-organic film growth precursors for zirconium and hafnium nitride films include $Zr(NMe_2)_4$,[238] $Zr(NMeEt)_4$,[238] $Zr(NEt_2)_4$,[187] $Hf(NMe_2)_4$,[188] and $Hf(NEt_2)_4$.[188] These precursors afford MN or M(C,N) films when used in film growth by various CVD methods.

A few metal-organic precursors to other phases have been reported. $TiCl_4(HSC_6H_{11})_2$[189] and $Cp_2Ti(S\mathit{t}Bu)_2$[239] serve as single-source precursors for the growth of TiS_2 films using MOCVD. $TiCl_4(SeEt_2)_2$ functions as a single source for the growth of $TiSe_2$ films by MOCVD.[190] $TiCl_4(H_2PC_6H_{11})_2$ is a single-source precursor for the growth of TiP films by MOCVD.[191,240]

3.2 Vanadium, Niobium, and Tantalum

CVD routes to vanadium oxide phases have employed a limited number of metal-organic precursors. $VO(acac)_2$ is the most widely used, and oxide films have been deposited from it by low pressure MOCVD[241] and PECVD.[192] Other precursor for vanadium oxide film growth include $VO(O\mathit{i}Pr)_3$[242] and $VO(OEt)_3$.[243]

Interest in film growth of niobium oxides is driven by the importance of several ferroelectric materials that contain niobium. The most widely used precursor is $Nb(OEt)_5$, which is a volatile liquid. Examples of materials that have been grown by MOCVD with $Nb(OEt)_5$ include $LiNbO_3$,[13] Pb-Ti-Nb-O,[244] and $KNbO_3$.[245] Owing to the extreme reactivity of $Nb(OEt)_5$ with water, attempts have been made to identify precursors that are easier to handle. Examples of such precursors include $Nb(tmhd)(O\mathit{i}Pr)_4$,[246] Nb(N-alkoxo-$\beta$-ketoiminato)$(OEt)_3$,[247] and $Nb(dbm)(OEt)_4$.[248] $Mg[Nb(OEt)_6]_2\cdot(EtOH)_2$ has been used as a single-source precursor for the growth of $Pb(Mg,Nb)O_3$ films.[249] Owing to their chemical similarity, niobium and tantalum complexes with identical ligands tend to have similar volatilities. As a result, several of the papers noted above have also reported related tantalum precursors.

The major technological impetus for the growth of tantalum oxide materials has been the growth of ferroelectric and high dielectric materials. As with niobium, the most widely used film growth precursor is $Ta(OEt)_5$, which is a volatile liquid. As illustrative examples, Ta_2O_5 films have been grown from $Ta(OEt)_5$ using MOCVD[193,250] and ALD.[251] $Ta(OMe)_5$ has also been used as an MOCVD precursor.[252] Since $Ta(OEt)_5$ is a dimer, several approaches have been pursued to increase the vapor pressure by creating monomeric precursors. $Ta(OEt)_4(OCH_2CH_2NMe_2)$, which contains a chelating aminoethoxy group, has been used in the photo-assisted CVD growth of Ta_2O_5 films.[253] Another approach is to replace one alkoxo ligand with a diketonato ligand, to create a monomeric complex and to increase the

hydrolytic stability. Examples of such precursors include $Ta(tmhd)(OMe)_4$,[254] $Ta(N\text{-alkoxo-}\beta\text{-ketoiminate})(OEt)_3$,[247] and $Ta(tmhd)(OEt)_4$.[255] $Ta(N\mathit{t}Bu)(NEt_2)_3$ has been used for the MOCVD growth of Ta_2O_5 films.[256] The single-source precursor $Sr[Ta(OEt)_5(OCH_2CH_2NMe_2)]_2$ has been employed in the MOCVD growth of $SrBi_2TaO_9$ films, and helps to control the Sr-Ta stoichiometry.[257] Other tantalum-containing single-source precursors include $Sr[Ta(O\mathit{i}Pr)_6]_2{\cdot}2\mathit{i}PrOH$,[249] $Sr[Ta(OEt)_6]_2$,[258] and $TaAl(O\mathit{i}Pr)_8$.[259]

Interest in the growth of metal nitride films by CVD methods arises from the use of TaN as a diffusion barrier between copper and silicon dioxide in microelectronics devices. TaN is one of the best copper diffusion barrier materials that have been identified. This area has been recently reviewed,[260] and the reader is encouraged to consult this article for a detailed discussion of film growth from metal-organic precursors. The predominant metal-organic precursors for are the dialkylamido complexes $V(NMe_2)_4$, $Nb(NEt_2)_4$, and $Ta(NMe_2)_5$.[194] Atmospheric pressure MOCVD using these precursors with ammonia as the coreactant afforded VN, Nb_3N_4, and Ta_3N_5 films, respectively. Since the original report, $Ta(NMe_2)_5$ has been used extensively for the growth of Ta-N phases by CVD techniques.[261,262] Problems include deposition of the insulating Ta_3N_5 phase (as opposed to the desired metallic TaN), high carbon content in the films, and unacceptably high film resistivities for use as barrier layers. Other precursors that have been evaluated for the growth of Ta-N phases include $Ta(N\mathit{t}Bu)(NEt_2)_3$,[263] $Ta(NEt)(NEt_2)_3$,[188] and $Ta(NEt_2)_5$.[264] A niobium imido complex has been used for the growth of superconducting NbN films.[265]

Metal-organic precursors to several other group 5-containing phases have been reported. $V(C_6H_6)_2$ (*see Arene Complexes*) provides V_8C_7 films in an MOCVD process.[266] $Ta(CH\mathit{t}Bu)(CH_2\mathit{t}Bu)_3$ was used as a single-source precursor to tantalum carbide films.[267] Cp_2VMe_2 was used as a precursor to Ti-V-N-C coatings.[268] A review article lists a range of precursors that have been evaluated as single-source precursors to VC and VN films.[269] $Nb_2Cl_8(PH_2C_6H_{11})_4$ functions as a single-source precursor for the growth of NbP films.[270] $[NbCl_4(S_2\mathit{i}Pr_2)_2][NbCl_6]$ served as a single-source precursor to films containing NbS_2 and Nb_2O_5.[271]

4 PRECURSORS FOR TRANSITION METAL GROUPS 6 AND 7

4.1 Chromium, Molybdenum, and Tungsten

Some MOCVD precursors containing these elements are listed in Table 4.

There have been relatively few metal-organic precursors reported for chromium materials. $Cr(acac)_3$ and other diketonate derivatives have been employed for the growth of oxide phases by MOCVD techniques.[272,283,284] $Cr(CO)_6$ was used for the MOCVD growth of Cr_2O_3 films by MOCVD.[273] $Cr(NEt_2)_4$ provides Cr(C,N) films when used as a single-source precursor.[285] $Cr(C_6H_6)_2$ (*see Arene Complexes*) serves as a precursor for chromium carbide films, but also provides chromium metal films in the presence of hydrogen or hexachlorobenzene.[286] Thin films of the molecular magnet $[Cr(C_6H_6)_2][TCNE]$ were grown by a CVD process from $Cr(C_6H_6)_2$ and TCNE.[287]

Table 4 MOCVD precursors of the group 6 and 7 metals

Compound	Vapor pressure
$Cr(acac)_3$[272]	3.3 torr, 150 °C
$Cr(CO)_6$[273]	subl 70 °C, 760 torr
$W(CO)_6$[274]	subl 30 °C, 2 torr
$W(OEt)_6$[275]	subl 190 °C, 760 torr
$W(N\mathit{t}Bu)_2(NMe_2)_2$[276]	bp 50 °C, 0.05 torr
$W(N\mathit{t}Bu)_2(NH\mathit{t}Bu)_2$[277]	bp 50 °C, 0.05 torr
$W(N\mathit{i}Pr)Cl_4(NCMe)$[278]	liquid delivery in benzonitrile
$Mo(NMe_2)_4$[279]	subl 40 °C, 0.1 torr
$Mn(tmhd)_3$[280]	subl 133 °C, 0.018 torr
$Mn(C_5H_4Me)(CO)_3$[281]	bp 233 °C, 760 torr
$MeReO_3$[282]	subl 65 °C, 10^{-3} torr

Molybdenum and tungsten oxides have been grown from several different metal-organic precursors. The most widely used precursors are $Mo(CO)_6$ and $W(CO)_6$ (*see* ***Carbonyl Complexes of the Transition Metals***).[274,288] Other precursors that have been employed for the growth of oxide phases include $W(OEt)_6$,[275] $W(OC_6H_5)_6$,[289] $W(CO)_4(P(OEt)_3)_2$,[290] $W(\text{methyl vinyl ketone})_3$,[291] and $W(\eta^3\text{-}C_3H_5)_4$.[292] MoS_2 films have been grown from the single-source precursor $Mo(S\mathit{t}Bu)_4$.[293] Tungsten carbide phases have been grown from a range of tungsten carbonyl precursors.[294]

W_2N is one of the most promising copper diffusion barrier materials for future microelectronics devices. Owing to the need for conformal film growth, there has been considerable interest in the growth of W_2N from metal-organic precursors using CVD techniques, particularly ALD. Precursors that have been employed include $W(CO)_6$,[295] $W(N\mathit{t}Bu)_2(NMe_2)_2$,[276] $W(N\mathit{t}Bu)_2(NEt_2)_2$,[296] $W(N\mathit{t}Bu)_2(NH\mathit{t}Bu)_2$,[277] and $W(N\mathit{i}Pr)Cl_4(NCMe)$.[278] Films with a composition of Mo_2N_3 were grown from $Mo(NMe_2)_4$ and ammonia by atmospheric pressure CVD.[279]

4.2 Manganese and Rhenium

Precursor development for these elements has been limited. Manganese oxide-containing thin films have been the subject of considerable interest, owing to the importance of manganese-containing magnetoresistive perovskite phases. The predominant metal-organic precursor is $Mn(tmhd)_3$, and manganese oxide-containing phases have been grown by ALD,[280] liquid-delivery MOCVD,[297] and low pressure MOCVD[298] using this precursor. MnSe films have been grown by MOCVD using $Mn(C_5H_4Me)(CO)_3$.[281] The single-source

Table 5 MOCVD precursors of the group 8 and 9 metals

Compound	Vapor pressure
$Fe(CO)_5$[300]	bp 103 °C, 760 torr
$Fe(C_5H_5)_2$[301]	subl 120 °C, 75 torr

$Ir(C_5H_4Me)(COD)$[313]	0.0001 torr, 100 °C

precursor $Ga(Mn(CO)_5)_2(CH_2CH_2CH_2NMe_2)$ was employed to grow Mn-Ga alloy films.[299] $MeReO_3$ has been used for the growth of rhenium-containing films by MOCVD.[282]

5 PRECURSORS FOR TRANSITION METAL GROUPS 8 AND 9

Some MOCVD precursors containing these elements are listed in Table 5.

5.1 Iron

Iron-containing thin films have many applications. Precursors for the MOCVD growth of iron-containing phases have included $Fe(CO)_5$ (*see* ***Carbonyl Complexes of the Transition Metals***),[300] $Fe(C_5H_5)_2$ (*see Ferrocene*),[301] $Fe(acac)_3$,[302] $Fe(tmhd)_3$,[314] $Fe(tbaoac)_3$,[315] and $[Fe(O\textit{t}Bu)_3]_2$.[316] $Fe_2(CO)_6(\mu\text{-}S_2)$ served as a single-source precursor for the MOCVD growth of FeS films.[317] $Fe(CO)_4(GaCH_2CH_2CH_2NMe_2)_2$ was used as a single-source precursor to Fe-Ga alloy films.[318] $FeSi_2$ films were grown from the single-source precursor $Fe(SiCl_3)_2(CO)_4$.[319]

5.2 Ruthenium and Osmium

Ruthenium dioxide has been of recent interest for use as a conductive material in microelectronics devices. A range of precursors has been used for the growth of ruthenium-containing thin-film materials, including $Ru(tmhd)_3$,[303] $Ru(tmhd)_2(COD)$,[320] $Ru(C_5H_5)_2$,[304] $Ru(C_5H_4Et)_2$,[321] $Ru(C_5H_4Et)(C_7H_{11})$,[322] $Ru(C_7H_{11})_2$,[323] $Ru(COD)(C_3H_5)$,[324] $Ru(hfac)_2(CO)_2$,[325] $Ru(CO)_2(OC(CF_3)_2CH_2NHMe)_2$,[326] $Ru(CF_3CCCF_3)(CO)_4$,[327] and $[Ru(CO)_3((CF_3)_2pz)]_2$.[328] Precursors for the growth of osmium metal thin films have included $Os(hfac)(CO)_3(CO_2CF_3)$[329] and $[Os(CO)_3((CF_3)_2pz)]_2$.[305] The single-source precursor $Ru(C_5H_5)((\eta^5\text{-}C_5H_3CH_2NMe_2)Pt(DMSO)Cl)$ served as a precursor to Ru-Pt alloy films.[330]

5.3 Cobalt

Recent interest in cobalt films has been driven by the importance of cobalt oxides as cathode materials in lithium batteries. Many different precursors have been employed for the MOCVD growth of cobalt-containing thin films. Diketonate-based precursors include $Co(acac)_2$,[306] $Co(tmhd)_2$,[307] $Co(tmhd)_3$,[331] $Co(hfac)_2$,[332] $Co(tmhd)_2(tmeda)$,[308] $Co(hfac)_2(H_2O)_2$,[333] and $Co(hfac)_2(H_2O)_2\cdot$tetraglyme.[334] Carbonyl-based precursors (*see* ***Carbonyl Complexes of the Transition Metals***) include $Co_2(CO)_8$,[309] $Co(C_5H_5)(CO)_2$,[309] various cobalt carbonyl clusters,[335] $Co(CO)_3(NO)$,[310,336] and $Co(CO)_2(NO)L$ ($L = PEt_3$, $TeMe_2$, $TeEt_2$).[337] Other cobalt precursors include $CoH(P(O\textit{n}Pr)(OMe)_2)_4$,[338] $Co(NO_3)_3$,[339] and $Co(\textit{t}BuNC(CH_3)N\textit{t}Bu)_2$.[340]

5.4 Rhodium and Iridium

The MOCVD of platinum group metals, including rhodium and iridium, has been recently reviewed.[341,342] A technological application of the metal films is as electrodes in microelectronics devices. Film growth precursors that have been reported for rhodium include $Rh(C_5H_5)(CO)_2$,[343] $Rh(C_5H_5)(COD)$,[343] $Rh(acac)(CO)_2$,[311] $[RhCl(CO)_2]_2$,[311,312] $Rh(C_3H_5)_3$,[311,343] and $Rh(hfac)(C_2H_4)_2$.[344] MOCVD precursors for iridium include $Ir(C_5H_4Me)(COD)$,[313] $Ir(acac)_3$,[345] $Ir(tmhd)(COD)$,[346] a range of precursors of the formula $Ir(X)(COD)$ ($X =$ *bidentate*, anionic donor),[347] and $[Ir(S\textit{t}Bu)(CO)_2]_2$.[348] Reference 345 gives a recent comprehensive listing of available iridium precursors.

6 PRECURSORS FOR TRANSITION METAL GROUPS 10 AND 11

Some MOCVD precursors containing these elements are listed in Table 6.

6.1 Nickel

Nickel is an important component in many thin-film materials. Precursors for the growth of nickel metal films have been recently summarized in a review.[360] Recently reported precursors for the CVD growth of nickel-containing materials include $Ni(tmhd)_2$,[349] $Ni(hfac)_2(en)$,[361] a series of nickel dioximato complexes,[362] $Ni(O_2CCF_3)_2(dmen)_2$,[363] $Ni(C_5H_5)_2$,[350] and $Ni(\textit{t}BuNC(CH_3)N\textit{t}Bu)_2$.[340] Single-source

Table 6 MOCVD precursors of the group 10 and 11 metals

Compound	Vapor pressure
$Ni(tmhd)_2$[349]	subl 90 °C. 0.1 torr
$Ni(C_5H_5)_2$[350]	subl 102 °C, 760 torr
$Pd(hfac)_2$[351]	subl 60 °C, 10–5 torr
$Pt(hfac)_2$[352]	subl 65 °C, 0.1 torr
$Pt(C_5H_4Me)Me_3$[353]	0.2 torr, 35 °C
Cu(hfac)(VTMS)[354]	1 torr, 60 °C
$Cu(tmhd)_2$[355]	1.75 torr, 107 °C
$Ag(hfac)(PMe_3)$[356]	subl 95 °C, 0.1 torr
Ag(tmhd)[357]	subl 230 °C, 0.01 torr
$Au(hfac)Me_2$[358]	0.5 torr, 23 °C
$Au(acac)Me_2$[359]	subl 25 °C, 0.01 torr

precursors have included $Ni(S_2CNRR')_2$ (for NiS_2 films),[364] $Ni(C_5H_5)(CO)In(CH_2CH_2CH_2NMe_2)_2$ (for Ni/In alloy films),[365] and $Ni(dmg{\cdot}GaEt_2)_2$ (for $NiGa_2$ films).[366]

6.2 Palladium and Platinum

Metal-organic precursors for the CVD growth of palladium and platinum films have been recently reviewed.[341,342,367] An issue for the growth of films of these elements is significant heteroatom incorporation from the precursor ligands. Carbon incorporation is a particular problem. Owing to the importance of palladium and platinum films, this area has seen a large amount of activity in the past ten years. Precursors containing alkyl ligands include $PtMe_2(COD)$,[368] $PdMe_2L_2$ (L = PMe_3, PEt_3, 0.5 tmeda),[369] $Pt(CH_2CH_2CH_2CH{=}CH_2)_2$,[370] $Pt(C_5H_4Me)Me_3$,[353,371] and $Pt(C_5H_4Et)Me_3$.[372] Diketonate-based precursors include $Pd(acac)_2$,[373] $Pt(acac)_2$,[374] $Pd(hfac)_2$,[351] $Pt(hfac)_2$,[352] $Pd(hfac)(C_3H_5)$,[375] $Pd(hfac)_2(SEt_2)$,[376] and $Pd(\beta\text{-diketonato})(C_3H_5)$.[377] Precursors containing various substituted β-ketoiminato ligands have included $Pd(\beta\text{-ketoiminato})_2$[378] and $Pd(\beta\text{-ketoiminato})(C_3H_5)$.[379] The allyl ligand-based precursors $Pd(C_5H_4Me)(C_3H_5)$[380] and $Pd(C_5H_5)(C_3H_5)$[381] have also been reported. Finally, the single-source precursor $Ru(C_5H_5)((\eta^5\text{-}C_5H_3CH_2NMe_2)Pt(DMSO)Cl)$ serves as a precursor to Ru-Pt alloy films.[330]

6.3 Copper

Growth of copper metal films by CVD methods is driven by the microelectronics industry, which employs copper as an interconnect metallization material. CVD methods are viewed as very promising by the microelectronics industry, owing to excellent conformal film growth that can be obtained with molecular precursors. Progress in this area has been the subject of several recent reviews.[354,355,382] The most commonly employed precursor is Cu(hfac)(VTMS), owing to its high vapor pressure and low growth temperatures.[354] Cu(hfac)(VTMS), while stable at ambient temperature, disproportionates at moderate temperatures to afford copper metal, $Cu(hfac)_2$, and VTMS. This disproportionation allows lower temperature growth of copper metal films, compared to copper(II) precursors. Related copper(I) precursors that differ in the identity of the neutral ligand include $Cu(hfac)(CH_2 = CH\textit{t}Bu)$,[383] Cu(hfac)(COD),[384] Cu(hfac)(VTMOS),[385] Cu(hfac)(2-methyl-1-hexen-3-yne),[386] and Cu(hfac)(L) (L = a range of terminal alkenes).[387] In spite of the low-temperature film growth with Cu(hfac)(VTMS), there is some residual fluorine contamination on the film surface, and subsequent layers adhere poorly to the copper film. Accordingly, there is considerable interest in fluorine-free precursors. Such precursors that have been reported include $Cu(acac)_2$,[388] $Cu(tmhd)_2$,[389] $Cu(OC(CF_3)_2CH_2NHCH_2CH_2OMe)_2$,[390] $Cu(OCH(Me)CH_2NMe_2)_2$,[391] $Cu(OC(CF_3)_2CH_2\text{-}NH\textit{t}Bu)_2$,[392] and $Cu(HBpz_3)(PMe_3)$.[393] In addition, a range of β-diketonate complexes of copper(I) and copper(II) have been evaluated as film growth precursors.[394]

6.4 Silver and Gold

Silver is of potential interest for use as the interconnect metal in microelectronics devices. The most commonly used precursors for the growth of silver containing phases are of the formula Ag(hfac)(L), where L = substituted phosphine,[356,395] SEt_2,[396] bis(trimethylsilyl)acetylene,[397] trans-1,2-bis(trimethylsilyl)ethylene,[398] mono-substituted alkenes,[399] vinyltriethylsilane,[400] tetraglyme,[401] and COD.[402] Ag(tmhd) has been used as a precursor, but has a low vapor pressure.[357] Carboxylate complexes of the formula $Ag(O_2CR_F)(PR_3)$ (R_F = perfluoroalkyl, R = alkyl, aryl) have been employed as precursors for the growth of silver metal films.[403–405] Single-source precursors to Ag-In-S films have included $[Ag(PPh_3)_2][In(SOCMe)_4]$[406] and $[Ag(PPh_3)_2][In(SMe)_4]$.[407] The low volatility of these ionic precursors required aerosol delivery of the precursors.

Gold thin films are of interest as substrates for a variety of applications, and also for metallic contacts. Reports of gold film depositions from metal-organic precursors are limited. Precursors have included $Au(hfac)Me_2$,[358] $Au(acac)Me_2$,[359] $AuMe(PMe_3)$,[408] $AuMe(PEt_3)$,[409] $AuMe(P(OMe)_2Me)$,[410] and $Au(O_2CR_F)(PR_3)$ (R_F = perfluoroalkyl, R = alkyl, aryl).[411]

1 INTRODUCTION

Metalloregulation refers to the concept that living organisms from bacteria to mammals must orchestrate the processes of metal import, utilization, sequestration, and export to optimize availability of metals for use in metabolism, while avoiding the toxicity that may arise from reactivity of free metal ions with the protein, nucleic acid and lipid contents of cells. Metalloregulation is necessary because virtually all cells and organisms require transition metals to facilitate basic cellular processes such as respiration and DNA biosynthesis. Proteins that incorporate metals such as iron, copper, and zinc into their structures gain various chemical reactivity and structural properties that they would not otherwise possess. As an example of how metals contribute to metabolism, iron and copper proteins allow cells to make efficient use of oxygen by activating oxygen and allowing it to readily participate in single electron transfer reactions.[1] Life on earth depends largely on the energy captured from complete oxidation of glucose by oxygen, but direct reactions between oxygen and organic molecules are energetically unfavorable in the absence of transition metals. In respiration, iron and copper proteins capture energy released from oxidation of food by synthesizing high-energy compounds such as NADH that are used to fuel cellular metabolism. Iron also enables hemoglobin in red cells of mammals to bind and transport oxygen to tissues throughout the body.[2]

To ensure that metals are available in non-toxic forms, complex regulatory systems have evolved to promote appropriate acquisition, distribution, and excretion of indispensable metals such as iron, copper, zinc, and manganese in organisms from all the kingdoms of life. In this chapter, we will discuss the mechanisms by which cells and organisms gauge their metal status and how they mobilize an appropriate response. In general, one or several proteins interact directly with the metal that requires regulation, and these metal-binding proteins then effect changes in transcription, mRNA stability, translation, protein stability, or subcellular localization of metal transporters and sequestration proteins. In general, metals are transported across lipid bilayers by unidirectional transporters that discriminate amongst the various metals. The rate of metal transport is determined by the level of expression of the transporter and/or an associated reductase, and expression levels change according to cellular needs.

In different organisms, different combinations of regulatory strategies are employed. As cells and organisms increase in their organizational complexity, more processes are subject to regulation. In prokaryotes, metals that reach the cytosol are readily made available to proteins involved in energy metabolism, replication and other important processes, because all of these processes are carried out within the bacterial cytosolic compartment. In eukaryotes, metals that cross the plasma membrane must traverse another membrane or set of membranes to reach organelles such as mitochondria, chloroplasts, the vacuole, peroxisomes, and endoplasmic reticulum. Not only do these membrane bound compartments require metal importers and exporters, but they must also possess a means of coordinating organellar metal homeostasis. At this point, little is known about the mechanisms by which appropriate organellar metal homeostasis is maintained. As will be discussed later, misregulation of organellar iron homeostasis causes some important human diseases, and elucidation of regulatory mechanisms that govern organellar iron homeostasis represents an important frontier in metalloregulation research.

In multicellular organisms, regulatory challenges are even more complex than those in unicellular eukaryotes, because regulation of metal uptake and excretion must also be exerted at the level of the whole organism. Uptake of dietary metals is regulated in the guts of animals, and uptake of metals from soil is regulated in the roots of plants. Thus, complex organisms need mechanisms that enable them to transmit information about overall organismal metal status to cells that are in direct contact with environmental metal sources. In mammals, tissues such as liver and spleen that are open to circulation of blood can synthesize factors that reflect their iron status, and these factors can then be transported through the circulation to the duodenum, the site of the mammalian gut in which most micronutrients are absorbed. To further add to the complexity of mammalian metalloregulation, some organs are separated from direct contact with circulating blood by layers of epithelial cells that are tightly attached to one another, forming a membrane that factors in the circulating blood cannot freely cross. These epithelial barriers, known as the blood-brain barrier and the blood-testis barrier, protect the brain and testis from exposure to toxins in the bloodstream.

Because these compartments are separated from the rest of the organism by epithelial cell layers with tight junctions between cells, these compartments must manage metal uptake and regulate metal homeostasis to appropriately meet the needs of these tissues.

In this article, we will focus mainly on the mechanisms of iron and zinc regulation, because regulation of these two metals illustrates many basic principles. We will also reference reviews that address regulation of copper and manganese metabolism, but regulation of these metals will not be discussed in depth here, in part because they will be discussed elsewhere.

2 REGULATION OF IRON METABOLISM

2.1 The Importance of Transcriptional Regulation in Unicellular Iron Metabolism

Free-living microorganisms and plants must overcome significant environmental barriers in order to use iron. In an aerobic atmosphere, iron is present in soil and water in the form of ferric oxyhydroxides, which have a very low solubility of 10^{-9} M at neutral pH.[3] This very low solubility means that iron is not typically present at a concentration that permits uptake through permeases that have micromolar or high nanomolar affinity. Three strategies are available to these organisms to increase the solubility of iron: (1) acidification of the environment, (2) reduction of ferric iron to the more soluble ferrous form, and (3) secretion of soluble iron-chelating molecules. All of these strategies are used to varying extents by microorganisms and plants, which often simultaneously employ multiple distinct iron-uptake systems.[4] These systems of iron uptake, as well as other proteins of the iron homeostatic machinery, are precisely regulated to adjust to iron availability and the cellular requirements for iron. In general, high-affinity iron acquisition systems are homeostatically regulated. That is, under conditions of iron scarcity, iron acquisition systems are expressed at high levels, and under conditions of iron abundance, these systems are expressed at very low levels. When iron is freely available, uptake occurs primarily through low-affinity uptake systems that may have broad metal specificity.

2.1.1 Iron Homeostasis in Bacteria

The iron acquisition systems of *E. coli* and many other bacteria are regulated at the level of RNA transcription by Fur (ferric uptake regulator), a transcriptional repressor that exhibits ferrous iron-dependent, DNA-binding activity.[5] Fur is expressed as a 17 kDa homodimer and, under conditions of iron sufficiency, it binds one iron ion per subunit, which increases its affinity for its preferred DNA binding sites by 1000-fold.[6] In some bacteria, Fur also contains one structural zinc ion per dimer. Under iron sufficient conditions, Fe^{2+}-Fur binds to specific promoter regions (known as Fur boxes) and represses the transcription of many genes. The genes directly repressed by Fur binding include those involved in the acquisition of iron, as well as numerous genes involved in other cellular processes. Under conditions of iron scarcity, Fur is present in the iron-free form and does not bind to DNA, thereby allowing the active transcription of the Fur-controlled genes. Fur also indirectly controls the iron-dependent induction of several proteins that store iron or require iron-containing prosthetic groups for activity by regulating transcription of a small regulatory RNA known as RyhB.[7] Under conditions of iron deprivation, *ryhB* is actively transcribed because Fur does not repress transcription from its promoter. This small RNA, RyhB, in conjunction with the RNA binding protein Hfq, mediates the degradation of messages encoding proteins of iron utilization (such as the Fe-S proteins succinate dehydrogenase, fumarase, and aconitase) and storage (such as the ferritins encoded by *ftnA* and *bfr*) by binding to complementary regions of the target RNAs. Because Fe^{2+}-Fur represses the transcription of *ryhB* under iron sufficient conditions, the RyhB target messages are not degraded and can be translated into proteins. The effect of RyhB expression is to prevent the synthesis of non-essential, iron-requiring proteins when iron is scarce.

Gram-positive bacteria utilize several different iron regulatory systems. In some Gram-positive bacteria, the DtxR (diphtheria toxin regulator) controls the expression of iron-regulated genes. Although DtxR exhibits little to no homology to Fur, it also acts as a Fe^{2+}-sensing transcriptional repressor.[8] Thus, different types of bacteria can coordinate the response to iron deprivation through the activity of a single iron-sensing transcription factor.

Under conditions of iron scarcity, bacteria express several high-affinity uptake systems that permit them to utilize iron from a variety of sources. Uptake of siderophore-iron chelates constitutes the primary source of iron for bacteria as well as fungi and some plants. Siderophores are low-molecular weight compounds that chelate ferric iron with very high affinity and specificity (*see* ***Iron Transport: Siderophores***). These compounds are synthesized and secreted in the iron-free form by bacteria, most fungi, and some plants. Secreted siderophores can then bind and solubilize ferric iron in the environment, and iron-siderophore chelates can be captured by specific cellular transport systems. Although microorganisms typically synthesize one or, at most, a few types of siderophores, they often express receptors for a variety of siderophores secreted by other organisms. Siderophores exhibit a variety of chemical structures, but the most common fall into two classes, the hydroxamates, which are synthesized primarily by fungi, and the catecholates, which are synthesized primarily by bacteria (Figure 1) (*see* ***Iron Transport: Siderophores***).

In Gram-negative bacteria, iron uptake is a complex process because siderophore uptake systems must facilitate

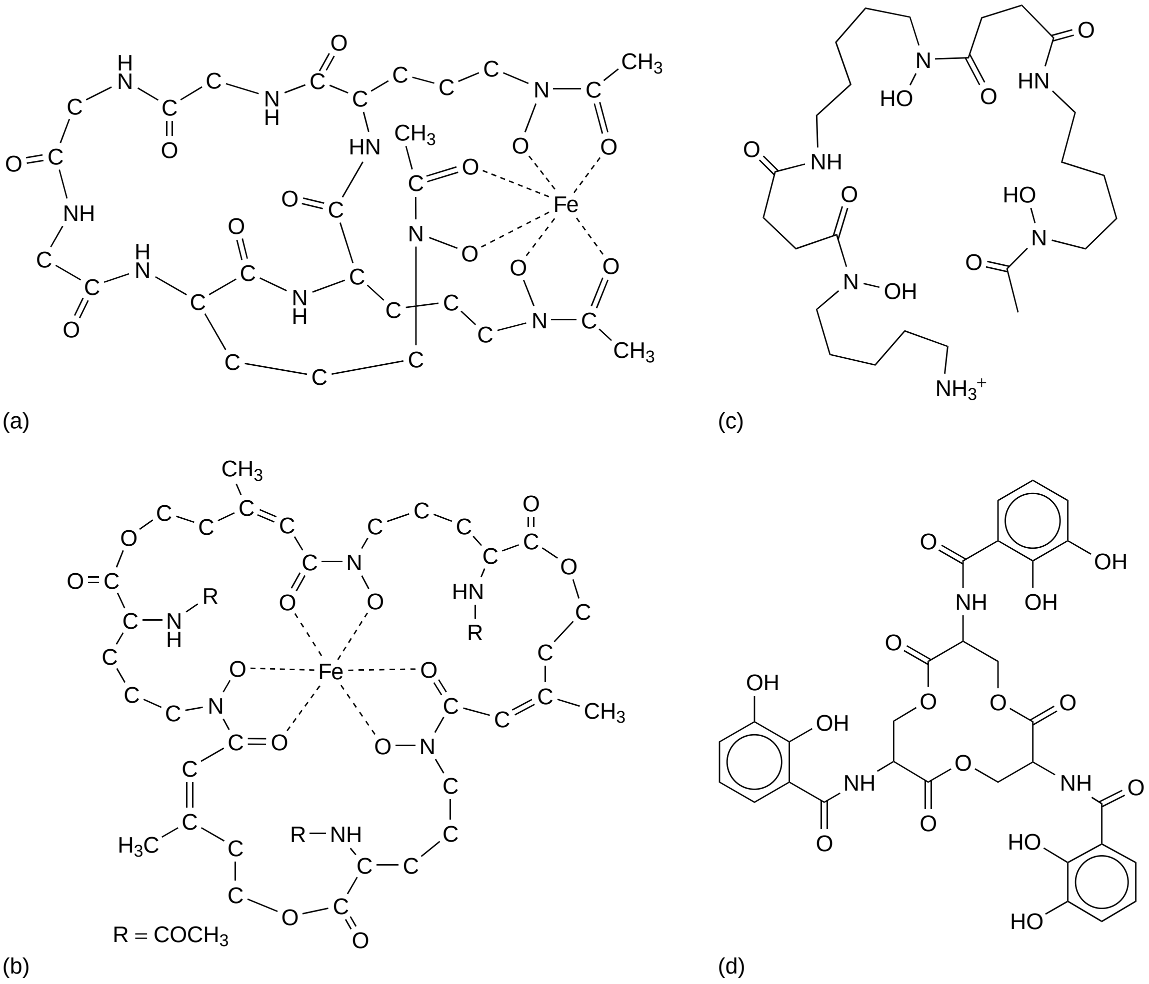

Figure 1 Representative siderophores of the hydroxamate and catecholate classes. The hydroxamates are synthesized from the amino acid ornithine that has been modified through hydroxylation and acetylation. Ferrichrome (a) is a prototypical example of the tri-hydroxamate class. Structurally, ferrichrome is a cyclic hexapeptide that consists of three modified ornithine residues (each of which has a hydroxamate side chain) and three glycines. Ferrichrome coordinates ferric iron through its three bidentate hydroxamate side chains. Triacetylfusarinine C (b) is also a cyclic tri-hydroxamate, but the three modified ornithine residues are joined by ester linkages rather than by peptide linkages. Ferrioxamine B (c) is a linear tri-hydroxamate consisting of three peptide-linked modified ornithine residues. Enterobactin (d) is a prototypical example of a catecholate siderophore. It consists of a tri-ester ring from which extend three side chains of dihydroxybenzoyl serine. Each of these siderophores binds ferric iron in a hexadentate manner, which results in full saturation of d orbitals and a very stable complex. Ferric forms are shown in (a) and (b). Desferri-forms are shown in (c) and (d)

the transport of iron across an outer membrane (OM), the periplasmic space, and an inner cytoplasmic membrane (CM) (Figure 2). Transport processes across the CM can be energized directly through the hydrolysis of cytosolic ATP or through the membrane potential generated by proton-ATPases. The outer membrane contains no energy source, however, and Gram-negative bacteria have evolved a system to overcome this energy barrier to transport. These bacteria have evolved four distinct components that facilitate the process of siderophore transport: 1) outer membrane receptors that bring siderophore-bound iron across the outer membrane to the periplasmic space, 2) an energy transmission system that conveys energy from the CM to the OM, 3) binding proteins that escort ferric siderophores across the periplasmic space to their respective CM transporters, and 4) CM transporters that carry the ferric siderophore into the cytosol of the cell (Figure 2).

Siderophore-bound iron is taken up through specific, high-affinity outer membrane receptors. Although the term 'receptor' is used to refer to this group of proteins, their activity goes beyond binding their siderophore ligands, as they also permit the movement of siderophore across the OM to the periplasmic space. *E. coli* K-12 expresses at least six OM receptors that exhibit specificity for a variety of siderophores and iron chelates, including enterobactin, an endogenously produced siderophore, and ferrichrome, a fungal siderophore.[6]

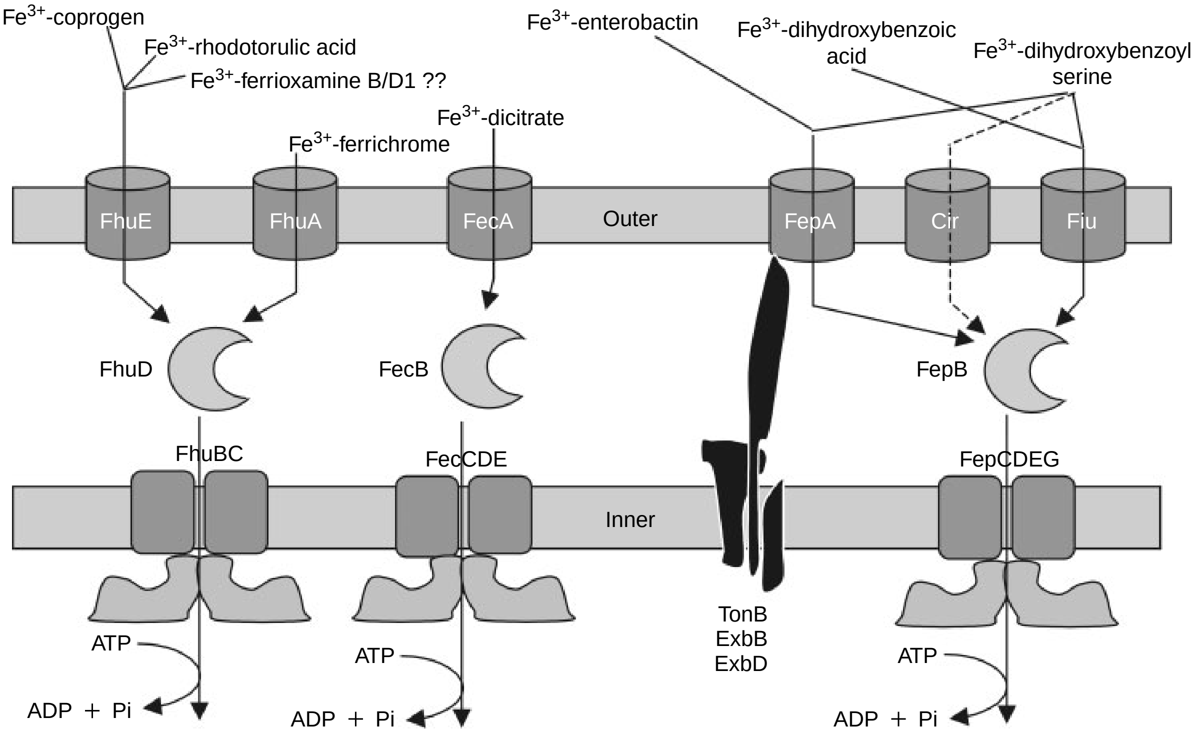

Figure 2 Siderophore-mediated iron-uptake systems in *E. coli*. Siderophore–iron complexes bind to transporter proteins located in the outer membrane (also known as OM), a barrier that is characteristic of Gram-negative bacteria. The region between the outer and inner is known as the periplasmic space. Specific carrier proteins such as FhuD transport iron from the outer membrane to the inner or cytosolic membrane (also known as CM). The TonB/ExbB/ExbD complex spans the inner and outer membranes and interacts with FepA, as shown, as well as all of the outer membrane receptors. The linkage that the TonB/ExbB/ExbD complex provides between the inner or cytosolic membrane to the outer membrane is thought to allow transmission of sufficient energy from the cytosol to drive siderophore-iron uptake across the outer membrane

Microorganisms typically express uptake systems specific for the siderophores that they synthesize as well as siderophores synthesized by other microbes, a strategy that allows them to compete for iron in an environment containing multiple microbial species. The structures of three OM receptors (FecA, FepA, and FhuA) are very similar to one another in that they are all β-barrel proteins containing 22 antiparallel β-strands that form a tube.[9] The N-terminus forms a mobile globular domain that can occupy and occlude the channel formed in the center of the tube. When FhuA binds the ferrichrome near the outer surface of the central channel, major conformational changes occur both at the outer surface and on the periplasmic face of the receptor. The position of the globular 'cork' domain then shifts to allow the bound siderophore to translocate across the membrane.

The energy that drives the proposed conformational change of the OM receptor may be transmitted to the OM by a complex of proteins anchored in the CM known as the TonB complex. Energy stored in the proton gradient of the CM may be transmitted to the OM receptors via the TonB/ExbB/ExbD complex.[9] *E. coli* expresses TonB, ExbB, and ExbD in a 1:7:2 ratio and together they form a complex of integral membrane proteins anchored in the CM. TonB extends from the CM across the periplasmic space to contact the periplasmic face of each of the OM siderophore receptors. There, TonB may induce a conformational change in the siderophore-bound form of the receptor that results in the transfer of siderophore to the periplasmic space. ExbB and ExbD form a complex with TonB within the CM and together they may enable TonB to mediate this conformational change.

Siderophores within the periplasmic space interact with periplasmic binding proteins (FhuD, FecB, and FepB in *E. coli*) that recognize a variety of siderophore substrates and bind them with micromolar affinity.[6,9] These periplasmic siderophore binding proteins are required to escort the siderophore-iron chelates to their respective siderophore-specific permease complexes in the CM. Structural studies of FhuD indicate that the periplasmic binding proteins are bilobal structures that bind siderophore in a shallow pocket between the two lobes. Amino acid residues in the binding pocket of FhuD interact with the iron-binding hydroxamate region of the siderophore, rather than its peptide backbone, thereby allowing the binding protein to recognize a variety of hydroxamate-type siderophores.

Uptake of the siderophore across the CM is dependent on specific ABC permease complexes. Each CM permease complex consists of four subunits: two identical or homologous integral membrane permeases and two cytoplasmic ATPases of the ATP-binding cassette (ABC) family that associate with the cytosolic faces of the permeases.[6,9] These complexes transport ferric siderophores, ferric citrate, and heme, although with less specificity than is observed in the OM receptors. Details of the process of siderophore transport across the CM are not known, but these transporters are presumed to operate similarly to the ABC transporters of maltose or vitamin B_{12}. On the basis of the structure of BtuCD, the vitamin B_{12} transporter, the integral membrane permeases are presumed to form a channel that is closed at the cytoplasmic surface.[10] The complex formed by association of the periplasmic binding protein with the ferric siderophore binds to the channel at the outer surface of the integral membrane permease of the CM, forming a cap that prevents leakage of the siderophore back into the periplasm. This binding of the complex also triggers the hydrolysis of ATP by the cytosolic ATP-binding cassettes, resulting in opening of the cytosolic face of the channel and the internalization of the siderophore.

Bacteria without an OM, such as Gram-positives, do not rely on OM receptors or periplasmic binding proteins for siderophore uptake.[6] Instead, extracellular ferric siderophores are bound by CM-anchored binding proteins that are similar to the periplasmic binding proteins, which then interact with ABC-type transport complexes similar to those employed by Gram-negative bacteria. Once internalized, iron is released from ferric siderophores by the activities of specific cytosolic esterases or reductases.

The ferric citrate transport system of *E. coli* is similar to the siderophore transport systems and is also subject to Fur-mediated regulation, but it is also specifically regulated at the transcriptional level by an independent mechanism dependent on the sigma factor FecI.[6] Sigma factors comprise a conserved family of bacterial proteins that specifically interact with promoter regions of genes and with RNA polymerase to stimulate transcription. When ferric citrate binds to its OM receptor (FecA), FecR senses binding, as FecR spans the CM and contains both a periplasmic N-terminal domain that interacts with FecA and a cytosolic C-terminal domain that mediates the activation of FecI. Activated FecI then induces the transcription of *fecABCD*, which encodes the ferric citrate uptake system.

Bacteria also express ferrous iron-uptake systems such as that encoded by *feoABC* of *E. coli* and other enteric pathogens.[6] These are unlike the siderophore-specific systems and are primarily expressed during growth under low oxygen tension, when ferrous iron is much more abundant than the oxidized, ferric form. FeoB contains an N-terminal GTPase domain that is required for ferrous iron uptake. It also contains 8–12 predicted membrane-spanning alpha helices in the C-terminal domain and may employ GTP hydrolysis to energize ferrous iron uptake. Ferrous iron uptake systems can be coupled with extracellular ferric reductases, which enable microbes to convert ferric iron to the reduced form before uptake by ferrous-specific systems. Although many bacteria have biochemically demonstrable ferric reductase activities, the genes encoding these proteins have not been identified.

Pathogenic bacteria are capable of using host iron proteins as nutritional sources of iron. OM receptors for the mammalian ferric iron-binding proteins transferrin and lactoferrin as well as heme and hemoglobin have been identified in a number of bacterial species. In the case of transferrin and lactoferrin, the OM receptors are composed of two subunits, one of which is homologous to the siderophore OM receptors and probably mediates transfer of the iron across the OM, and another that is structurally quite distinct. Initially iron is removed from Fe-transferrin and Fe-lactoferrin by the OM receptor, and the newly released iron is transferred across the periplasmic space via a ferric binding protein to a ferric-iron-specific ABC permease, which transports the iron into cytosol. Heme iron is taken up as an intact molecule after interacting with heme-specific OM receptors in a TonB-dependent manner. No periplasmic binding protein for heme is required and heme, like iron, is transferred into the cytosol by an ABC permease. Cytosolic heme can apparently be incorporated directly into heme proteins, or the iron can be released from heme after degradation by heme oxygenase. Cytosolic iron can then be diverted into ferritins for storage, utilized by heme or iron–sulfur cluster biosynthetic machinery, or directly incorporated into other iron–binding proteins.

2.1.2 *Iron Homeostasis in Fungi*

Unicellular eukaryotes, such as yeast and fungi, differ fundamentally from prokaryotes in that they contain multiple membrane bound organelles. The significance of this difference in terms of iron homeostasis is that fungi must not only coordinate uptake of iron with the metabolic demands of the cell, but they must also coordinate and regulate distribution of iron to different compartments within the cell. Metal metabolism has been studied in greatest detail in the model organism *Saccharomyces cerevisiae*, also known as baker's yeast, although molecular details of metal metabolism in other fungi are beginning to emerge. Under iron replete conditions, yeast import iron through low-affinity metal transporters of low specificity, such as Fet4p.[11] Excess iron and manganese are transferred to the vacuole for storage by the vacuolar transporter Ccc1p.[12] The response of baker's yeast to iron depletion includes up-regulation of high-affinity iron acquisition systems, mobilization of iron stores, sequestration of other metals, reutilization of heme iron, and down-regulation of non-essential, iron-consuming pathways.[13] These responses are primarily controlled at the transcriptional level by the transcriptional activator Aft1p.

Aft1p is a 78 kDa protein that binds to specific sites within the promoters of iron regulated genes and activates

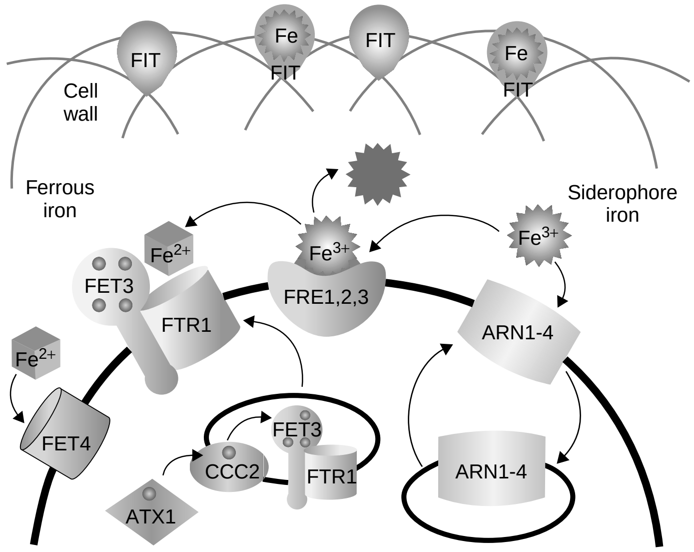

Figure 3 Iron-uptake systems of *S. cerevisiae*. The plasma membrane of yeast is surrounded by a porous cell wall that protects the cell from osmotic lysis and excludes only larger macromolecules. The *FIT* mannoproteins of the cell wall facilitate retention of siderophore-iron in the cell wall, but are not required for siderophore uptake. Many siderophores likely cross the cell wall through nonspecific pores. Siderophore-bound iron can be reduced and released from the siderophore by the *FRE* reductases. Reduced iron can then be taken up through either the high-affinity ferrous iron transporter (the Fet3p and Ftr1p complex) or the low-affinity transporter (Fet4). Ferric iron salts and low-affinity chelates are also reduced by the *FRE* reductases prior to uptake. Fet3p is a ferroxidase that requires copper for function. Fet3p does not become functional until it is loaded with copper intracellularly through the activities of the copper chaperone Atx1p and the copper transporter Ccc2p. Although the Fet3p/ Ftr1p complex mediates uptake of much of the iron released from siderophores, there is also another uptake route. Intact siderophore-iron chelates can be taken up via members of the *ARN* transporter family. The Arn transporter binds siderophore-iron, and the transporter-siderophore complex undergoes endocytosis prior to translocation of the siderophore-iron chelate across the membrane

transcription.[14] The N-terminal half of Aft1p contains a DNA-binding domain and the C-terminal half contains a transcriptional activation domain. Although the levels of Aft1p do not change with iron depletion or iron sufficiency, the subcellular localization and DNA binding activity of Aft1p is regulated by iron.[15] Aft1p is located in the cytosol and is inactive in iron-replete cells. Under conditions of iron deficiency, Aft1p translocates to the nucleus to activate transcription. Aft1p was initially identified as a dominant mutant allele, termed Aft1-1^{up}, which contains a cysteine to phenylalanine mutation in the center of the coding region. Expression of Aft1-1^{up} results in nuclear localization and transcriptional activation under conditions of iron sufficiency as well as iron deficiency.[15] A recent report indicates that mutant yeast strains with defects in heme biosynthesis are also defective in the transcription of Aft1p target genes, indicating that heme may play a role in Aft1p-dependent transcription.[16] Although Aft1p appears to act as an iron sensor in yeast, it is not known how iron is sensed or whether Aft1p binds iron. A second transcription factor with homology to Aft1p is Aft2p. Aft2p activates the transcription of a subset of the Aft1 target genes as well as a unique set of genes.[14] The role of Aft2p in iron homeostasis is not yet clear.

Aft1p target genes contain a heptanucleotide promoter sequence termed the iron-responsive element, PyPuCACCC. Most of these genes are involved, either directly or indirectly, in the uptake of iron at the plasma membrane (Figure 3). A family of cell wall proteins encoded by *FIT1*, *FIT2*, and *FIT3* is involved in the retention of siderophore-iron complexes in the yeast cell wall and the facilitation of the uptake of iron.[17] Two systems of high-affinity iron uptake are expressed in baker's yeast: one relies on the external reduction of ferric iron before uptake through a ferrous-specific transporter whereas the other relies on the direct uptake of ferric-siderophore complexes (reviewed in[18,19]). The reductive system of uptake begins with the reduction of ferric ions and ferric chelates by members of the *FRE* family of plasma membrane metalloreductases. Four members of this family catalyze the reduction of either ferric ions (Fre1p and Fre2p) or ferric siderophore chelates (Fre1p, Fre2p, Fre3p, and Fre4p). Two additional family members (Fre5p and Fre6p) have not been characterized and a seventh (Fre7p) is regulated by copper through Mac1p and is presumed to function in copper homeostasis. Reduced iron is taken up through a high-affinity transporter complex consisting of the Fet3p multicopper oxidase and the Ftr1p permease.[11] The oxidase activity of Fet3p is required for transport and the activities of the copper chaperone Atx1p and the intracellular copper transporter Ccc2p are required for copper loading of Fet3p.

The nonreductive system of iron uptake in *S. cerevisiae* is specific for ferric-siderophore complexes.[18] Although

S. cerevisiae and *Schizosaccharomyces pombe* do not synthesize or secrete siderophores, both species are capable of taking up siderophore-iron chelates. *S. cerevisiae* relies on a subfamily of four transporters of the major facilitator superfamily for siderophore uptake, and these are termed Arn1p, Arn2p/Taf1p, Arn3p/Sit1p, and Arn4p/Enb1p. These secondary transporters are predicted to contain 14 transmembrane domains and are likely energized by proton symport. Each of the Arn transporters exhibits specificity for different siderophores of the hydroxamate or catecholate class, with some overlapping specificity. Arn1p exhibits specificity for ferrichromes, Arn2p for fusarinines, and Arn3p for both ferrichromes and ferrioxamines. Arn4p exhibits no activity towards these hydroxamate siderophores and exclusively transports enterobactin, a catecholate siderophore.

The siderophore substrates of the Arn transporters influence the intracellular trafficking of the transporters, and this trafficking is important for transporter activity.[20] The ferrichrome transporter Arn1p has been the focus of studies on intracellular trafficking of siderophore transporters. When yeast cells are iron depleted, but there is no ferrichrome available for uptake, Arn1p is not expressed on the plasma membrane, but is instead located intracellularly, cycling between early and late endosomes. Integral membrane proteins of the late endosome can be sorted to the vacuole for degradation, and this is likely the fate of Arn1p when its transport substrate is not available. When ferrichrome is present in the growth medium at low concentrations, Arn1p relocalizes to the plasma membrane, and at higher ferrichrome concentrations, Arn1p begins cycling between the plasma membrane and early endosomes. This plasma membrane cycling is important for Arn1p function, as blocks to endocytosis result in decreased ferrichrome uptake. Arn1p exhibits two surface binding sites for ferrichrome and substrate binding to these sites may control the intracellular trafficking of the transporter.[21]

Aft1p also activates the expression of a group of genes that are not involved in the uptake of iron from the environment (reviewed in[13]). Some of these genes are intracellular metal transporters that are located in the membranes of the vacuole, a site of iron storage in yeast. Fet5p and Fth1 form a vacuolar transporter complex similar to the plasma membrane complex, Fet3p/Ftr1p, which likely functions in the mobilization of iron from the vacuole. Smf3p is a divalent metal ion transporter located in the vacuole with homology to the mammalian iron transporter DMT1. Cot1p is a vacuolar transporter involved in cobalt resistance and zinc transport, and is thought to function in the sequestration of divalent metals in the vacuole. Iron-depleted yeast cells also express a heme-degrading enzyme, Hmx1p, which has similarity to mammalian heme oxygenases. Aft1p also activates the transcription of the biotin permease, Vht1p, thereby linking biotin uptake to iron homeostasis.

Similar to *E. coli*, yeast down-regulate the transcription of non-essential proteins that require iron for activity when the cells become depleted of iron. *BIO2* and *GLT1* encode iron-sulfur cluster proteins that are involved in the synthesis of biotin and glutamate, respectively. These genes plus the remaining genes of the biotin biosynthetic pathway are down-regulated by iron depletion.[13] Yeast can therefore switch from biotin synthesis to biotin uptake when iron becomes limiting. The transcription factors that control this down-regulation in response to iron depletion have not been identified, but this process appears to be independent of Aft1p.

Other species of fungi express reductive and non-reductive systems of iron uptake similar to those of *S. cerevisiae*, including homologues of the *ARN* siderophore transporters, the *FRE* reductases, and the Fet3/Ftr1 oxidase/permease complex.[22] In addition, most species synthesize and secrete one or more types of siderophores, a capacity that *S. cerevisiae* and *S. pombe* lack. *Aspergillus nidulans* seems to lack a reductive system of iron uptake and is completely dependent on siderophores for iron uptake. *S. cerevisiae* also seems to be unique in the use of the transcriptional activator Aft1p. Other fungi, including *S. pombe*, *A. nidulans*, *Neurospora crassa*, and *Ustilago maydis* express an iron-dependent transcriptional repressor of the GATA family of transcription factors. Why these organisms use different transcriptional regulators to express a similar set of genes in response to iron depletion is not known.

2.2 The Challenges of Understanding Plant Iron Homeostasis

Plants also express a precisely controlled system that coordinates the uptake of iron with the nutritional requirements of the plant. A plant can be divided into two organ systems, the root and the shoot. The root includes all structures below ground and is the site of nutrient uptake. The shoot includes all plant structures above ground including stems, leaves, buds, flowers, and fruit. Plants must coordinate the uptake of iron in the root with the nutritional requirements for iron in the shoot to achieve homeostasis. Iron-deficient plants can be readily identified by their chlorosis, a yellowing of the leaf due to a lack of chlorophyll. Higher plants can be separated into two groups according to the primary strategy that they use to obtain iron from the environment (reviewed in[23,24]). Strategy I plants include dicotyledonous and non-graminaceous plants such as pea, tomato, and the model organism *Arabidopsis thaliana*. These plants utilize uptake systems similar to the reductive system of baker's yeast. In this system, ferric iron is solubilized through the pH-lowering activity of a proton-ATPase, the ferric iron is reduced to the ferrous form by a ferric chelate reductase, and the reduced iron is taken up through a high-affinity ferrous transporter. These plants also exhibit morphological changes in response to iron deficiency, with marked increases in root hair density and the appearance of specialized cells in the epidermis. Strategy II plants include the grasses (graminaceous plants) such as maize, rice, and barley. These plants rely on a siderophore-mediated uptake system that is, again, similar to that of baker's yeast. Regulation of

these systems occurs through both transcriptional and post-transcriptional mechanisms, although detailed knowledge of these processes is very limited.

mRNA transcripts of the proteins involved in iron transport accumulate rapidly in the roots of strategy I plants in response to iron deficiency. The tomato *FER* gene encodes a candidate transcription factor that may mediate this response.[23,24] *FER* encodes a basic helix-loop-helix transcription factor that is constitutively expressed in the epidermis and pericyte of the root. Absence of the *FER* protein in tomato *fer* mutants results in a complete loss of the iron-deficiency response, including the expression of ferric reductase and ferrous uptake activities and the morphological changes in roots. Whether *FER* interacts directly with promoter elements in the genes induced during the iron-deficiency response or indirectly by altering the transcription of other genes in a signal transduction cascade is not known.

Although the iron-deficiency response in roots may result from localized sensing of iron deficiency, plants must also be able to coordinate root iron uptake with the nutritional needs of the entire plant. Two pea mutants with defects in the root iron-deficiency response make clear that there is a shoot-derived transmissible signal that governs root iron uptake.[23,24] The pea mutants *brz* and *dgl* exhibit constitutively high levels of ferric reductase and ferrous uptake activities in the root, even when iron is abundantly available in the soil and within the plant. Excessive iron uptake results in necrotic bronze-spotted leaves and degenerate leaflets, respectively, due to an over-accumulation of iron in the leaves. These mutations are recessive and non-allelic, and grafting of mutant shoots onto the roots of wild-type plants results in the expression of the mutant phenotype in the roots, thus indicating the existence of a transmissible signal from shoots.[25] The genes that correspond to the *brz* and *dgl* mutations have not been identified. The *Arabidopsis* mutant *frd3* also exhibits constitutively high levels of ferric reductase and ferrous uptake activities, resulting in accumulation of iron in roots and leaves.[23,24] *FRD3* encodes a polytopic transmembrane protein of the multidrug and toxin efflux (MATE) family and likely facilitates the transport of small molecules across a membrane. *FRD3* is expressed solely in roots and may be involved in the transport of a signaling molecule from the shoot to the root. Alternatively, *FRD3* may act as a receptor for a signaling molecule from the shoot. This molecule might signal iron sufficiency to the root, and, in the absence of *FRD3*, the root fails to receive the iron sufficiency signal and continues to express the iron-deficiency response.

Genes involved in the acquisition of iron in the root have been identified for both strategy I (reductase and ferrous transport) and strategy II (siderophore uptake) plants. In response to iron deficiency, strategy I plants acidify the soil through the activity of a plasma membrane-based, proton-extruding ATPase. A candidate gene encoding this activity is *AHA2*.[23,24] Ferric iron salts and chelates must be reduced prior to uptake and a family of ferric chelate reductases has been identified in *Arabidopsis*. *FRO2* was identified by a PCR-based strategy through its homology to the baker's yeast *FRE* family of plasma membrane metalloreductases. Similar to yeast Fre1p, FRO2 contains putative binding sites for heme and nucleotide cofactors, and expression of FRO2 restores ferric reductase activity in reductase-deficient mutants. *FRO2* is part of a five-member gene family in *Arabidopsis*. Although the other members of this family have not been characterized, they may be involved in reductive iron transport across membranes in other parts of the plant. Iron transport across the plasma membrane of root epidermal cells occurs through the IRT1 ferrous iron transporter. IRT1 is a member of the ZIP family of metal transporters that are found in many eukaryotes, including yeast, plants, worms, and mammals. *Arabidopsis* IRT1 was initially identified through its capacity to restore growth and iron uptake to a yeast *fet3fet4* mutant that completely lacks high-affinity iron uptake. Plants that are homozygous for a deletion mutation in *irt1*exhibit a chlorosis that is typical of iron-deficient plants and a severe growth defect in soil. This growth defect is rescued by the addition of high concentrations of iron to the soil. The roots of *irt1* mutant plants are also defective in the accumulation of zinc, manganese, cadmium and cobalt, indicating that IRT1 has broad transition metal specificity. A homologue of IRT1 from tomato can also restore growth to yeast deficient in copper uptake, although *Arabidopsis* IRT1 cannot. Arabidopsis expresses a second ZIP family member, IRT2, and ZIP family members have been identified in strategy II plants as well. These transporters may have roles in intracellular metal transport or metal transport in other organs of the plant.

Strategy II plants synthesize and secrete iron-chelating phytosiderophores of the mugineic acid (MA) family in response to iron deficiency.[23,24] MA is produced from *S*-adenosyl methionine by the enzymes nicotianamine synthase and nicotianamine aminotransferase, and the levels of these enzymes increase in response to iron deficiency. The molecular details regarding the secretion of MAs are unknown, but the maize mutant *yellow-stripe-3 (ys3)* exhibits an iron-deficient phenotype due to impaired secretion of MAs. Following chelation of iron in the soil, ferric-MAs are taken up by a MA-specific, high-affinity transporter that was identified in the *maize yellow-stripe-1 (ys1)* mutant. Maize *ys1* mutants are iron deficient owing to a defect in the uptake of ferric-MAs, and the *YS1* gene was identified through transposon tagging. YS1 is a member of the oligopeptide transporter family and expression of YS1 in a yeast *fet3fet4* mutant restores growth when cells are exposed to ferric-MAs, but not ferric citrate. Maize YS1 and its homologues are expressed in shoots as well as roots, suggesting that these transporters may have a role in iron transport throughout the plant. The genome of the non-graminaceous plant *Arabidopsis* contains eight genes with homology to YS1, although this plant is not known to secrete or take up MAs. The function of YS1 homologues in these plants is not clear, but the homologues may function

in the transport of iron-nicotianamine chelates within and between plant tissues. Nicotianamine, the precursor to MA that is synthesized in all higher plants, is similar to MA in both its structure and capacity to bind iron. The tomato mutant *chloronerva (chln)* is deficient in nicotianamine synthase and completely lacks the capacity to synthesize nicotianamine. The *chln* mutant exhibits constitutively high amounts of iron uptake and accumulates iron-phosphate precipitates in its roots and shoots. Despite high levels of iron uptake, *chln* mutants exhibit an iron-deficient phenotype, including chlorosis in young leaflets and altered root morphology. These data suggest that nicotianamine may be required to keep iron in a form that is metabolically available to cells, or that iron-nicotianamine complexes could act as signaling molecules for the iron-deficiency response. A small iron-binding protein was recently identified in the phloem of castor bean seedlings. ITP (iron transport protein) binds ferric iron in vivo and has the capacity in vitro to bind copper, zinc, and manganese as well. *ITP* was cloned and found to encode a 96-amino acid peptide of the late embryogenesis abundant family and a homologous gene is present in *Arabidopsis*. Thus, ITP may contribute the movement of ferric iron within the vascular system.

Additional genes with homology to mammalian iron transport proteins have been identified in the genome of *Arabidopsis*.[23] These include *NRAMP1*, *3*, and *4*, which exhibit homology to the duodenal iron transporter of mammals, DMT1, and the manganese and iron transporters of baker's yeast, Smf1, 2, and 3. NRAMP1 was shown to rescue the iron-dependent growth defect of a yeast *fet3fet4* mutant as well as to cause increased iron sensitivity when overexpressed in Arabidopsis. The Arabidopsis genome also contains three genes that are homologous to the IREG1/Ferroportin 1/MTP1 iron exporter found in vertebrates. These transporters may have roles in the transport of iron from one cell type to another or in the movement of iron across membranes within the cell.

2.3 Regulation of Mammalian Iron Metabolism

2.3.1 Iron Regulatory Proteins 1 and 2 (IRP1 and 2) are Important Cytosolic Iron Sensors that Regulate Expression of Ferritin, Transferrin Receptor and Other Iron Metabolism Proteins

In the cytosol of mammalian cells, there are two proteins known as iron regulatory proteins 1 and 2 (IRP1 and 2) that are responsible for regulation of several important genes of mammalian iron metabolism. Unlike regulatory factors involved in bacterial and yeast iron homeostasis, IRPs influence the expression of major iron metabolism genes through direct interactions with mRNA transcripts. IRPs are not transcription factors and they do not interact with known transcription factors. These proteins are designed to sense cytosolic iron levels and accordingly regulate expression of major iron metabolism proteins by regulating translation of some new proteins from pre-existing transcripts or by regulating mRNA stability of other transcripts (reviewed in[26–28]).

Before we describe how IRPs function, a description of the proteins encoded by their target transcripts is needed. Two primary targets of IRP regulation are the ferritin genes that encode ferritin H and L subunits (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). Upon coassembly of ferritin H and L subunits into 24-subunit heteropolymers, iron traverses channels through the ferritin shell into its hollow interior, undergoes oxidation by a ferroxidase activity of the ferritin H subunit, and is deposited as a ferric hydroxyphosphate precipitate within the ferritin heteropolymer. Ferritin molecules can store up to 4,000 atoms of iron. Because the iron is stored as a ferric iron precipitate, the iron is not free to engage in undesirable reactions with lipids, proteins and nucleic acids. Thus, ferritin serves as a safe repository for stored iron (reviewed in[29]). Ferritin iron likely remains unavailable to cellular metabolic processes until ferritin molecules are degraded in lysosomes, an organelle responsible for turnover of many proteins in cells. After degradation of the protein shell by numerous proteases found in lysosomes,[30] the iron precipitate likely gradually solubilizes within the highly acidic interior of the lysosome[31] from whence it may be exported to the cytosol by a metal transporter known as the divalent metal transporter or DMT1.[32] Ferritin competes with other iron metabolism proteins to bind iron, and when excess ferritin is present, the cell can become functionally iron deficient.[33] Thus, cells need to avoid synthesizing ferritin until essential iron proteins such as those involved in the mitochondrial respiratory chain have incorporated sufficient iron for function.

Transferrin receptor is another iron protein that cells express according to their iron needs (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). There are two transferrin receptors encoded by two different homologous genes. The two transferrin receptors differ in that one is abundantly expressed in virtually all cell types (TfR1) whereas the second (TfR2) is expressed mainly in the liver.[34] TfR1 facilitates the cellular uptake of iron into cells throughout the body by binding serum transferrin, an abundant high-affinity ferric iron-binding protein found in the mammalian bloodstream. Upon binding transferrin, a complex of proteins including the TfR and transferrin internalizes in vesicles that bud from the plasma membrane of the cell. The newly formed vesicle undergoes acidification, whereupon ferric iron is released from transferrin, and newly released free iron is reduced and exported from the vesicle into the mammalian cytosol, most likely by the iron transporter DMT1.[32] When cells are iron-deficient, they synthesize more TfR, resulting in greater uptake of transferrin-bound iron, which in turn leads to an increase in available cytosolic iron.

2.3.2 *IRPs Regulate Expression of Iron Metabolism Proteins Mainly by Enhancing Transcript Stability or Repressing Translation*

Transcripts of both subunits of ferritin and TfR1 contain RNA stem-loop structures known as iron-responsive elements or IREs. Unlike DNA, single-stranded RNA can fold into many complex structures. In the IRE, RNA folds back upon itself to form a structure that consists of a relatively stable base-paired stem and a six-residue loop in which the first five residues have the sequence CAGUG (Figure 4). A solution NMR structure of the IRE revealed that a bulged cytosine that separates the upper and lower stems of the IRE and a guanosine residue in the six-membered loop are unusually mobile, consistent with the possibility that these residues are important recognition sites for RNA binding proteins (Figure 4).[35]

As is shown in (Figure 5), IRE stem-loops are found in the 5'UTR of ferritin transcripts and in the 3'UTR of the TfR1 transcript. In cells that are iron deficient, IRP1 and IRP2 bind to IREs in transcripts. When IRPs bind to IREs that are near the 5'end of the transcript, they interfere with binding of translation initiation factors and association of ribosomes with the transcript, thereby inhibiting new ferritin synthesis.[36] In the 3'UTR of the TfR1 transcript, there are 5 IREs that flank an endonucleolytic cleavage site. When IRPs are bound, access of endonucleases to the potential cleavage site in the transcript is blocked, and the transcript accordingly has a long half-life. When IRPs are not bound, the unprotected site

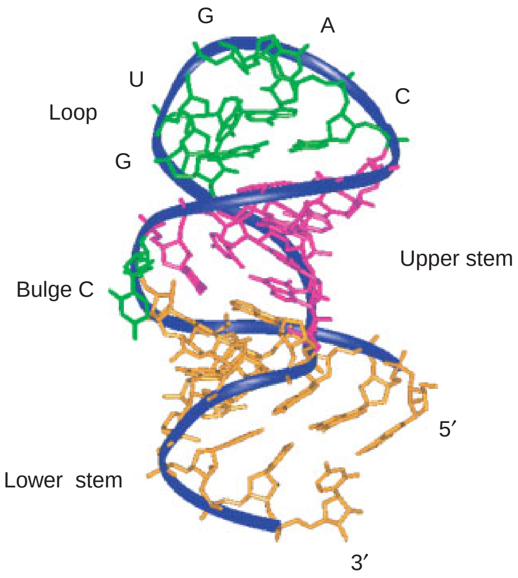

Figure 4 Structure of the iron-responsive element. Iron-responsive elements (IREs) are RNA stem-loop structures found in iron metabolism transcripts such as those that encode ferritin and the transferrin receptor. There is base-pairing between residues that creates a lower stem and an upper stem separated by an unpaired cytosine. A six-membered loop is characterized by base-pairing between residues one and five and unusual mobility of the guanosine at position 3[35]

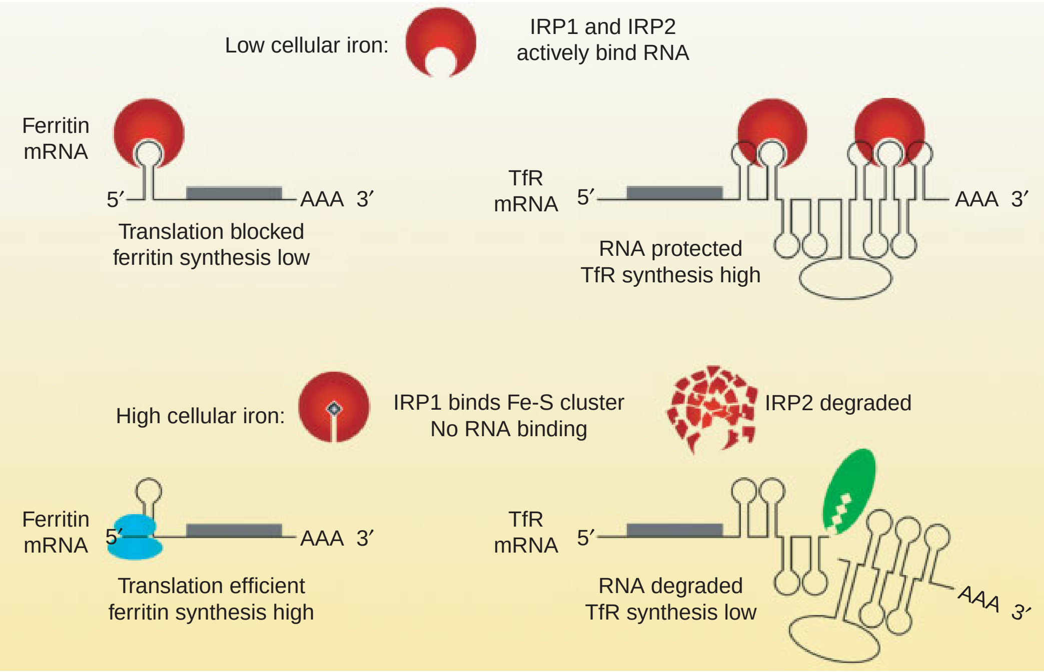

Figure 5 IRP binding to IREs. In cells that are depleted of iron, IRP1 and 2 bind to IREs. When IRPs bind to IREs at the 5′ end of the transcript, they inhibit translation and new protein synthesis from the transcript. When they bind at the 3′ end of the TfR, they protect the transcript from endonucleolytic cleavage. In iron-replete cells, IRPs do not bind to transcripts. Ferritin biosynthesis accordingly increases, whereas TfR biosynthesis drops because the transcript levels decrease

undergoes cleavage and the unprotected ends on both sides of the cleavage site undergo rapid degradation by exonucleases that are common within cells; thus, levels of TfR transcript can decrease significantly without any change in transcription rate. The decrease in transcript levels results in a decrease in the rate of synthesis of new TfR, which in turn leads to a decrease in functional TfR protein and a decrease in uptake of transferrin-bound iron (reviewed in[26–28]).

Several other iron metabolism proteins contain IREs, including ferroportin, an iron exporter,[37] the erythrocyte form of aminolevulinic acid synthase,[38] an enzyme important in heme biosynthesis, an alternatively spliced transcript of the iron transporter DMT1,[32,39] and mammalian mitochondrial aconitase.[40] The importance of these IREs in regulation of these transcripts is the subject of ongoing research.

It is important to note that although much regulation of ferritin and TfR is post-transcriptional, significant transcriptional regulation of ferritin[29] and TfR[41] occurs in some settings.

2.3.3 *Mechanisms of IRP 'Sensing' of Iron Levels*

An important question in metalloregulation is to understand how IRP1 and IRP2 sense iron levels and modify their IRE-binding capability (reviewed in[26,27]). IRP1 and IRP2 are 58% identical to one another at the amino acid level, and inspection of the exon-intron structure suggests that IRP2 arose as a result of duplication of the IRP1 gene. IRP1 is a member of the aconitase gene family.[42] Aconitases are iron-sulfur proteins that interconvert the citric acid cycle intermediates, citrate and isocitrate, and are found in bacteria, yeast, animals and plants.[43] In eukaryotes, the citric acid cycle operates in mitochondria. Mammalian mitochondrial aconitase is the product of a unique gene, and it resides exclusively in mitochondria because the N-terminus of the newly synthesized protein contains information required to target the protein to mitochondria. IRP1 has sequence homology to mitochondrial aconitase, but IRP1 encodes an aconitase that resides in mammalian cytosol rather than mitochondria. Like mitochondrial aconitase, this cytosolic IRP1 contains a cubane [4Fe-4S] cluster (*see* ***Iron–Sulfur Proteins***) at the active site cleft and functions as an aconitase, interconverting citrate and isocitrate in mammalian cytosol. However, when the iron–sulfur cluster is absent, the apo form of IRP1 binds IRE stem-loops with high-affinity. Thus, the presence or absence of the iron–sulfur cluster determines whether IRP1 will function as a cytosolic aconitase or as an IRE-binding protein.[44] In animal tissues, the vast majority of IRP1 is in the form of cytosolic aconitase. IRP1 is highly expressed in brown fat and kidney, two tissues where its role in citrate metabolism could be particularly important. However, animals that lack IRP1 do not have obviously compromised intermediary metabolism, and iron metabolism is minimally compromised in these tissues, suggesting that the functions of IRP1 are not unique and essential.[45]

Although IRP2 is homologous to IRP1, it does not function as an aconitase and does not appear to incorporate an iron–sulfur cluster. Unlike IRP1, IRP2 is degraded and is therefore physically absent in iron-replete cells, whereas IRP1 converts to its aconitase form in iron-replete cells. The rate of IRP2 degradation is enhanced by increases in both iron and oxygen concentrations.[46,47] IRP2 also contains an extra exon that encodes 73 amino acids that are unique to IRP2, and IRP2-like genes that contain this extra exon are found only in mammals.[48] IRP2 degradation is carried out by the ubiquitin-proteasomal degradation system.[49] Proteasomes are cylindrical multimeric proteins that project multiple proteases into the inside of the cylindrical structure. When proteins are marked as abnormal by multiple covalent additions of the peptide ubiquitin, the polyubiquitinated proteins bind to proteasomes. Proteasomes utilize energy captured from ATP hydrolysis to unfold ubiquitinated proteins and thread the denatured peptide through the proteasomal 'cylinder,' where it undergoes proteolysis. IRP2 readily undergoes iron-dependent oxidation and cleavage in vitro,[50] but it is unclear whether direct iron-binding is important an important step in IRP2 degradation in living cells.[47,51] It is also possible that heme binding is important in the ability of IRP2 to correctly sense intracellular iron concentrations.[47,52] Initially, a group of conserved cysteines unique to IRP2 that bind iron and mediate metal-catalyzed oxidation and degradation of the protein in vitro were thought to bind iron and mediate oxidation of IRP2 in vivo. Indeed, mutagenesis of these cysteines inhibits direct iron-dependent oxidation of IRP2 in vitro.[50] However, full-length IRP2 that contained the same cysteine mutations still was iron-dependently degraded when expressed in cells.[47] Thus, function of a well-defined iron-binding site in IRP2 is surprisingly not needed for cellular iron-dependent degradation of IRP2, and the exact molecular mechanisms that enable IRP2 to function as a cytosolic iron sensor remain unclear.

2.3.4 *IRP2 Dominates Regulation of Iron Homeostasis in Mammals*

In mice and many other animals, it is possible through recombinant DNA techniques to assess the role of particular genes by selectively eliminating the ability of mice to manufacture the protein encoded by a specific gene of interest. Mice in which the gene is interrupted are commonly referred to as 'knockout mice' and are said to be 'genetically ablated' or 'null' at a particular locus. Mice that are genetically ablated at the IRP2 locus have been generated and are referred to as IRP2-/- mice.[53] Studies of cells in tissue culture indicate that both IRP1 and IRP2 respond to changes in 'free' iron levels in cells and participate in post-transcriptional gene regulation. To evaluate the role of IRPs in living animals, genetic ablations of IRP1 and IRP2 have been performed. These studies have yielded a somewhat surprising result: they indicate that IRP2 is overwhelmingly responsible for

post-transcriptional regulation of iron metabolism in mice, whereas IRP1 contributes much less to mammalian iron homeostasis.[45] IRP2-/- mice over-express ferritin in liver, kidney, spleen and brain, as would be expected if IRP2 is responsible for repressing ferritin translation in these tissues. In the brain, levels of TfR are decreased, consistent with what we expect if there is little IRE-binding protein available to protect the TfR transcript. An unexpected result of the IRP ablation studies was that IRP2-/- mice develop adult-onset neurodegeneration with features of Parkinson's disease.[53,54] This interesting result implies that primary misregulation of iron metabolism in the central nervous system can lead to dysfunction and death in neurons in adult animals.[55] Although these iron metabolism abnormalities affect virtually all tissues, only the central nervous system develops significant pathology, whereas the other tissues such as the liver and kidney continue to function despite abnormalities in iron metabolism. Abnormalities of numerous iron metabolism genes are now implicated in neurodegenerative disease,[56,57] and these results underscore the importance of understanding metal homeostasis in animals.

2.3.5 *Mitochondrial Iron Homeostasis May be Regulated by an Iron-sulfur Protein*

Earlier we mentioned that metalloregulation of organelles is an emerging important topic. Mitochondrial iron homeostasis presents an interesting challenge in metalloregulation. Iron-sulfur clusters are synthesized and inserted as prosthetic groups into mitochondrial proteins, and much iron is needed for assembly and function of these respiratory chain proteins. In addition, insertion of iron by ferrochelatase in the final step of heme biosynthesis also takes place in mitochondria. Yet, we still do not know with certainty how elemental iron enters or exits mitochondria, and we also do not know how heme is exported. In yeast, uptake of elemental iron into mitochondria may be mediated by the Mrs3 and 4 transporters.[58,59] Mammalian counterparts to these genes exist,[60,61] raising the possibility that regulation of mammalian mitochondrial iron import can be studied by analyzing mRNA and protein levels of the mammalian homologue of the Mrs3/4 transporter in various settings. In yeast and mammals, it is now recognized that mutations in genes involved in iron-sulfur cluster assembly genes are associated with marked mitochondrial iron overload.[62–66] Abnormal iron-sulfur cluster biogenesis plays a causal role in several human diseases, including Friedreich's ataxia[67] and some sideroblastic anemias.[68] The observation that abnormalities in iron-sulfur biogenesis lead to mitochondrial iron overload raises the interesting possibility that perhaps an iron-sulfur protein regulates mitochondrial iron homeostasis. When iron-sulfur cluster synthesis is compromised, this proposed regulatory protein registers mitochondrial iron starvation and acts to increase iron uptake and to decrease iron export. Many other possible interpretations are possible, but the fact that IRP1 can become an IRE-binding protein in the absence of an intact iron–sulfur cluster is a reminder that apoproteins can change conformationally and acquire new functions.

2.3.6 *A Peptide Hormone Synthesized in Liver, Hepcidin, Coordinates Mammalian Iron Physiology*

In mammals, multiple tissues must act in concert to ensure that iron is sufficiently available in the bloodstream to support the needs of various tissues and processes. Most circulating transferrin-bound iron gets incorporated into hemoglobin. Red blood cells use hemoglobin to transport iron through the bloodstream, and new red cells are constantly being manufactured in the bone marrow by a process known as erythropoiesis. Red blood cells that are more than 120 days old are phagocytosed by macrophages in spleen and liver.[69] These spleen and liver macrophages comprise the reticuloendothelial system, which plays a major role in retrieving iron from senescent red cells and returning elemental iron to the circulation. Iron exported by macrophages binds to serum transferrin, which transports the iron to tissues that are high iron consumers, such as bone marrow, the site of new red cell synthesis. The rate of red cell turnover by macrophages is so high that macrophage iron-release is the major source of iron used for the manufacture of new red cells. However, about 1 mg of iron is absorbed per day through the duodenum. Duodenal iron transport increases markedly in iron-deficient animals because transcription of proteins involved in iron transport and reduction and oxidation of metal ions increases markedly.[70] Epithelial cells that line the duodenum are highly polarized, and import machinery for free iron and heme is found on the apical membrane of these cells, in direct contact with dietary iron sources. At the opposite end of the cell on the basolateral membrane, iron export machinery operates to release iron to the bloodstream. At the apical membrane, an iron transporter known as DMT1 (Divalent Metal Transporter) was identified recently through a cloning project designed to find a gene responsible for iron-deficiency anemia in mice and also through a project designed to identify iron transporters by expressing mRNAs in Xenopus oocytes.[69] This transporter has multiple membrane-spanning domains and couples transport of Fe^{2+} to transport of a proton. As dietary iron is often found in the Fe^{3+} oxidation state, it is perhaps not surprising that a ferric reductase known as Dcytb is highly regulated by iron status.[71] Dcytb provides Fe^{2+} for transport by DMT1 at the apical surface of epithelial cells.

Recently, a peptide hormone known as hepcidin has been implicated as a major circulating molecule that coordinates iron metabolism responses in the reticuloendothelial system and the duodenum.[72] The presence of a circulating factor helps to explain how sites that are physically distant from one another, such as the duodenum and spleen, can coordinately regulate the amount of iron that they release into the bloodstream. Hepcidin negatively regulates iron absorption through the small intestine, iron transport across the placenta,

and iron release from macrophages. Hepcidin is synthesized in hepatocytes, and its synthesis is repressed in anemic animals. Hypoxia directly represses hepcidin synthesis in hepatocytes by unknown mechanisms,[73] but activation could involve an oxygen/iron sensor known as hypoxia inducible factor.[74] Hepatocytic hepcidin transcription can also be activated by signals from adjacent macrophages, which release factors including interleukin-6 that activate the hepcidin promoter. Like many hormones, hepcidin likely binds to specific receptors on the surface of cells that activate or repress transcription of multiple genes in the target cell. The nature of the receptor is still unknown, but another gene likely to be in the same pathway has recently been described.[75] An important future research area will involve determining how interaction of hepcidin with the cells of the duodenum and reticuloendothelial system results in regulation of iron export from these tissues.

3 REGULATION OF ZINC METABOLISM

Zinc is a required cofactor for hundreds of catalytic enzymes (*see* ***Zinc Enzymes***) and a required structural component of numerous proteins such as transcription factors (*see* ***Zinc: DNA-binding Proteins***) in organisms ranging from bacteria to man. Unlike other transition metals, zinc has a stable oxidation state. Zinc can easily shift its coordination number, and through its positive charge, it acts as a Lewis acid, facilitating formation of hydroxide ion from bound water and polarizing various substrate compounds to facilitate chemical rearrangements (*see* ***Zinc Enzymes***). These unique features likely account for the fact that zinc is a cofactor for enzymes from every recognized category, including oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases.[76,77] In zinc finger domains, zinc provides a structural center which directs folding of proteins into finger-like structures that are well-suited to binding of DNA (*see* ***Zinc: DNA-binding Proteins***). Zinc finger motifs are a common feature of transcription factors as well as numerous other proteins in cells.[78] Zinc is also highly concentrated in synaptic vesicles of some neurons, where its exact role remains unclear.[79] Because zinc is required by numerous proteins, zinc homeostasis is highly regulated in all cells and organisms to optimize availability. Excess zinc is toxic, but unlike some other metals, its toxicity is not directly attributable to redox activity. Rather, it appears likely that excess zinc may compete for the protein binding sites of other metals and thereby interfere with the normal functions of these metalloproteins.[80]

3.1 Regulation of Zinc Homeostasis in Prokaryotes

Much interesting work has been done on zinc regulation in *E. coli*, and this work will serve as the basis for discussion of prokaryotic zinc metalloregulation. In *E. coli*, zinc homeostasis is achieved by independently regulating two separate processes, the import of zinc across the plasma membrane into the bacterial cytosol, and the export of zinc from cytosol. Since there are no membranous organelles within bacteria, sensing of cytosolic zinc levels drives the appropriate regulatory response. There are two known prokaryotic cytosolic sensors: Zur, a protein in which zinc binding leads to dimerization and transcriptional repression of genes involved in zinc uptake, and ZntR, a zinc-binding protein that activates transcription of a zinc efflux gene.

Zinc uptake in *E. coli* is mediated by an import system known as *znuABC* (Zn^{2+} uptake), which encodes a periplasmic binding protein, ZnuA, an ATPase known as ZnuC, and an integral membrane protein, ZnuB.[81,82] Transcription of the *znuACB* gene cluster is regulated by the Zur gene product, which acts as a transcriptional repressor when it binds zinc.

Zinc efflux is mediated by a zinc exporter known as ZntA (Zn^{2+} transport or tolerance), a membrane protein which was identified through studies of bacterial strains that were hypersensitive to zinc and cadmium. Sequence inspection revealed that ZntA was a member of the family of cation transport P-type ATPases,[83] a major family of ion-translocating membrane proteins in which ATPase activity in one portion of the protein is used to phophorylate an aspartate within a highly conserved amino acid sequence, DKTG, in another portion of the protein. The cysteine rich N-terminus of these soft metal transport proteins contains several metal-binding sites.[84] How the chemical energy released by ATP hydrolysis results in metal ion transport is not yet known, in part because there is only partial information about the structures of these proteins.[85] The bacterial zinc exporter also pumps cadmium and lead and is therefore also involved in protection from heavy metal toxicity[84,86] (*see* ***Metal Ion Toxicity***).

The increase in zinc efflux is achieved through transcriptional activation of the *zntA* gene, which in turn leads to increased ZntA protein levels. When cytosolic zinc levels rise beyond a certain point, the transcription factor ZntR[87] activates transcription of the *zntA* gene. ZntR is related to MerR, a mercury binding protein that regulates expression of mercury detoxification genes. Like MerR,[88] ZntR binds constitutively to the promoter of its target gene whether it contains or lacks zinc (apo-ZntR). Apo-ZntR distorts the promoter of *zntA* and inhibits transcription, but when zinc binds, the conformation of the ZntR changes to allow active transcription from the *zntA* promoter.[89]

Until recently, it was difficult to approach the question of how zinc concentrations are sensed within cells. Zinc proteins are abundant, and total zinc concentrations are quite high within cells (0.2 mM), even though most zinc is tightly bound to proteins and is therefore unlikely to be sensed by cytosolic regulatory proteins. The idea that cytosolic regulatory proteins sample a pool of free or loosely bound zinc at micromolar to picomolar concentrations has recently been discarded in favor of a model in which it is postulated that there is virtually

no free zinc within the cytosol of bacterial cells.[90] This interesting conclusion was arrived at by performing in vitro transcription assays of Zur and ZntR as a function of free zinc concentrations. Since each of these transcription factors is repressed (Zur) or activated (ZntR) by zinc binding, the amount of zinc required for their activation could be directly assessed. Surprisingly, the sensitivity of these proteins was determined to be in the femtomolar range. The extraordinary affinity of these zinc sensors implies that there is virtually no free zinc in *E. coli*. These results are consistent with the possibility that zinc trafficking proteins exist which escort zinc to recipient proteins, analogous to the situation which has been described for copper trafficking by chaperone proteins (*see* ***Metallochaperones & Metal Ion Homeostasis***).[91] Another impressive and interesting result was that repression of the zinc uptake apparatus by Zur occurred at a free zinc concentration of approximately 2×10^{-16} M, whereas zinc efflux was not activated by ZntR until the concentration of zinc rose to approximately 11×10^{-16} M. If these two values are taken to represent the concentrations that respectively define physiologic zinc deficiency and zinc toxicity, then it is clear that intracellular zinc levels are very tightly controlled. These results also reveal that different affinities for a given metal allow a hierarchy of responses, in which metal uptake is repressed well before the cell goes to the extra effort of actively exporting the metal.[90]

3.2 Eukaryotic Zinc Homeostasis

In yeast, a transcription factor known as Zap1 regulates expression of at least 40 genes in the genome.[80] Intriguingly, Zap1 encodes a zinc finger protein that transcriptionally activates genes that contain a promoter consensus site known as a zinc-responsive element (ZRE). Direct binding of zinc in the zinc fingers determines whether Zap1 is active: in the absence of zinc, Zap1 activates transcription in target genes.[92] Among the targets of Zap1 are transporters in the solute carrier 30 family of proteins (SLC30).[93] All of the members of this large gene family, which has multiple yeast and mammalian examples, mediate zinc efflux from cytosol into intracellular compartments or across the plasma membrane to the external milieu. Another family of proteins known as the SLC39 proteins consists of proteins that transport zinc into cytosol, the opposite direction of the SLC30 family members.

One of these genes encodes a transporter known as Zrt1, which is not only a target of the transcription factor Zap1, but is also regulated post-translationally. When cells are exposed to high levels of zinc, this plasma membrane zinc transporter undergoes ubiquitination, which leads to targeting to the vacuole and degradation. Thus, in yeast, there is a two-tiered regulatory system, in which a transcriptional activator mediates effects on expression of over 40 genes, but the cell can protect itself from toxic zinc uptake almost immediately by degrading zinc importers that are present on the plasma membrane at the onset of zinc stress.[80] The fact that Zap1 activity is determined by zinc-binding is consistent with the recurring theme that regulation of metal homeostasis is usually implemented by a protein that directly binds the metal in question. Plants regulate zinc transport and distribution, but the mechanisms of regulation are not yet well understood.[94] In mammals, there is little known about Zap1 counterparts, but this will represent an interesting area for further research.

4 REGULATION OF COPPER, MANGANESE AND NICKEL HOMEOSTASIS

Recent reviews on copper homeostasis in *E. coli*[95] and yeast are available.[96,97] Copper and iron metabolism are often intertwined. For instance, mammalian iron metabolism depends on the copper protein, ceruloplasmin, a ferroxidase that facilitates iron efflux from cells (*see* ***Copper Proteins: Oxidases***).[98] Several important human diseases, including Menkes disease and Wilson's disease, result from mutations in copper transport (*see* ***Metal-related Diseases of Genetic Origin***).[99]

Less is known about regulation of manganese homeostasis than other metals. However, several recent reviews of regulation of manganese in bacteria are available.[100,101]

The reader is referred to a recent review on bacterial nickel uptake for information on nickel regulation.[102]

1 INTRODUCTION

Metallothionein (MT) is a generic name for a superfamily of ubiquitous low molecular mass proteins or polypeptides (*see Polypeptide*) possessing a novel type of sulfur-based metal clusters (*see Cluster*; *Polynuclear Complexes*; and ***Polynuclear Organometallic Cluster Complexes***), usually formed by the preferential coordination of d^{10} metal ions (*see* d^n *Configuration*). The designation 'metallothionein' reflects the extremely high thiolate sulfur and metal content, both of the order of 10% (w/w). More than four decades after their discovery by Margoshes and Vallee in 1957,[1] the biological role of MTs is often considered to be enigmatic. However, in the postgenomic era it is increasingly clear that MT fulfills protein functions, the relative importance of which depends very much on specific evolved requirements of the particular organism. This is not unexpected, as its unique structural characteristics, potent metal binding, and striking chemical reactivity have bearing on numerous biochemical processes. Vital roles for this pleiotropic protein often result from sequestration of environmental toxic metals cadmium and mercury or its involvement in homeostasis of essential trace metals zinc and copper (*see* ***Metal Ion Toxicity*** and ***Metalloregulation***). They also play a critical role in the chemotherapy of certain cancers, both in the development of tolerance to chemotherapeutics and as an adjunct to reduce toxic side effects. In mammalian cells, the binding of copper to MT plays mainly a role in copper sequestration in copper-related disorders such as Menkes and Wilson's disease (*see* ***Metal-related Diseases of Genetic Origin***). In contrast, in lower organisms and fungi, solely copper-containing MT forms are often present, signifying their functional importance. However, it is becoming increasingly clear that MTs, the major intracellular zinc-binding proteins, play an important regulatory role in zinc uptake, distribution, storage, and release. Apart from their role in zinc metabolism, recent studies suggest their involvement in a number of biological processes, among others, protection against reactive oxygen species, adaptation to stress, protection against brain injury, antiapoptotic effects, or regulation of neuronal outgrowth.[2–4]

The purpose of this article is to cover the structure and chemistry of these proteins and related nonproteinaceous polypeptide complexes with divalent and monovalent metal ions, thereby updating our contribution to the first edition of the Encyclopedia of Inorganic Chemistry.[5] The different aspects of MT structures[6,7] and the recent advances in our knowledge regarding their function have been described.[2,3] A number of general reviews and conference proceedings covering all aspects of MT research are also available.[8–11] As the number of references in this contribution is to be kept to a minimum, in many instances only these review articles will be quoted.

2 OCCURRENCE, DEFINITION, AND ELEMENTARY STRUCTURE

2.1 Occurrence and Definition

MTs have been isolated from vertebrates, invertebrates, plants, and eukaryotic microorganisms (*see Eukaryote*) and from some prokaryotes. Most MTs isolated to date are inducible cellular products (*see Gene Expression*). All vertebrates examined contain two or more distinct MT isoforms, designated MT-1 through MT-4. In mammals, MT-1 and MT-2 are expressed in most tissues, whereas MT-3 is primarily confined to the central nervous system (CNS) and MT-4 to the stratified squamous epithelia. The expression of the best studied MT-1 and MT-2 is regulated at the transcriptional level (*see Gene Expression*). They are inducible by a variety of compounds and stress conditions, including glucocorticoids, cytokines, reactive oxygen species, and metal ions. MT-1 and MT-2 induction by zinc is regulated through its binding to the metal-responsive transcription factor (MTF-1). Zinc binding to two out of the six zinc fingers activates MTF-1, which then binds to specific DNA motifs termed metal-responsive elements (MREs). In contrast, the MT-3 and MT-4 isoforms are relatively unresponsive to these inducers. Although MT is a cytoplasmic protein, during development and in regenerative processes it translocates to the nucleus. The significance of the nuclear retention of MT is unknown.[12] The recent introduction of recombinant-DNA technology has proven an effective alternative to their isolation from natural

sources, thereby providing a significant stimulus to the further chemical and biological characterization of this family of metalloproteins.

The first MTs isolated were those from mammalian species. They are composed of a single polypeptide chain of 61–68 amino acids, 20 of which are cysteine residues and none of which are aromatic amino acids or histidine, with a molecular mass between 6–8000 Da. All cysteines occur in the reduced form and are usually coordinated to 7 divalent metal ions (Zn^{II}, Cd^{II}) and up to 12 monovalent copper ions through mercaptide bonds, giving rise to spectroscopic features characteristic of metal-thiolate complexes (*see **S-donor Ligands***). In view of this distinct common physico-chemical signature, the MTs have been categorized into three different classes.[13] Class I comprises MTs with amino acid sequences related to the mammalian forms. Class II encompasses analogous proteins, which are only distantly related to the mammalian forms. Class III are polydisperse peptides, also known as phytochelatins, produced by plants, algae, and certain fungi to detoxify heavy metal ions. They are atypical, nontranslationally synthesized polypeptides that have a primary structure consisting of repeating sequences of the γ-glutamyl-cysteinyl dipeptide and a carboxyterminal glycine.[14] More recently, on the basis of sequence similarities and phylogenetic relationships a new classification has been proposed (http://www.expasy.ch/cgi-bin/lists?metallo.txt).[13]

2.2 Primary Structure and Metal Content

The characteristic feature of all MTs is the occurrence of Cys-Xaa-Cys tripeptide sequences (*see Sequencing*), where Xaa stands for an amino acid residue other than Cys (Table 1). Interestingly, the amino acid sequence of protist MT (approx. 100 aa) possesses a repeating Cys-Cys-Cys motif.[13] Most MTs are devoid of aromatic and histidine residues. In all mammalian isoforms, MT-1 through MT-4, the Cys are the most highly conserved residues followed by the basic residue Lys. Compared to the amino acid sequences of widely occurring MT-1/MT-2, the primary structure of brain MT-3 shows a novel Cys(7)-Pro-Cys(8)-Pro motif and two inserts that is, an acidic hexapeptide in the C-terminal region and one Thr in the N-terminal region (Table 1).[15] Only this isoform shows a growth inhibitory activity in neuronal assays. Mutational analysis has shown that the unique Thr(5)-Cys-Pro-Cys-Pro(9) motif appears to be necessary and sufficient for the observed bioactivity.[16]

The metal composition of native MTs depends on the natural source and/or on the previous exposure of the organism to metals. The inducible MT-1 and MT-2 isoforms isolated from adult and fetal human livers contain mainly zinc, while those isolated from adult human kidney contain mainly cadmium with some copper or zinc. It may be noted that in higher organisms MTs are the sole proteins in which cadmium accumulates naturally. Both mammalian tissue specific forms MT-3 and MT-4 contain zinc and copper. In contrast to MTs from mammalian sources, in which zinc, cadmium, and copper can be simultaneously bound, yeast (53 aa) and fungal (25 aa) MTs contain exclusively copper. Specific binding of cadmium or copper to different tissue specific MT forms in vivo has been encountered in the snail *Helix pomatia*.[17]

The bound Zn^{II} and/or Cd^{II} ions to MT are readily released from the protein by acidification (pH 2) yielding the metal-free protein designated as thionein or apoMT. The release of tightly bound Cu^{I} from the MT structure requires more harsh conditions such as 0.5 M HCl or treatment with specific copper chelators.[8] From ^{1}H NMR and far-UV CD studies, apoMT was estimated to contain a predominantly disordered structure.[6] From this protein form, a number of various metal derivatives have been prepared through the method of metal reconstitution (see Section 6.1).[8]

3 THREE-DIMENSIONAL STRUCTURE OF M(II)-BOUND METALLOTHIONEINS

3.1 Spatial Structure

In metallothioneins, the metal-free protein or apoMT, appears to possess a predominantly disordered structure. This conclusion has been drawn from ^{1}H NMR studies of apoMT in which the chemical shifts of proton resonances are comparable with those observed in a mixture of the constituent amino acids. In addition, the rapid exchange rate of the amide protons in

the apoprotein is also consistent with a mainly disordered structure.[18] However, upon binding of metal ions to apoMT a well-defined protein fold develops. The first elucidated three-dimensional (3D) MT structure was that of mammalian MT-2 both by multidimensional/multinuclear NMR (*see Protein Structure by NMR*) and X-ray crystallographic methods (*see* ***Diffraction Methods in Inorganic Chemistry***). The crystal structure of rat Cd_5,Zn_2-MT-2[19] and the solution NMR structures of $^{113}Cd_7$-MT-2 from rabbit,[20] rat,[21] and human[22] sources showed identical metal-thiolate cluster structures and closely similar global polypeptide folds (Figure 1).[23]

Thus, the monomeric proteins possess a dumbbell-like shape with uniformly sized and almost spherical C-terminal α- and N-terminal β-domains, each with a diameter of 15–20 Å and containing at their centers the respective four and three metal clusters: $M^{II}{}_4Cys_{11}$ and $M^{II}{}_3Cys_9$. The metal ions in both clusters are tetrahedrally coordinated by both terminal and μ_2-bridging thiolate ligands and the two-protein domains are connected by a flexible hinge region composed of a conserved Lys–Lys segment (residues 30 and 31) in the middle of the polypeptide chain. The discontinuity in the NMR structure between these two residues (Figure 1(b)) is due to the lack of NOE-based information in the NMR data as to the mutual orientation of the two domains. Comparative 2-D ^1H NMR studies of human Zn_7- and $^{113}Cd_7$-MT-2 revealed closely similar secondary structure elements and ^1H–^2H amide exchange properties indicative of a closely similar molecular architecture in the two metal derivatives.[22,24] Also, the NMR solution structure of recombinant mouse $^{113}Cd_7$-MT-1 showed a high similarity to that of Cd_7-MT-2. Within the β-domain, however, evidence for increased flexibility compared to the β-domain of MT-2 was found.[25] Relevant information is also available on the structure of the mammalian isoform MT-3. Spectroscopic data on recombinant human Zn_7- and Cd_7-MT-3 have shown that, similarly to $M^{II}{}_7$-MT-1/-2, $M^{II}{}_7$-MT-3 possesses two-protein domains, each encompassing a metal-thiolate cluster: a 3-metal cluster, $M^{II}{}_3Cys_9$, located in the N-terminal β-domain (residues 1–30) and a 4-metal cluster, $M^{II}{}_4Cys_{11}$, in the C-terminal α-domain (residues 31–68).[26] However, markedly increased structural flexibility and cluster dynamics were observed in this isoform (see Section 5). Consequently, only the solution structure of the α-domain of mouse $^{113}Cd_7$-MT-3 could be determined by NMR,[27] revealing a peptide fold and cluster organization very similar to those found in MT-1 and MT-2. The only exception being a short peptide loop in MT-3 that accommodates the acidic insert (Lys52-Glu60) relative to these isoforms (Figure 2). A β-domain peptide fold of Cd_7-MT-3 similar to that found in Cd_7-MT-1/-2 has been suggested by homology modeling studies.[27]

Complete 3-D solution structures have also been elucidated for a nonmammalian vertebrate and for three invertebrate M^{II}-MT forms: fish Cd_7-MT_nc (*Notothenia coriiceps*, 60 aa), crustacean blue crab Cd_6-MT-1 (*Callinectes sapidus*, 59 aa), lobster Cd_6-MT-1 (*Homarus americanus*, 58 aa), and echinoidal sea urchin Cd_7-MTA (*Strongylocentrotus purpuratus*, 64 aa). By analogy to mammalian MTs, all these structures reveal a monomeric protein composed of two globular domains, each encompassing a metal-thiolate cluster: two 3-metal-thiolate clusters in crustacean MTs, and a 3- and a 4-metal cluster in the same or reverse orientation with respect to mammalian MTs in the fish or urchin protein, respectively.[6,28,29] The recent NMR structure of the bacterial metallothionein SmtA (*Synechococcus* PCC 7942, 56 aa) has provided evidence for the first MT structure in which, besides

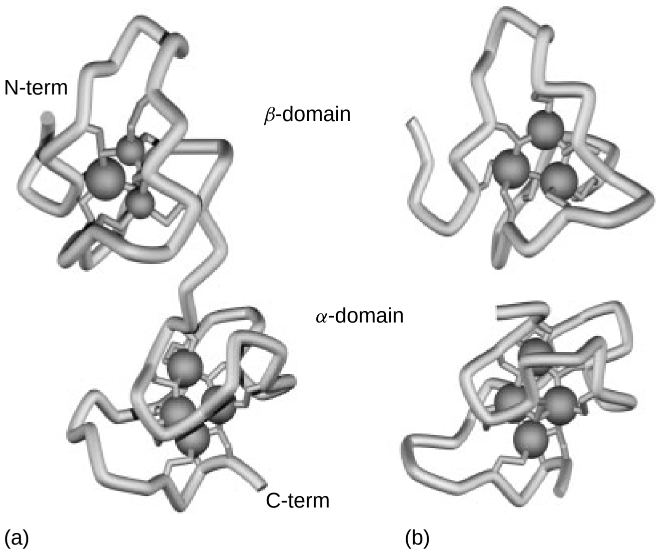

Figure 1 Three-dimensional structure of rat MT-2 as determined (a) by X-ray crystallography, Cd_5,Zn_2-MT-2 and (b) by NMR in aqueous solution, $^{113}Cd_7$-MT-2. Metals are shown as shaded spheres connected to the protein backbone by cysteine thiolate ligands (4mt2, 1mrt, and 2mrt)

cysteine thiolates, histidine ligands are also involved in metal binding.[30]

3.2 Geometry of M^{II}-Thiolate Sites and Clusters in Metallothioneins

The general structural properties that characterize all metallothioneins are the formation of metal-thiolate clusters that involve terminal and bridging cysteinyl thiolate ligands of the peptide chain. Consequently, the tertiary structure of the metallated protein is dominated by metal-thiolate clusters, bound in a single domain for the yeast, fungal, or bacterial proteins and in two domains for vertebrate and invertebrate forms. The structure of the M^{II}-clusters in mammalian MT derived from the X-ray diffraction data is shown in Figure 3.[19] The crystallographic structure fully confirmed the geometrical organization of the ligands in the metal binding sites and the topological arrangement of the metal ions in the clusters deduced previously from a number of different spectroscopic and chemical studies, which are discussed below.

The first unambiguous evidence for a pseudo-tetrahedral geometry of metal sites involving the cysteine thiolate ligands was provided by the spin-allowed ν_3 [$^4A_2 \rightarrow {}^4T_1(P)$] ligand field transition (*see Ligand Field Theory*) present in the electronic absorption and magnetic circular dichroism (MCD) spectra of Co^{II}- (*see* ***Cobalt: Inorganic & Coordination Chemistry***) substituted MT (Co_7-MT), displaying well resolved spin-orbit coupling components at 600, 690, and 743 nm (Figure 4), and by the broad ν_2 [$^4A_2 \rightarrow {}^4T_1(F)$] absorption band in the near-IR region at 1275 nm.[31]

The same coordination geometry was also inferred from the analysis of the lowest energy LMCT bands (*see Ligand-to-Metal Charge Transfer*) in the far-UV absorption spectra of Zn_7- and Cd_7-MT, and those of corresponding tetrahedral halide complexes (*see* ***Cadmium: Inorganic & Coordination Chemistry***; *see* ***Zinc: Inorganic & Coordination Chemistry***).[32] Further support came from

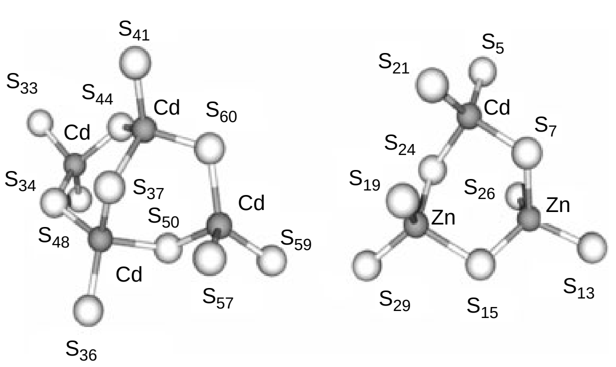

Figure 3 Schematic drawing of the two metal-thiolate clusters in mammalian Zn_2,Cd_5-MT-2: A Cd_4Cys_{11} cluster in the C-terminal α domain and a Zn_2CdCys_9 cluster in the N-terminal β domain. S^{γ} atoms are labeled by Cys residue number (4mt2)

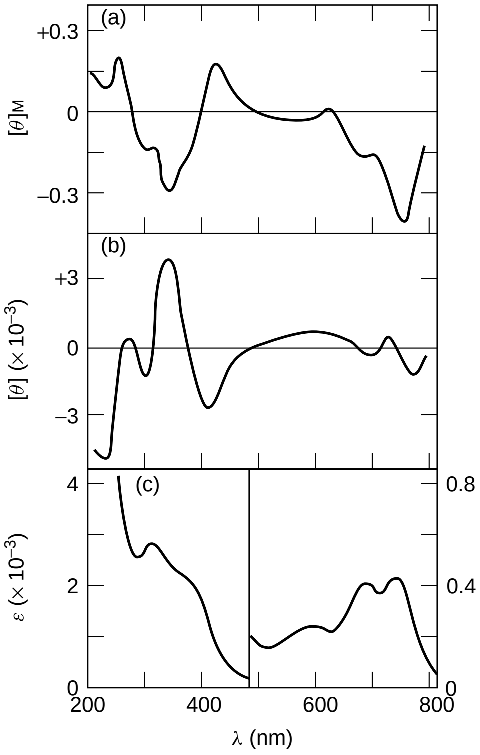

Figure 4 (a) Magnetic circular dichroism, (b) circular dichroism and (c) electronic absorption spectra of Co_7-MT-1 from rabbit liver in 20 mM Tris/HCl, pH 8.6. (Reprinted with permission from Ref. 31. © 1981 American Chemical Society)

the presence of the ligand field ν_2 [$^5E \rightarrow {}^5T_2$] transition in the electronic absorption spectrum of Fe_7-MT and from corresponding ^{57}Fe Mössbauer studies (*see* ***Iron: Inorganic & Coordination Chemistry***) in which the zero-field spectrum revealed Mössbauer parameters diagnostic of tetrahedral tetrathiolate metal coordination.[33] The T_d-type of symmetry was also deduced from Zn and Cd K-edge EXAFS (*see Extended X-ray Absorption Fine Structure*) measurements of M^{II}_7-MT ($M = Zn^{II}$, Cd^{II})[34] (Figure 5) as well as from perturbed angular correlation of gamma-ray (PAC) spectra of ^{111m}Cd-labeled MT.[35]

Similar spectroscopic approaches provided evidence for a tetrahedral tetrathiolate metal coordination with divalent metal ions in invertebrate MT forms (see Section 3.1).[6,35]

The first and most direct evidence for the existence of the $M^{II}_3S_9$- and $M^{II}_4S_{11}$-cores in mammalian MTs came from the homonuclear ^{113}Cd NMR decoupling studies on ^{113}Cd reconstituted Cd_7-MT-2.[36] Evidence for a similar cluster organization involving the tetrahedral $M^{II}S_4$ centers was also obtained for Co^{II}- and Fe^{II}-containing MT derivatives. For Co_7-MT such evidence has come indirectly from the temperature dependence of isotropically shifted proton resonances (between −50 and 300 ppm) of the Cys residues of the Co_4-cluster in the C-terminal domain.[37] This was further confirmed by MCD, ESR (*see Electron*

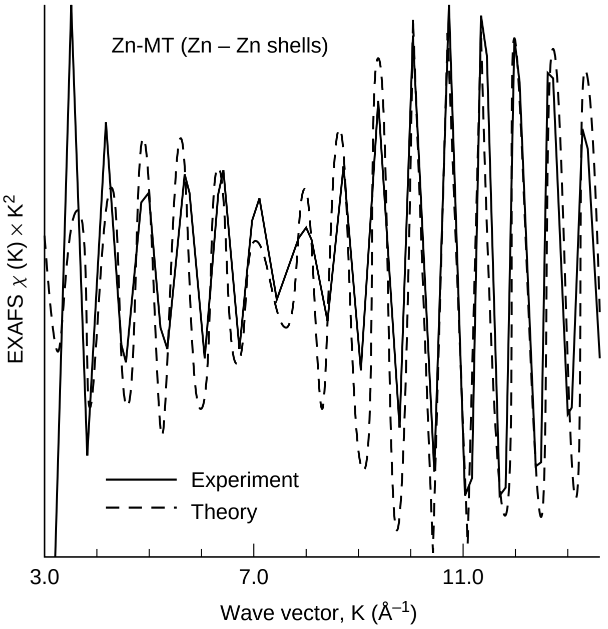

Figure 5 Fourier filtered EXAFS data (R = 4.6–5.8 Å) of Zn_7-MT from rabbit liver and a theoretical simulation with two Zn–Zn separations at 4.8 Å and 5 Å. (Reproduced with permission from Ref. 34. © the Biochemical Society)

Paramagnetic Resonance) and magnetic susceptibility studies of Co_7-MT[35] as well as by ^{1}H NOESY experiments (*see Paramagnetism*).[38] As for Fe^{II}_7-MT, the magnetic properties of the Fe^{II} binding sites provided the information concerning the cluster structure (*see Magnetic Susceptibility*). Thus, whereas an adamantane-like 4-metal cluster similar to that found in other M^{II}_7-MTs (Figure 3) was inferred from strong antiferromagnetic couplings, the weak magnetic exchange couplings between the remaining three adjacent Fe^{II} ions were consistent with a pseudoplanar Fe_3-cluster being present in Fe_7-MT.[39] Analogous magnetic properties have been reported for a number of crystallographically characterized trinuclear $[Fe_3(SR)_3X_6]^{3-}$ clusters ($X = Cl^-$, Br^-; R = Ph, *p*-tolyl, 2,6-$Me_2C_6H_3$) distinguished by the preferential formation of a planar $Fe_3(\mu_2\text{-SR})_3$ ring.[40]

Apart from the 3-metal cluster in Fe_7-MT, which would represent the first example of structural differences in binding divalent metal ions to MT, there is a remarkable overall structure similarity among the 4- and 3-metal clusters in different M^{II}_7-MT forms. The cluster geometry of the 3-metal clusters can be best described as a distorted boat cyclohexane-like ring, and all 4-metal clusters possess an adamantane-related geometry with the metals and donor atoms arranged in two fused six-membered rings, which almost exclusively adopt distorted boat conformations. A detailed analysis of the metal-thiolate cluster geometries in MTs and inorganic models have recently been reported.[7] This analysis revealed that the predominance of boat-type conformations in MTs contrast with the chair-type usually found in related metal-thiolate complexes. Interestingly, it should be noted that among the extensive family of homoleptic thiolate complexes, those of the formula $[M_3(SR)_9]^{3-}$ and $[M_4(SR)_{11}]^{3-}$ ($M = Zn^{II}$ or Cd^{II}) are unreported.[7] The available inorganic models which approximate best the metal-thiolate clusters in MT are those of adamantane-like cages with monodentate thiolate ligands of the general formula $[M_4(SPh)_{10}]^{2-}$ ($M = Cd^{II}$, Zn^{II}, Co^{II}, Fe^{II}) (Figure 6).[41]

Information on cluster formation in MTs has been forthcoming from various chemical and spectroscopic studies. For instance, by monitoring the intensity of the rhombically distorted Co^{II} EPR signal of Co-MT at pH 8.6 as a function of increasing Co^{II} to apoMT ratios, it was found that cluster formation sets in above four Co^{II} equivalents added, as documented by the occurrence of antiferromagnetic coupling through the bridging μ_2-S-Cys ligands.[35] The transition from mononuclear tetrahedral $M^{II}S_4$ sites to a cluster structure was also manifested by a red shift of the low-energy CysS-M^{II} LMCT bands ($M = Zn^{II}$, Cd^{II}, Co^{II}, Fe^{II}) in the corresponding absorption spectra. Although the electronic basis for the red shift remains to be established, it most likely reflects the reduction of the electronegativity of the thiolate sulfur when μ_2-S-Cys ligands are involved in metal coordination. In the formation of a cluster structure in Cd-MT, this red shift occurred in parallel with a change of the originally monophasic to a biphasic CD profile with a crossover point coinciding with the position of the first LMCT band in the absorption spectrum (at 249 nm). This CD effect has been interpreted in terms of excitonic splitting of the polarized transition dipole moments in the cluster structure (Figure 7).[6,35]

The ^{113}Cd titration studies of apoMT followed by ^{113}Cd NMR measurements both at pH 7.2 and 8.6 showed that at neutral pH the successive addition of $^{113}Cd^{II}$ equivalents leads

successively to the cooperative formation of the Cd_4Cys_{11}-cluster followed by the Cd_3Cys_9-cluster. By contrast, under alkaline conditions, $^{113}Cd^{II}$ binds at first to isolated sites and the cluster formation sets in only when at least 4 metal equivalents have been added, again with the 4-metal cluster formation preceding the 3-metal cluster. This observed pH dependence of the cluster formation pathway in MT results from the difference in Gibbs' free energy consumed for the deprotonation of the Cys side chains upon binding of Cd^{II} at the two pH values.[42]

4 THREE-DIMENSIONAL STRUCTURE OF Cu(I)-BOUND METALLOTHIONEINS

The structural features of Cu^I-thiolate clusters in proteins, for example, transcription factors Ace1 and Amt1, MTs, and related proteins have been studied by various spectroscopic techniques including electronic absorption, CD, luminescence, XAS (*see X-ray Absorption Spectroscopy*), and EXAFS.[11] The absorption spectrum of Cu^I-containing MTs shows a broad absorption envelope characterized by a prominent shoulder at 262 nm and a weak shoulder at about 300 nm (Figure 8). The bands in the high-energy region (below 280 nm) originate predominantly from CysS-Cu^I LMCT transitions, whereas those in the low-energy region with

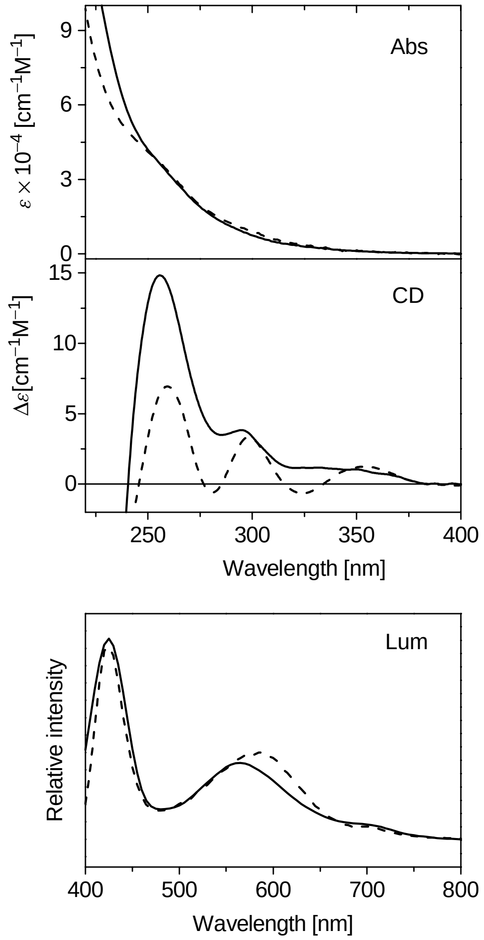

Figure 8 Electronic absorption (Abs), circular dichroism (CD) and luminescence (Lum) spectra, at 77 K and excitation at 300 nm, of human Cu_4,Zn_4-MT-3 (———) and the corresponding Cu_4-cluster in MT-3 (- - - -) at pH 8.0. The spectral features shown originate from the Cu_4-cluster in both species. (Reprinted with permission from Ref. 45. © 2003 American Chemical Society)

very weak molar absorptivities, but rather strong CD bands originate from formally spin-forbidden 3d-4s metal cluster-centered transitions brought about by Cu^I-Cu^I interactions in polynuclear Cu^I complexes.[43] A prominent feature of all Cu-MT complexes is their room temperature luminescence (*see* ***Luminescence***). Upon excitation at 300 nm, yellow or orange emission bands with maxima in the 550 to 650 nm region are observed with a lifetime of about 140 μs at 77 K. The occurrence of an additional high-energy band at 425 nm in the Cu^I luminescence of certain Cu^I-containing MTs at 77 K (lifetime of about 50 μs), has been attributed to the presence of a Cu_4-cluster (Figure 8).[43,44] The measured lifetimes are consistent with the emissions from two distinct triplet excited state manifolds (*see Excited State*). The lower energy emission has been assigned to a triplet LMCT excited state and the higher energy to a triplet cluster-centered excited state, being of mixed d-s/LMCT character.[43]

At present, our knowledge about the structure of the Cu^I-containing mammalian MT-1 and MT-2 isoforms is limited to the fact that fully Cu-loaded MT form contains 12 Cu^I ions organized in two metal-thiolate clusters, where, in contrast to divalent metal ions, the monovalent copper ions are coordinated by two or three cysteine ligands (*see* ***Copper: Inorganic & Coordination Chemistry***).[11,43] It may be noted that in a number of in vitro studies, even higher Cu^I/MT stoichiometries have been inferred from optical studies.[11,46,47] In MT-3, a mixed Cu^I/Zn MT form, Cu_4,Zn_3-MT-3, was isolated from brains of different mammalian species (see Section 2.2). The EXAFS studies on this species revealed the presence of two homometallic metal-thiolate clusters containing $3Zn^{II}$ and $4Cu^I$ ions with tetrahedral and predominantly trigonal coordination geometry, respectively.[48,49] Evidence for the specific formation of a Cu_4-thiolate cluster in the N-terminal β-domain of MT-3 was obtained by combination of spectroscopic and immunological techniques (Figure 8).[50] A striking feature of this cluster is its remarkable stability against air oxidation. In contrast, the Zn-cluster was found to be air sensitive (see Section 6.3).[45]

The only reported 3-D structure of a Cu^I-containing MT protein is that of yeast (*Saccharomyces cerevisae*) MT of 53 amino acids. The NMR solution structure was determined for the native copper-containing form and for the NMR-active $^{109}Ag^I$ derivative, both showing that 10 out of the 12 available cysteines bind 7 Cu^I or Ag^I ions in a single cluster.[51] However, since it is not certain that Cu/Ag isomorphous replacement can be assumed, a NMR reinvestigation of Cu_7-MT from the same species has been undertaken.[52] In this work, a highly refined structure of the polypeptide chain was determined and the seven Cu^I ions were fitted into the protein cleft formed by a spatial arrangement of the Cys ligands. The subsequent calculations suggested a variety of possible Cu^I-cluster structures fully compatible with the determined geometrical constraints of the protein. Therefore, although no violations of these constraints were found when the previously published sequence specific Cys-Ag^I coordinative bonds were considered, it was concluded that the structure of the Cu_7-cluster derived from the $^{109}Ag_7$-MT derivative is not necessarily correct as the coordination number for Cu^I tends to be larger than that for Ag^I.[52] A recent analysis of the structurally characterized homoleptic thiolate complexes of general formula $M_x{}^I(SR)_y$, M = Ag^I or Cu^I, strongly supports the uncertainty of the Cu^I/Ag^I isomorphous replacement in MTs.[7]

Less detailed structural information is also available for fungal Cu-MT from *Neurospora crassa*, which consists of only 25 amino acids out of which 9 are cysteines. Although the obtained NMR data were not sufficient to permit a structural model to be calculated, they were consistent with the presence of a single protein domain harboring 6 Cu^I ions in a Cu_6Cys_9 cluster.[53]

5 STRUCTURAL FLEXIBILITY

The mobility of the protein backbone structure enfolding the metal core in mammalian MTs is well documented.[54] Both the calculated rmsd values from NMR data and the crystallographic B-factors indicate that a considerable degree of dynamic structural disorder exists (*see Fluxional Molecule*).[19,21] More direct evidence for the nonrigid nature of the MT structure comes from the ^{1}H NMR $^1H-^2H$ amide exchange studies of Cd_7-MT-1/-2.[25,55] In these studies, the enhanced flexibility of the less constrained β-domain compared to the α-domain in both isoforms has also been demonstrated. Molecular dynamics simulations of the β-domain of rat liver MT-2 in aqueous solution also show that the polypeptide loops between cysteine ligands exhibit an extraordinary flexibility without disrupting the geometry of the 3-metal cluster.[56]

Apart from the conformational flexibility of the polypeptide chain, dynamic processes within the metal-thiolate clusters have also been recognized. Thus, in the Zn K-edge EXAFS studies of Zn_7-MT, substantial movements within the cluster are believed to preclude the observation of Zn–Zn backscattering (second shell) at room temperature.[36] Similarly, in the PAC spectra of ^{111m}Cd-MT, the damping of the major oscillatory component was attributed to inordinately large charge fluctuations in the immediate environment of the ^{111m}Cd nuclei.[35]

The best evidence for metal fluxionality in Cd_7-MT was provided by ^{113}Cd NMR saturation transfer experiments, which established the presence of inter- and/or intramolecular metal exchange within the 3-metal cluster of the β-domain with a half-life of the order of 0.5 s. The confirmation of similar processes taking place within the 4-metal cluster, but with a half-life of about 16 min, was afforded by metal exchange studies using the radioactive ^{109}Cd isotope.[57] In this context, it should be noted that the intersite cadmium exchange measured in the 3-metal cluster of MT-1 was found to be much faster than that in MT-2.[25] This finding was in line with the enhanced backbone flexibility recognized in the NMR studies of the former isoform.[25]

Unprecedented structural flexibility and cluster dynamics was found in the biologically active MT-3 (see Section 3.1). Thus, in the ^{113}Cd NMR spectra of $^{113}Cd_7$-MT-3 (Figure 9(b)), the significant broadening of all ^{113}Cd signals and the very low and temperature-independent intensity of the Cd_3Cys_9-cluster resonances have been interpreted in terms of dynamic events involving *coupled* fast and slow exchange processes, on the ^{113}Cd chemical shift time scale, between conformational and configurational cluster substates in the N-terminal β-domain of the protein.[26] Accordingly, the detected ^{113}Cd signals of the Cd_3Cys_9-cluster in the β-domain reflect only a part of the cluster population, whereas the ^{113}Cd signals of the majority of configurational cluster substates remain undetected, because of an extensive exchange broadening and/or to their low population. The existence of interchanging configurational

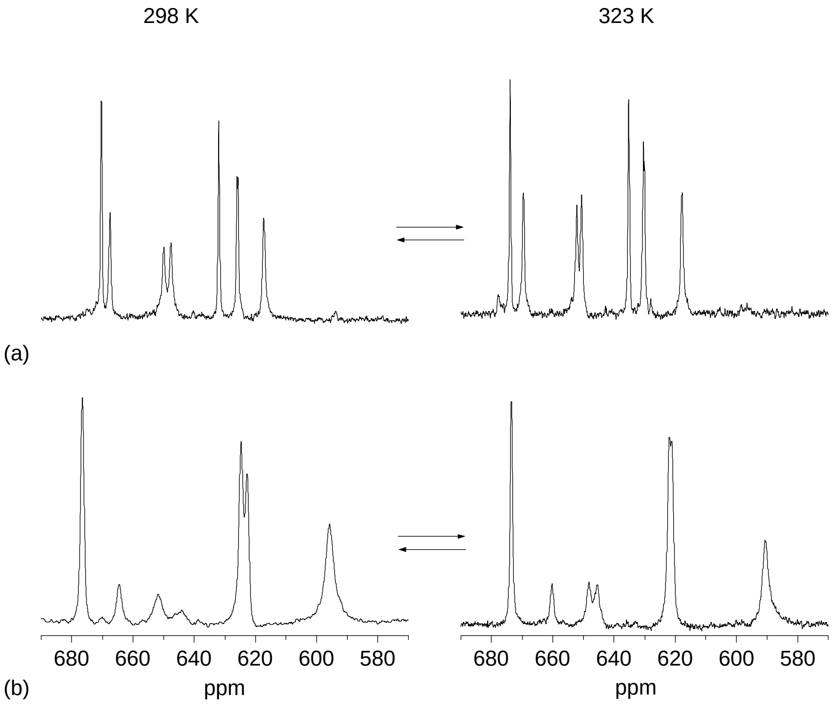

Figure 9 113-MHz ^{113}Cd NMR spectra of (a) mouse $^{113}Cd_7$-MT-1 and (b) human $^{113}Cd_7$-MT-3; (a) at 298 and 323 K[16]. (Reproduced by permission of the American Society for Biochemistry & Molecular Biology)

cluster substates, which can be visualized as the temporary breaking and reforming of the metal-thiolate bonds, have already been demonstrated for inorganic adamantane-like metal-thiolate clusters.[41]

Further structural and biological studies on mutated MT-1/-3 forms led to the proposal that the structure/cluster dynamics is required for the biological activity exhibited by MT-3 (see Section 2.2).[16,58] MTs belong to a growing class of proteins with a nonregular protein structure under physiological conditions.[59] In this context, it is worth noting that there is increasing awareness of compact but incompletely folded states of proteins that contain much of the native secondary structure but lack fixed tertiary interactions, playing an important role in many cellular processes.[60]

6 REACTIVITY

6.1 Metal Binding and Exchange

A variety of metal ions has been reported to bind to MT in vivo or in vitro. Homogeneously substituted metal derivatives with stoichiometries, ranging from 7, 10, to 12 and even up to 20 metal ions per protein molecule have been prepared and characterized. These include derivatives containing divalent metal ions such as Zn^{II}, Cd^{II}, Co^{II}, Hg^{II} and trivalent metal ions such as In^{III}, Sb^{III}, Bi^{III}, and TcO^{III}.[7,11] The overwhelming proportion of these metal MT derivatives contain seven metal equivalents, similar to the native Zn_7-MT form. Higher metal-to-protein stoichiometries up to 20 are usually observed with monovalent metal ions such as Au^I, Ag^I and Cu^I.[11] As a result of these binding properties different coordination geometries from tetrahedral, square-planar, to linear have been reported. The affinity of the metal ions for the binding sites in MTs follows the order found for inorganic thiolates, that is, $Hg^{II} > Ag^I \sim Cu^I > Cd^{II} > Zn^{II}$.[6] The displacement of one metal by another results in the formation of mixed-metal MT complexes. At neutral pH, closely similar average apparent stability constants have been determined for mammalian $M^{II}{}_7$-MT by different methods, with values on the order of $10^{11}\,M^{-1}$ and $10^{14}\,M^{-1}$ for Zn^{II} and Cd^{II}, respectively.[6] The ability of the MT structure to accommodate widely different metal ions led to the suggestion that the protein acts as a 'metal sponge' and that no metal selectivity exists.

The metal selectivity of metal-thiolate clusters in MT has been examined by offering seven equivalents of two metal ions in different relative proportions to apoMT that is, Co^{II}/Cd^{II}, Zn^{II}/Cd^{II}, Co^{II}/Zn^{II} and Fe^{II}/Cd^{II}. Subsequently, the respective metal distributions within the clusters were determined using electronic absorption, MCD, ^{113}Cd NMR, ^{57}Fe Mössbauer and EPR spectroscopy, as required.[61,62] The results of the cluster forms in mixed-metal MT derivatives are summarized in Table 2.

Table 2 Cluster types in mixed-metal MT complexes. In parentheses are the spectroscopic methods used in their characterization

MT complexes	Cluster type
Zn_3,$^{113}Cd_4$-MT	distinct heterometallic (^{113}Cd NMR)
Zn_3,Co^{II}_4-MT	distinct heterometallic (MCD, EPR)
Co^{II}_3,$^{113}Cd_4$-MT	distinct homometallic (Absorption, MCD, ^{113}Cd NMR)
Fe^{II}_3,Cd_4-MT	homometallic, Fe_7-, and Cd_7-MT (Mössbauer spectroscopy)

Overall, homometallic clusters were formed with Co^{II}/Cd^{II} or Fe^{II}/Cd^{II}, while heterometallic clusters of distinct composition were formed in MT derivatives incubated with varying proportions of Zn^{II}/Cd^{II} or Co^{II}/Zn^{II}. Thus, an appreciable selectivity in metal partitioning among and within the clusters is indeed observed in this protein. These results are opposite to those obtained in the studies of inorganic adamantane-like cages with monodentate thiolate ligands of the general formula $[M_4(SPh)_{10}]^{2-}$ ($M = Cd^{II}, Zn^{II}, Co^{II}, Fe^{II}$) where, despite the differences in the metal-thiolate affinities and in the homometallic cluster volumes, a simple mixing of two homometallic cages always produced an almost statistical distribution of heterometallic cage complexes.[41] Since the same metal ions were employed in the studies of metal selectivity of the protein, properties of the MT structure are responsible for this effect. In these studies, it was concluded that an interplay between both the chemistry of metal ions and the steric requirements of the polypeptide chain would determine the diversity of metal-thiolate cluster structures in MT.

Despite the high thermodynamic stability of metal-thiolate MT complexes, and as a consequence of the dynamic properties of the MT structure (see Section 5), they are kinetically very labile (*see Kinetic Lability*), i.e, the thiolate ligands undergo both metallation and demetallation rapidly. This process is reflected by the facile metal-exchange reactions. MT, with multidentate cysteine thiolates, would resemble chelating inorganic ligands with long bridges, for which a low level of ligand preorganization and hence a high kinetic lability has been shown.[63] Qualitatively, the order of the metal replacement in MT follows that of the stability of thiolate model complexes, that is, $Zn^{II} < Cd^{II} < Cu^{I}, Ag^{I}, Hg^{II}, Bi^{III}$. Rapid metal-exchange rate with a half-life of seconds and minutes found in M^{II}_7-MT (see Section 5) also occurs in the binuclear Zn_2Cys_6 cluster of a GAL4 protein involved in the stabilization of the DNA binding domain of this transcription factor as well as in zinc-containing DNA binding proteins, 'zinc-finger proteins' (*see* ***Zinc: DNA-binding Proteins***). By contrast, in zinc enzymes (*see* ***Zinc Enzymes***) for example, alkaline phosphatase, carboxypeptidase, the exchange half-life is on the order of hours and days. Thus, the actual exchange rates of metal ions of protein complexes are not an intrinsic feature of bonding properties of the metal but are determined by the energies and kinetics of protein folding.

Intermolecular metal transfer between MT forms or between MT and other metalloproteins has also been observed.[6] Interestingly, in vitro studies have shown that the intermolecular zinc exchange mediated by Zn_7-MT is orders of magnitude faster than the direct exchange between free zinc and a number of other zinc proteins. Moreover, Zn_7-MT has been shown to be able to transfer zinc to apoproteins possessing a much lower affinity for this metal ion, for example, alkaline phosphatase or carboxypeptidase. In this case, however, only one Zn^{II} ion out of the seven in Zn_7-MT was transferred, implying the presence of one weakly bound metal ion.[64]

6.2 Ligand Substitution

Studies on ligand-substitution reactivity (*see Ligand Substitution*) have revealed that small multidentate ligands, for example, polyamines, polyaminocarboxylates, bis(thiosemicarbazones), are effective competitors for zinc bound to MT in reactions which are much faster than the dissociation rate constant for zinc in Zn-MTs.[9] Biphasic kinetics and differential reactivity of the two metal clusters (α- and β-domain) in mammalian M^{II}_7-MT have been measured with ethylenediaminetetraacetic acid (EDTA) $\beta > \alpha$,[65] and, in opposite order $\alpha > \beta$, with nitrilotriacetate (NTA).[66] On the other hand, bidentate ligands such as ethylenediamine diacetate and triethylenetetramine were found to be ineffective even at thermodynamically competent concentrations. From these studies, it has been suggested that a tripod configuration of ligands is required in ligand substitution and that only specific regions of the protein domains may provide easy access to the metal clusters.

6.3 Sulfur Reactivity

Although the thiol groups in MT are masked through their interaction with metal ions, they retain a substantial degree of the nucleophilicity (*see Nucleophile*) seen with the metal-free protein. This property is reflected by the extremely high reactivity of the coordinated Cys side chains with alkylating and oxidizing agent such as iodoacetamide or 5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB), respectively.[6] Cysteine residues of the zinc-thiolate clusters in Zn_7-MT can also be oxidized by mild cellular oxidants like oxidized glutathione (GSSG),[64] releasing bound metal in this process. Experiments in the presence of the GSH/GSSG redox pair gave evidence for an oxidoreductive mechanism modulating the zinc affinity of the cysteine thiolate ligands in vitro.[67,68]

Another interesting aspect of MT reactivity is its ability to react with radical species.[69] Thus, it has been shown that mammalian M^{II}_7-MT ($M = Zn^{II}$ and/or Cd^{II}) and yeast Cu_7-MT are efficient scavengers of free radicals such as hydroxyl ($OH^{\bullet}$), superoxide ($O_2^{-\bullet}$), or nitric oxide (NO).[6] In all cases, the free radical attack occurs at the metal-bound thiolates, leading to protein oxidation and/or modification and

subsequent metal release. Interestingly, in many instances these effects could be reversed under reductive conditions and the presence of the appropriate metal ion.

Differential sulfur reactivity of the domains of mammalian MTs has also been reported. Thus, kinetic, mass spectrometric, and NMR studies have shown that the kinetically preferred reaction of mammalian MT with electrophiles may be localized in either the α- or the β-domain depending on the specific attacking reagent. Additionally, modification site selectivity has been observed with some reagents (*see Regiochemistry and Regioselectivity*).[6] A redox-labile site in the Zn_4-thiolate cluster containing α-domain of Cu_4,Zn_3-MT-3 and Zn_7-MT-3 has also been observed.[45] Thus, while under anaerobic or reducing conditions, a Zn_4-thiolate cluster is formed in the α-domain of MT-3, its oxidation in air resulted in Zn^{II} release giving rise to a Zn_3-cluster.[45] These results indicate an increased nucleophilic reactivity of specific thiolate ligands of the protein.

Thiolate coordination is an integral part of a great number of zinc metalloproteins. These sulfur-rich zinc centers fulfill one of two basic roles, either as structural elements, as for example in zinc fingers (*see* ***Zinc: DNA-binding Proteins***), or as a reactive entity for alkyl-group transfer, as for instance in the Ada DNA repair protein. At present, the nondissociative mechanism for alkylation of a specific thiolate ligand is favored. In this context, it is worth noting that studies on inorganic model systems have established that selective reactivity of a bound thiolate in a multithiolate zinc-binding site can be controlled by differences in thiol pK_a.[70] Another structural attribute that has been postulated to determine which thiolate ligand in the zinc center is susceptible to modification is its shielding by hydrogen bonding.[71] Recent synthetic modeling studies with mononuclear zinc-thiolate complexes have provided quantitative assessment of the role of H-bonding in altering the reactivity of a metal thiolate. Thus, intramolecular hydrogen bonding of an amide N–H to the thiolate sulfur has been shown to reduce the nucleophilicity and consequently the rate of alkylation more than 30-fold at 25 °C.[72,73] This would be in line with the presence of deprotonated thiolate ligands in the metal coordination environment as featured by spectroscopic structural analysis of several zinc-binding proteins. However, it is interesting to note that thiol protonation and, thus, electroneutrality of $M^{II}Cys_4$ and $M^{II}Cys_3His$ cores in metalloproteins has also been claimed on the basis of mass spectrometric and alkylation studies.[6,74]

7 METAL-(γ-EC)$_n$G PEPTIDE COMPLEXES (PHYTOCHELATINS)

Apart from the widely occurring MTs, some plants and microbial cells have evolved a number of other mechanisms to resist the cytotoxic effect of heavy metal ions. Thus, a family of short gluthatione-related peptides capable of sequestering the metal ions in stable intracellular complexes is synthesized in plants and fungal species exposed to metal salts (see Section 2.1).[14] They usually have the general formula (γ-Glu-Cys)$_n$Gly (n is the number of γ-Glu-Cys diisopeptide repeats, typically 2–8) and are designated as γ-EC peptides. In these compounds, the peptide linkages between the glutamate and cysteine residues involves the γ-carboxylate group of glutamate rather than the α-carboxylate group. These γ-EC peptides have been reported under the nondescriptive name phytochelatins. In contrast to metallothioneins, only limited structural data are at present available on metal-γ-EC peptide complexes.

8.1 Cu- and Cd-γ-EC Peptide Complexes

Cu(I)-γ-EC peptide complexes were isolated from the cultured cells of the fission yeast *Schizosaccharomyces pombe* when exposed to copper salts. Based on the similarity of the observed Cu(I) luminescence properties in the 600 nm region with those of Cu-MT (see Section 4), Cu^I-thiolate coordination was suggested.[75]

Upon exposure of cultured cells of the yeast *S. pombe* to Cd^{II} ions, two types of Cd-γ-EC complexes were isolated.[14,76] The major difference between these two types is the presence of sulfide ions in the structure. The Cd-γ-EC peptide complexes lacking sulfide (M_r between 2500–3500) are characterized by the onset of electronic absorption below 270 nm and a biphasic CD profile (between 270 and 240 nm), features similar to those observed in mammalian Cd_7-MT (Figure 7). Accordingly, for these complexes the presence of bridging μ_2-S-Cys ligands and, hence, a cluster structure was proposed. However, the nonexistence of cluster structure in Cd-γ-EC was claimed by an independent EXAFS study. This discrepancy has recently been reconciled by X-ray absorption spectroscopy of the Cd-γ-EC peptide complexes isolated from maize and their comparison with crystallographically defined inorganic model systems. The studies established the presence of a polynuclear Cd^{II}-cluster in maize phytochelatin with each cadmium being tetrahedrally coordinated by four cysteine ligands.[77]

8.2 CdS Crystallites in Yeast

The best studied Cd-γ-EC peptide complexes containing acid labile sulfide as an additional component were isolated from yeasts *S. pombe* and *Candida glabrata* where γ-EC peptides were shown to coat the CdS particles. Ratios of S:Cd in these heterogenous complexes vary from 0.1 to 0.6. This diversity is paralleled by a nondiscrete variation in apparent molecular mass between about 3500–6400 Da, determined by gel exclusion chromatography.[76,78] These complexes exhibit a red-shifted absorption profile with a new band in the near-UV region (between 270–320 nm) when compared to the

spectrum of complexes lacking CdS centers. The extent of the red shift of the first absorption maximum correlates with increasing particle size. A similar correlation between the location of the red edge of the absorption spectrum and the particle size has been observed with many semiconductor (*see* ***Semiconductors***) crystallites, for example, ZnS and CdS, and is generally referred to as a 'quantum size effect'.[79] In such nanostructures (*see Nanocrystals*), the conducting band continuum of the bulk solid state gives way to more molecular features with discrete excitonic (electron/hole pair) transitions. Owing to the spatial confinement of the exciton in such structures, its energy increases with the reduction of the physical particle size. Photoexcitation of such nanoparticulates also yields luminescence and facilitates electron transfer reactions absent in the bulk solid. Electron transfer reactions of the excited electrons are reflected in the reducing properties of these particles, for example, with electron accepting dyes such as methyl viologen.

The 20 Å diameter monodisperse crystallites isolated from *S. pombe* and *C. glabrata* have been calculated to contain 85 CdS pairs in the lattice coated with approximately 30γ-EC peptides (Figure 10). The particle size was determined using transmission electron microscopy and powder X-ray analysis.[78] The analysis of the X-ray diffraction patterns was inconclusive in discriminating between a four-coordinate zinc blende and six-coordinate rock salt lattice structure. The presence of a short coherence length (8 Å) can be attributed either to internal disorder or to deviation from pure crystallinity. The absorption red edge of the crystallites is located at about 320 nm. The other properties characteristic of semiconductor nanoparticulates such as luminescence with emission near 460 nm, and electron transfer to methyl viologen have also been demonstrated. In vitro reconstitution studies by sulfide ions addition into a Cd-γ-EC peptide mixture led to similar crystallite formation. Thus, the Cd-γ-EC complex provides a matrix for this biomineralization process. Overall, the γ-EC-peptide-metal-sulfide system in yeast offers an interesting possibility to study the initiation and control of metal sulfide biomineralization and may be technically useful in the synthesis of catalytically active nanocrystallites.

In summary, MTs represent a ubiquitous but atypical class of diamagnetic metal-thiolate cluster proteins. The unique biological and chemical properties of these proteins have drawn the attention of disciplines as diverse as inorganic chemistry, physics, molecular biology, toxicology, and medicine. The low level of apoprotein preorganization, the abundance and sequence position of cysteine residues, and the chemistry of the bound mono- and divalent d^{10} metal ions provide the highly unusual structural properties of these proteins. The protein fold of a few MTs containing Cu^{I}-thiolate clusters was determined in solution by NMR. In these NMR structures the precise organization of the corresponding Cu^{I}-cores is largely unknown. However, during the proofreading of this article the crystal structure of yeast Cu_8-MT was reported.[81] The structure shows the largest known oligonuclear Cu^{I}-thiolate cluster in biomolecules, consisting of six trigonally and two digonally coordinated Cu^{I} ions. Although a number of three-dimensional structures of MTs with divalent metal ions are currently available, structural features such as cluster reactivity, dynamics, and metal selectivity of the protein structure remain unexplained. Thus, more studies on the proteins and inorganic models are needed to gain a better understanding of the functional role of MT clusters in biological systems.

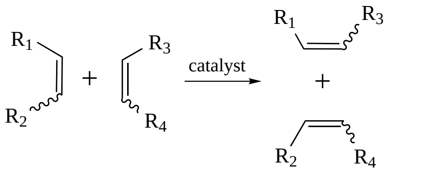
1 INTRODUCTION

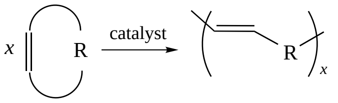
The term alkene (olefin) metathesis refers to the equilibrium reaction shown in equation (1) in which the alkylidene groups of a pair of alkenes are exchanged with one another in the presence of a transition metal-containing catalyst. The reaction involves the net cleavage of the bonds of the substrate(s) and formation of the new carbon–carbon double bonds of the products. Once equilibrium has been established, the resultant product mixture has a distribution of alkenes (including isomers) that is determined solely by the relative thermodynamic stabilities of the products.



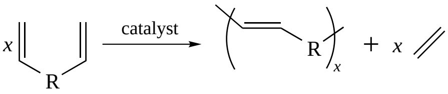
(1)

Both homogeneous and heterogeneous catalysts are effective for this reaction.[1,2] Homogeneous catalysts are usually composed of a transition metal compound combined with a main group metal alkyl cocatalyst, or they consist solely of a well-defined transition metal carbene complex. The most common transition metals used in these catalysts are Mo, W, and Re, although other metals from groups 4–9 have also been used. Literally thousands of different catalyst compositions have been employed in the alkene metathesis reaction, including a variety of heterogeneous catalyst mixtures. An extensive discussion of the properties of all these catalysts is clearly beyond the scope of this review. The discussion presented here will concentrate on the well-defined catalyst systems and their use in polymer synthesis; the extensive literature available on the alkene metathesis reaction provides more detailed information.[1,2]

The metathesis reaction was discovered serendipitously in industrial laboratories in the 1950s during investigations of Zeigler–Natta-type alkene polymerization catalysts,[3] where the surprising observation of ring opening polymerization products (equation 2) rather than the expected addition-type polymers signaled the presence of a new reaction type (*see Ring Opening Metathesis Polymerization Reactions*). This discovery led to the synthesis of numerous polymers via alkene metathesis chemistry using a cyclic alkene monomer as shown in equation (2).



(2)



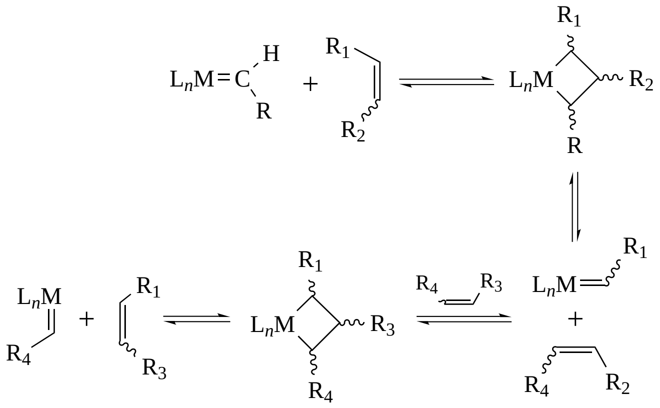
(3)

Ring opening metathesis polymerization, which has been known since the discovery of the alkene metathesis reaction, has been given the acronym ROMP in recent years.[4] In fact, the ROMP reaction was the first observation made in alkene metathesis chemistry, while the discovery of the exchange reaction in equation (1) actually occurred later.[5] Acyclic diene metathesis (ADMET) polymerization (equation 3) has only recently been shown to be a viable method for polymer synthesis, and it has been termed ADMET polymerization.[6] ROMP reactions are driven by the release of ring strain from the monomer, while ADMET polymerization is driven by a shift in the equilibrium caused by the removal of one of the reaction products.

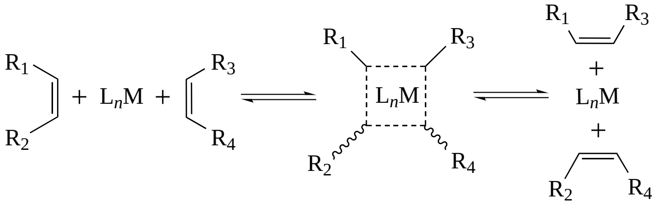
The mechanism of the alkene metathesis reaction is now very well understood and is shown in Scheme 1. The initial mechanistic proposal[7] of a pairwise reaction (the pairwise mechanism) of two alkenes at a transition metal center in a pseudocyclobutane transition metal complex has been discarded in favor of the carbene mechanism (the *Chauvin Mechanism*) of Scheme 1.[8]

Evidence for the carbene mechanism is now so overwhelming (as discussed below) that the pairwise mechanism is only mentioned in this review for historical reasons. All alkene metathesis reactions are catalyzed by a metal carbene complex of some description, and the widely variable compositions used as catalysts are necessary to generate an active metal carbene group.

Alkene metathesis and ROMP reactions have been used industrially to produce a number of chemicals



Scheme 1



Scheme 2

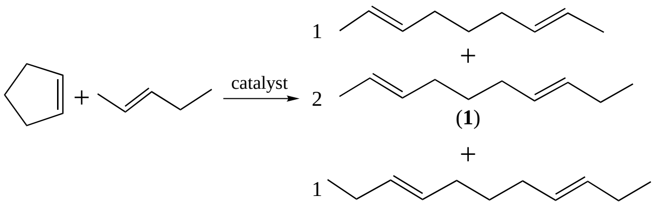
and polymers.[1,2] Commercial polymers produced using metathesis chemistry include polyoctenamer, polynorbornene, and polydicyclopentadiene,[9] while the metathesis of acyclic alkenes has been used in the synthesis of neohexene and propene, and is a key step in the Shell Higher Olefin Process (SHOP). The polymerization of acyclic dienes has only recently been demonstrated to be feasible, and commercial applications are now under consideration.

2 FUNDAMENTAL MECHANISTIC ASPECTS OF METATHESIS CHEMISTRY

The mechanism described in Scheme 1 (the Chauvin mechanism) is the accepted mechanism of alkene metathesis, and its validity has been demonstrated in two ways. First, classical kinetic studies, including isotopic labeling and crossover experiments performed using poorly defined catalysts, conclusively demonstrated that the carbene mechanism was consistent with the experiments, while the pairwise mechanism was not.[10,11] More recently, the synthesis of isolable carbene complexes that catalyze the reaction has allowed a more direct observation of the reaction.[12,13] Each individual step in the Chauvin mechanism has now been observed spectroscopically for several of the well-defined catalyst systems.

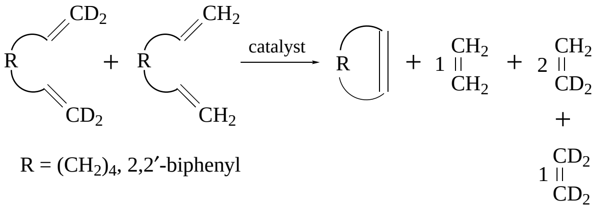
In the mid 1960s, the Goodyear research group led by Calderon recognized that the ring opening polymerization of cyclic alkenes and the alkene exchange chemistry were one and the same reaction.[14] This group coined the term alkene metathesis to describe this chemistry, and soon thereafter an intense amount of study was devoted to understanding the mechanism of this reaction. The ‘pairwise mechanism’ was proposed in which two substrate alkenes reacted with the transition metal to form a pseudocyclobutane complex (Scheme 2). The exchange of the alkylidene groups was thought to occur by way of the pseudocyclobutane complex to give products. While this was a somewhat appealing explanation of the phenomenon, further mechanistic scrutiny showed that not all the experimental results could be explained with such a simple mechanism.

In 1970, Chauvin[8] proposed a mechanism in which the catalytically active species was a transition metal carbene complex. The carbene mechanism was proposed to account for the products observed when cyclopentene and pent-2-ene were metathesized in the presence of the catalysts WCl_4/Bu_4Sn or $WOCl_4/Et_2AlCl$ (equation 4). The products were observed in a 1:2:1 ratio, even as the initial products. A simple pairwise mechanism, however, would have predicted that compound (**1**) will be the only product initially formed.



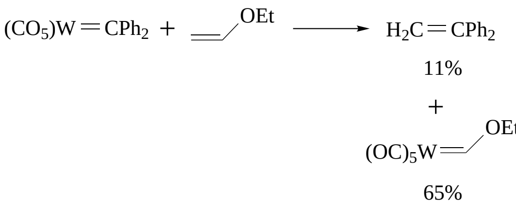
(4)

The suggestion that a metal carbene was the active metal-containing species involved in the reaction inspired an impressive number of elegant experiments, designed to test the validity of this mechanism. The results of double crossover experiments as well as isotopic labeling experiments showed conclusively that a pairwise mechanism could not account for the observed data.[10,11] The reaction shown in equation (5) shows the possible products of the metathesis of two isotopically labeled dienes, and these products include a cyclic alkene derived from the closing of the diene as well as a series of deuterated ethylenes. At very low conversions, the observed ratio of ethylenes was 1:2:1 (d_0:d_2:d_4). A detailed analysis of these results[10] demonstrated that the pairwise mechanism could not possibly account for this result, while the carbene mechanism could.

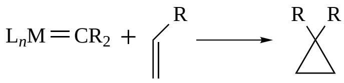


(5)

Although transition metal carbene complexes had been known for six years at the time of Chauvin's proposal, initially there was no evidence that this type of carbene complex would react with an alkene to give metathesis products.[15] Furthermore, the typical alkene metathesis catalysts consisted of metals that were in their highest oxidation states, while the *Fischer-Type Carbene Complexes* complexes (the only ones known at the time) consisted of low-valent metal centers and typically had electron-donating substituents bonded to the carbene carbon. The discovery that the tungsten complex $(CO)_5\,W{=}CPh_2$ could catalyze the polymerization of various cycloalkenes as well as the exchange of the CPh_2 group with ethyl vinyl ether (equation 6) was an example of a single-source metal carbene complex that catalyzed the alkene metathesis reaction.[16] These types of compounds also undergo stoichiometric carbene transfer reactions with alkenes that result in the formation of cyclopropanes, as shown in equation (7). Since 'classical' catalyst systems do not generally give cyclopropanation products, the relevance of the low-valent carbene complexes as models of the typical high-valent transition metal/main group alkyl catalysts was questionable. These complexes did show that isolated metal carbenes could catalyze metathesis reactions and supported the carbene mechanism. The synthesis of better initiators for the metathesis reaction seemed reasonable if the correct type of carbene complex could be synthesized.

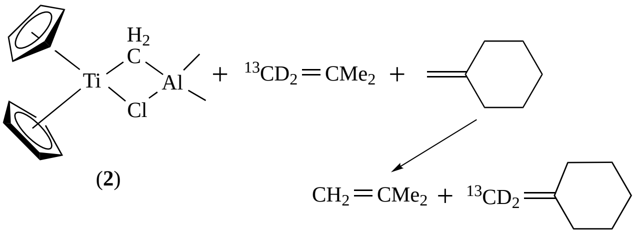


(6)

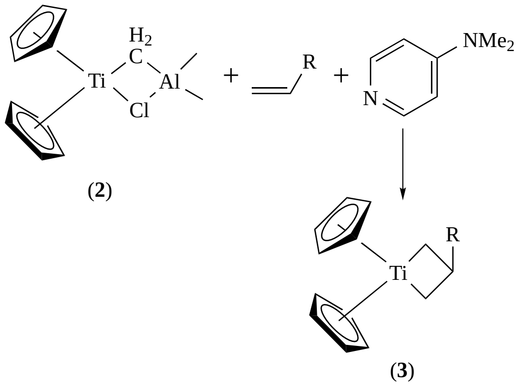


(7)

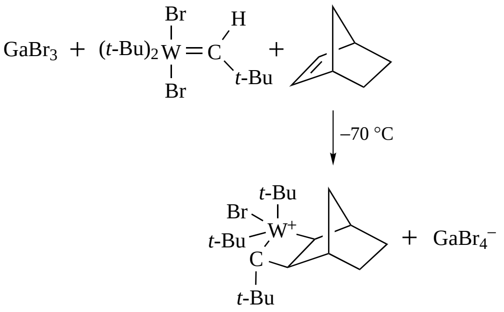
The synthesis of d[0] *Alkylidene* complexes by Schrock[17] demonstrated that carbene complexes could be isolated that were electronically similar to those postulated to be involved in the alkene metathesis reaction (*see Schrock-type Carbene Complexes*). Eventually, this pioneering work led to the synthesis of a class of compounds that are among the most active catalysts known for metathesis chemistry. The first observation that a d[0] carbene complex was involved in metathesis chemistry was when Tebbe showed that the Ti complex (**2**) would catalyze the degenerate metathesis of deuterated ethylenes (note that this compound can be viewed as a Ti methylene complex that is stabilized by coordination to an aluminum reagent), as shown in equation (8).[18] Reaction of this compound with alkenes in the presence of a Lewis base (equation 9) results in the formation of the metallacyclobutane complexes (**3**).[19] These observations solidified the validity of the carbene mechanism and intensified the search for more efficient, well-defined catalysts.



(8)

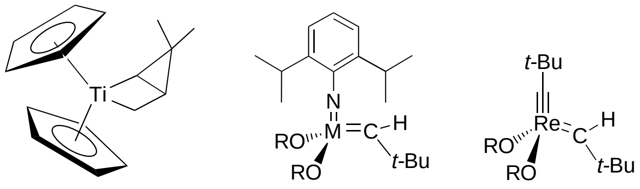


(9)



(10)

The initial observation of a metal carbene that reacted with an alkene to give a metallacyclobutane complex was reported by Osborn and coworkers[20] for the reaction shown in equation (10). This reaction was observed by ^1H NMR spectroscopy at low temperature ($-70\,°C$). When this reaction mixture was allowed to warm to higher temperature, polynorbornene was produced in high yield. Shortly after this discovery, the titanocene complex (**4**) was shown to be an efficient catalyst for the synthesis of monodisperse polynorbornenes.[21] These discoveries, along with the synthesis of a new family of tungsten (**5a**), molybdenum (**5b**), and rhenium (**6**) catalysts,[22] shown in Figure 1, have opened a new era of ROMP chemistry in which the polymer synthesis is guided by the selection of a catalyst

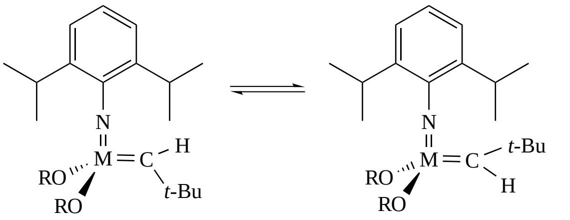


(**4**) (**5a**) M = W, (**5b**) M = Mo (**6**)

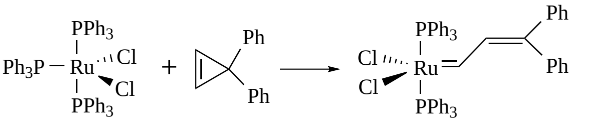
Figure 1 A family of well-defined metathesis catalysts

that has a well-defined active site that reacts by way of a well-understood mechanism.

More recent developments in the mechanistic aspects of the alkene metathesis reaction include the observation that the alkene coordinates to the metal carbene complex prior to the formation of the metallacyclobutane complex.[23] Thus a 2 + 2 addition reaction of the alkene to the carbene is very unlikely, and a vacant coordination site appears to be necessary for catalytic activity. It has also been shown that the metal carbene complex can exist in different rotameric forms (equation 11) and that the two rotamers can have different reactivities toward alkenes.[24] The latter observation may explain why similar ROMP catalysts can produce polymers that have very different stereochemistries.[25] Finally, the synthesis of a well-defined Ru carbene complex (equation 12) that is a good initiator for ROMP reactions suggests that carbenes are probably the active species in catalysts derived from the later transition elements.[26]



(11)

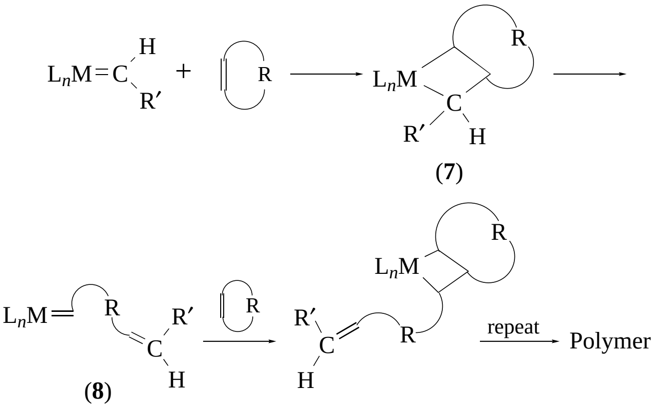


(12)

3 RING OPENING METATHESIS POLYMERIZATION (ROMP) CHEMISTRY

3.1 The Chain Propagation, Addition-type Nature of ROMP Chemistry

The ROMP reaction is a special example of the alkene metathesis reaction as shown in equation (2), and the mechanism of the ROMP reaction is shown in Scheme 3. The first step in the reaction involves coordination of the substrate to the metal center, followed by the formation of the metallacyclobutane intermediate (**7**). Opening of the metallacyclobutane ring generates the first new carbene in the system (**8**), and this carbene incorporates the first equivalent of the monomer in what will become the polymer chain. Repetition of the preceding three steps leads to the formation of a polymer that is terminated by the original alkylidene group at one end and by the metal catalyst fragment at the other end. This is chain propagation, addition-type chemistry, where the driving force for the ROMP reaction is the loss of ring strain from the monomer.



Scheme 3

In general, the termination reactions of these polymerizations are not well understood but, depending upon the metal and the monomer, reductive coupling of the metal carbene fragments to give alkene and reduced metal complexes is one possibility. Another termination reaction appears to be initiated by *β-Hydride Elimination* from the carbene complex. These mechanisms have been observed in well-defined catalyst systems, and are possible in the ill-defined systems also.[28] The fact that most catalysts are sensitive to oxygen and moisture (or other proton sources) means that termination of the polymer chain by added or adventitious sources of water is a common problem, especially for the ill-defined catalysts.

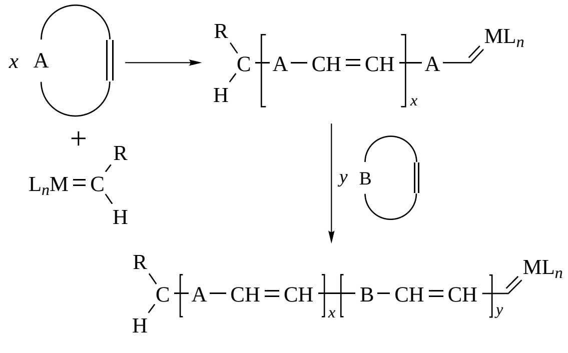
The details of the ROMP mechanism are useful to help to explain the properties of this reaction. As long as the polymer chain is terminated by the metal carbene, complex (**8**), the growing polymer chain is more reactive toward the monomer than the monomers are with each other. This is one of the necessary requirements for a chain-growth polymerization reaction. The result is that the catalyst will grow a long polymer chain until some reaction occurs to cleave the chain or start a new one (a chain termination, or a chain transfer reaction). In chain propagation chemistry, such as, radical polymerization, the number average molecular weight, M_n, of the polymer is independent of the extent of conversion of the monomer,[27] and this is the behavior of a typical ROMP catalyst, especially the ill-defined catalyst systems, for example, $WCl_6/EtAlCl_2$.[1]

A special case arises when both the rate of chain initiation is greater than the rate of chain propagation and when chain transfer and termination rates are much smaller than

the initiation and propagation rates. When such conditions exist during a chain polymerization reaction, the M_n of the polymer is directly proportional to the extent of monomer consumed by each initiator. Thus a plot of M_n verses percent monomer consumed is linear with an intercept of zero.[27] When these conditions are met, a very narrow molecular weight distribution of the polymer results and such polymerization reactions are usually referred to as living polymerizations.

In the context of ROMP chemistry, living polymerization reaction conditions have only been observed when well-defined carbene complexes are used as the catalysts. The first catalyst to behave in this fashion was the titanocene complex (**4**),[21] while more recently, complexes containing Ta, W, and Mo have been shown to be catalysts for the living ROMP of a variety of cyclic alkenes.[22] The Mo complex (**5b**) is an especially promising catalyst since it is compatible with a number of functional groups and thus can be used to synthesize a variety of functionalized polymers.

Another consequence of living polymerization systems is that they can be used to synthesize block copolymers. Under these conditions, once the initial quantity of monomer in a given reaction is consumed, the resultant polymer chains are terminated with metal carbene end groups that are still active for alkene metathesis. As long as these carbenes do not react rapidly with the acyclic alkenes in the polymer chain, addition of a second monomer will result in the synthesis of a block copolymer. This reaction is illustrated in equation (13) for the synthesis of a polymer that consists of block of x repeat units of monomer A followed by a block of y repeat units of monomer B.



(13)

3.2 Polymers Synthesized by ROMP Chemistry on a Commercial Scale

Concurrent with the development of the mechanistic explanations for the chemistry has been the creation of new polymers based on ROMP chemistry. While a wide variety of strained cyclic monomers have been polymerized with a significant emphasis on monomer structure/reactivity relationships,[1] three ring structures deserve special attention, since they are or have been produced on a commercial scale. These polymers are polyoctenamer (from cyclooctene), polynorbornene (from norbornene), and polydicyclopentadiene (from dicyclopentadiene). The first two structures are linear (thermoplastic) polymers while the last is a network (thermoset) polymer.

The polymerizations yield high molecular weight, linear polymers, under both solution and bulk polymerization conditions. Given their useful physical properties, their commercial synthesis is of particular value. The network polymer, polydicyclopentadiene, is a unique polymer structure (equation 14). This network polymer can be synthesized via bulk polymerization as well and, because of its cross-linked nature, the polymer combines toughness with solvent resistance, chemical inertness, and long-term durability, and its importance in society will continue to grow. The existence of polydicyclopentadiene perhaps is the most important tribute to the success of the ring opening polymerization chemistry done to date.

3.3 Other ROMP Polymers of Particular Interest

Research over the past 30 years has produced a large number of ROMP polymers, and virtually all of these polymerizations have been reviewed elsewhere.[1] The most recent work has revolved about the 'living' or 'pseudoliving' nature of ROMP polymerization, and a few words regarding this chemistry are worth mentioning here.

The discovery that Ti complex (**4**) was an effective catalyst for living ROMP chemistry resulted in the synthesis of several new types of polymers that were inaccessible with conventional catalysts. Narrow polydispersity polymer and di- and triblock copolymers were synthesized soon after living ROMP was discovered. Because polymer chains that are formed in a living ROMP reaction are terminated with metal carbene groups, functionalization of the chain ends is possible. Reaction of the carbene with an aldehyde occurs in a Wittig-like fashion, making a metal oxo complex that is inert to further metathesis chemistry and terminates the chain with the alkylidene group of the aldehyde.

The living ROMP reactions of norbornene and norbornene derivatives have been used to make a variety of polymers possessing unusual properties. Copolymerization of selected functionalized norbornenes with norbornene has been used to synthesize star polymers[29] and side-chain liquid crystal polymers.[30] This chemistry has also resulted in the preparation of phase separated block copolymers that contain uniform sized metal or semiconductor nanoparticles.[31,32] The

synthesis of soluble polyacetylenes[33] and well-defined polyene oligomers[34] has also been achieved using the well-defined tungsten catalysts discussed above.

Clearly, an enormous number of new polymers have and continue to be synthesized using ROMP reactions. The development of the new generation of single-site alkylidene catalysts has introduced a new level of control over ROMP chemistry. Control of polymer microstructure should, in turn, result in a better understanding of the interplay between microstructure and macroscopic properties. The use of living ROMP chemistry is still in its infancy. It will be interesting to observe whether or not useful materials can be developed from this chemistry.

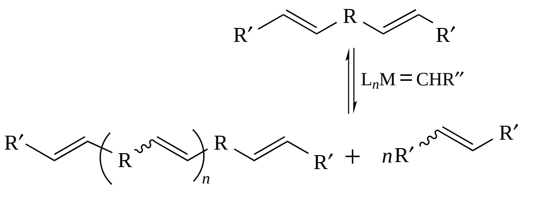
4 ACYCLIC DIENE METATHESIS (ADMET) POLYMERIZATION CHEMISTRY

4.1 The Step Polymerization Mechanism in ADMET Chemistry and Catalyst Selection

The productive metathesis exchange reaction of two acyclic alkenes produces two new alkenes yet, unlike ROMP chemistry, no obvious reference to driving force is noted, except for the increase in entropy associated with an equilibrium process (equation 15).

$$\begin{array}{c} \mathrm{MeCH{=}CH_2} \\ + \\ \mathrm{MeCH{=}CH_2} \end{array} \underset{}{\overset{\text{catalyst}}{\rightleftharpoons}} \begin{array}{c} \mathrm{MeCH} \\ \| \\ \mathrm{MeCH} \end{array} + \begin{array}{c} \mathrm{CH_2} \\ \| \\ \mathrm{CH_2} \end{array} \qquad (15)$$

If one of the newly formed alkenes is removed selectively from the reaction, however, then the productive metathesis equilibrium is shifted further and faster to product. When applying the scenario to an acyclic reactant containing two metathesizable alkenes (dienes), polymerization should result if high conversions can be achieved. This reaction (equation 16) falls under the category of equilibrium step polymerization chemistry, which, regardless of the chemistry involved, is dictated by strict statistical requirements.[35]



(16)

More specifically, the metathesis polymerization of acyclic alkenes is defined as an equilibrium step propagation, condensation-type polymerization, where the term ‘condensation-type’ arises from the liberation of a by-product that advances the reaction. The other possibility for step polymerization is addition-type, where the resulting polymer linkage is an adduct of the two monomers, and no atoms are lost (e.g. polyurethanes).

Step polymerizations proceed in a stepwise fashion. Monomer is consumed early in the reaction to form dimers, trimers, tetramers, and so on, and the molecular weight is governed by the statistics associated with linking ends of monomer groups. All step polymerizations obey these statistics, oblivious to the nature of the functional groups being connected, and require complete (99.99%) conversions before high molecular weight polymer is formed. In order to achieve these conversions, the stoichiometry of functional groups must be strictly balanced, and side reactions must be completely obviated. The average degree of polymerization (X_n) is dependent upon conversion and stoichiometry, which is governed by the relationship:

$$X_n = \frac{1+r}{(1+r-2r\rho)} \qquad (17)$$

Clearly, the average degree of polymerization, X_n (number of repeat units), depends only on the stoichiometric imbalance ratio, r ($r \leq 1$), and the extent of conversion, ρ (expressed as fractional percentage of functional groups consumed). Considering a step polymerization that contains only one type of functional group, as is the case for metathesis polymerization of acyclic dienes, then stoichiometry is perfectly balanced and equation (17) reduces to the Carothers equation.[36]

$$X_n = \frac{1}{(1-\rho)} \qquad (18)$$

A simple plot of the Carothers equation illustrates how functional group conversion governs step polymerization chemistry (Figure 2). Conversions of above 99% are required for high polymer to form.

Although attempts to produce unsaturated polymers by the metathesis of acyclic dienes, using classical-type catalyst systems described earlier, received sparse attention from 1967 to 1987, the strict statistical requirements of step-growth polymer chemistry condemned these early efforts to only limited success.[37–40] Dall’Asta *et al.*[38] were the first to report

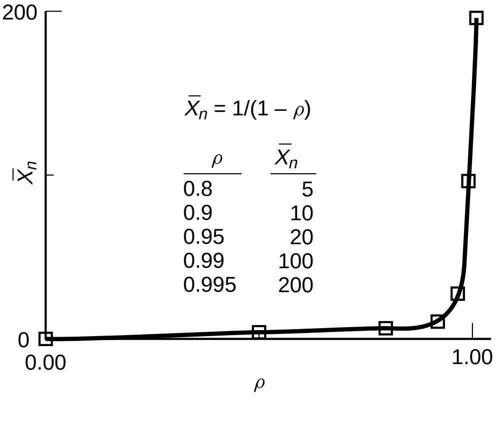


Figure 2 Plot of the Carothers equation in step chemistry

the polycondensation of α,ω-dienes by demonstrating that 1,4-pentadiene and 1,5-hexadiene reacted with traditional Lewis acidic metathesis catalysts to give linear unsaturated oligomers and ethylene. Other early attempts by Doyle[39] and Zuech *et al.*[40] further illustrated the restrictions exhibited by metathesis condensation whereby the use of classical catalyst systems did not result in the formation of high polymer. These Lewis acidic catalysts result in nonselective and highly reactive propagating species where competing reactions destroy the opportunity for the high conversions required for successful step polymerization.

In 1987 it was shown[41] that the early failures of this reaction were due to competing cationic vinyl addition chemistry, and that the elimination of chain propagating carbocations was absolutely essential before successful ADMET polymerization could occur. Attempts to polymerize 1,9-decadiene and 1,5-hexadiene to polyoctenamer and polybutadiene, respectively, using the $WCl_6/EtAlCl_2$ catalyst system, resulted in low conversions of oligomers accompanied by an intractable solid.[41] The solid was rationalized as being a cationically initiated chain polymerization product of the oligomers, where cationic polymerization is done by the Lewis acid. Since most classical catalysts involve a Lewis acid cocatalyst to generate the active alkylidene, the possibility of vinyl addition chemistry had always been present.

To prove the point, model studies were done to demonstrate that crosslinking via cationic initiation was indeed the reaction that competed with metathesis polycondensation.[6,41,42] Substituted styrenes were used to test the hypothesis of cation formation, since styrene is a well-known cationic polymerizable alkene that gives an easily characterized product.[35] When various styrenes were treated with classic Lewis acidic catalyst systems like $WCl_6/EtAlCl_2$, only polystyrene was produced, whereas metathesis products (substituted stilbenes) were not observed (Scheme 4).[41]

These 1987 results concluded that classical metathesis catalyst systems were not sufficient and that Lewis acid cocatalyst-free systems were necessary if successful ADMET condensation polymerization were to become a reality. The key to successful ADMET polymerization was demonstrated[6,42] using the Lewis acid-free tungsten alkylidene metathesis catalyst (**5a**), the structure of which had been reported by Schrock *et al.*[43] just one year earlier. When this catalyst was combined with the styrene model, quantitative metathesis occurred producing only substituted stilbenes.[6,42]

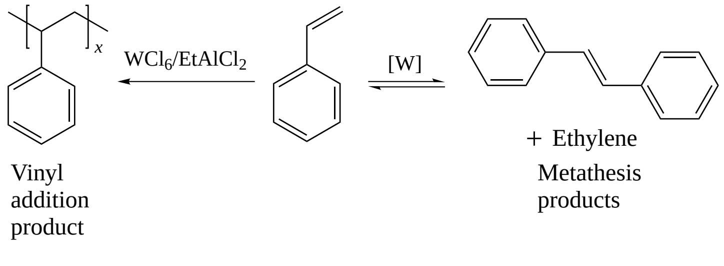
The mechanism of ADMET polymerization (Scheme 5) contains intermediates similar to those found in ROMP chemistry in that both polymerizations contain, inclusively, various metallacyclobutane/carbene species.[44] Although ROMP propagates exclusively via trisubstituted metallacycles, whereas ADMET requires disubstituted metallacycles, the major difference is that ADMET step chemistry is an equilibrium process driven by condensation and ROMP chain chemistry propagates irreversibly owing to the high reactivity of the carbene with strained cycloalkenes. Therefore ROMP is much faster than ADMET simply because competing equilibria, absent during ROMP, decrease the net productive rate in ADMET chemistry.

Studies involving the specific exchange mechanisms,[45,28] as well as theoretical calculations[46–48] of alkene metathesis reactions, generally agree that the mechanism begins with π-coordination of the alkene to the electrophilic metal as shown for a general diene in Scheme 5.

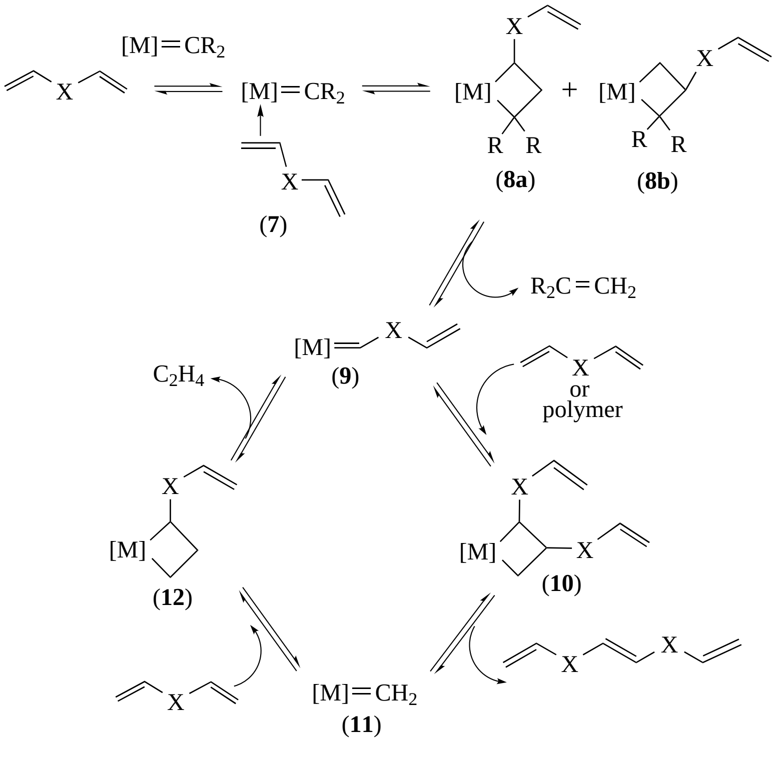
The alkene metal complex (**7**) shown in Scheme 5 undergoes carbene migratory insertion, forming two possible metallacyclobutane complexes (**8a,b**). Cleavage of (**8a**) gives a new carbene (**9**), which is derived from monomer. Productive cleavage of (**8b**), which is not shown in Scheme 5, will generate the methylene complex (**11**). The carbene derived from monomer (**9**) must undergo complexation/metallacycle formation with another equivalent of monomer to generate the α,β-disubstituted metallacycle (**10**). Cleavage of (**10**) gives the methylene complex (**11**), which then reacts with monomer to generate the monosubstituted metallacycle (**12**). Complex (**12**) then extrudes ethylene to regenerate (**9**). These reactions constitute the minimum set of steps that are necessary to form one new C=C double bond and one equivalent of ethylene. The extent of these productive reactions affects the rate of polymerization and depends upon the monomer structure, conversion, and metal catalyst used. Despite the complexity of the catalytic reaction, every reversible condensation cycle gives linear polymer terminated with vinyl end groups.

Summarizing, the mechanism[44] is supported by the following experimental evidence:

1. ethylene is continuously produced during the reaction;



Scheme 4



Scheme 5

2. high molecular weight polymer is not observed at low monomer conversions;
3. unpurified polymer reaction mixtures exhibit monomodal molecular weight distributions approaching 2;
4. molecular weight determination by end group analysis (NMR) compare well with colligative property measurements (vapor-pressure osmometry) and relative measurements (gel-permeation chromatography);
5. the average geometric configuration of ADMET polymer increases in trans content as the reaction proceeds, indicative of a dissociative catalysis;
6. an existing ADMET polymer can be polymerized to higher molecular weight or copolymerized with an additional diene by the removal of a monene condensate[49] and;
7. the equilibrium cycle is truly reversible since ADMET polymer can be depolymerized to its original diene monomer by shifting the equilibrium with excess ethylene.[50]

The mechanism sufficiently explains how productive condensation metathesis occurs since terminal alkenes are contained in every step of the productive cycle (Scheme 5). In this kinetically controlled regime (high concentration of terminal alkene present), alkylidene reactions with unsubstituted (terminal) alkenes are favored over interchain redistribution reactions or other degenerate equilibria. However, when terminal alkene concentration decreases near the end of the polycondensation reaction, competing equilibria involving the excess internal alkenes within the polymer are significantly enhanced, and a 'resting state equilibrium' is established. Metathesis reactions that occur in this thermodynamic regime, such as back biting, have been, for the most part, negligible in ADMET chemistry yet do contribute remarkably under some conditions.

4.2 Polymers Synthesized by ADMET Chemistry

Lewis acid-free Schrock alkylidenes provide the means by which successful ADMET polymerization can be achieved, and the scope of this polymerization reaction has been found to be broad. The first high molecular weight polymer was produced by the ADMET condensation of 1,9-decadiene to polyoctenamer (equation 19).[6,42]
